(a) Acetylene forms an explosive compound with copper when moist or when certain impurities are present and the gas is under pressure. Alloys containing less than 65% Cu are satisfactory for this use. When gas is not under pressure, other copper alloys are satisfactory.

(b) Copper and copper alloys resist corrosion by most food products. Traces of copper may be dissolved and affect taste or color. In such cases, copper metals are often tin coated.

Whenever there is a lack of operating experience, whenever reported test conditions do not closely match the conditions for which alloy selection is being made, and whenever there is doubt as to the applicability of published data, it is always best to conduct an independent test. Field tests are the most reliable. Laboratory tests can be equally valuable, but only if operating conditions are precisely defined and then accurately simulated in the laboratory. Long-term tests are generally preferred because the reaction that dominates the initial stages of corrosion may differ significantly from the reaction that dominates later on. If short-term tests must be used as the basis for alloy selection, the test program should be supplemented with field tests so that the laboratory results can be reevaluated in light of true operating experience.

Erroneous conclusions based on laboratory results can also be reached by measuring corrosion damage inaccurately, especially when corrosion is slight. It is common practice to express test results in terms of penetration or average reduction in metal thickness, even when corrosion was actually measured by weight loss. Weight loss or average-penetration data are valid only when corrosion is uniform. When corrosion occurs predominantly by pitting or some other localized form or when corrosion is intergranular or involves the formation of a thick, adherent scale, direct measurement of the extent of corrosion provides the most reliable information. A common technique is to measure the maximum depth of penetration observed on a metallographic cross section through the region of interest. Statistical averaging of repeated measurements on one or more specimens may or may not be warranted. Despite the deficiencies in laboratory testing, information gained in this manner serves as a useful starting point for alloy selection. Operating experience may later indicate the need for a more discriminating selection.

Atmospheric Exposure

Comprehensive tests conducted over a 20-year period under the supervision of the American Society for Testing and Materials (ASTM), as well as many service records, have confirmed the suitability of copper and copper alloys for atmospheric exposure (Table 7). Copper and copper alloys resist corrosion by industrial, marine, and rural atmospheres except atmospheres containing NH_3 or certain other agents where SCC has been observed in high-zinc alloys (>20% Zn). The copper metals most widely used in atmospheric exposure are C11000, C22000, C23000, C38500, and C75200. Alloy C11000 is an effective material for roofing, flashings, gutters, and down-spouts.

(b) Although obsolete, this alloy indicates the corrosion resistance expected of C71500.

The colors of different copper alloys are often important in architectural applications, and color may be the primary criterion for selecting a specific alloy. After surface preparation, such as sanding or polishing, different copper alloys vary in color from silver to yellow to gold to reddish shades. Different alloys having the same initial color may show differences in color after weathering under similar conditions. Therefore, alloys having the same or nearly the same composition are usually used together for consistency of appearance in a specific structure.

Copper alloys are often specified for marine atmosphere exposures because of the attractive and protective patina they form during the exposure. In marine atmospheric exposures, this patina consists of a film of basic copper chloride or carbonate, sometimes with an inner layer of Cu_2O. The severity of the corrosion attack in marine atmospheres is somewhat less than that in industrial atmospheres but greater than that in rural atmospheres. However, these rates decrease with time.

Individual differences in corrosion rates do exist between alloys, but these differences are frequently less than the differences caused by environmental factors. Thus, it becomes possible to classify the corrosion behavior of copper alloys in a marine atmosphere into two general categories: those alloys that corrode at a moderate rate and include high-copper alloys, silicon bronze, and tin bronze and those alloys that corrode at a slower rate and include brass, aluminum bronze, nickel silver, and copper nickel. The average metal loss, *d,* of the former group can be approximated by $d = 0.1\ t^{\frac{2}{3}}$; the latter group can be approximated by $d = 0.1\ t^{\frac{1}{3}}$. In both equations, *t* is exposure time. These relationships are shown as solid lines in Fig. 3.

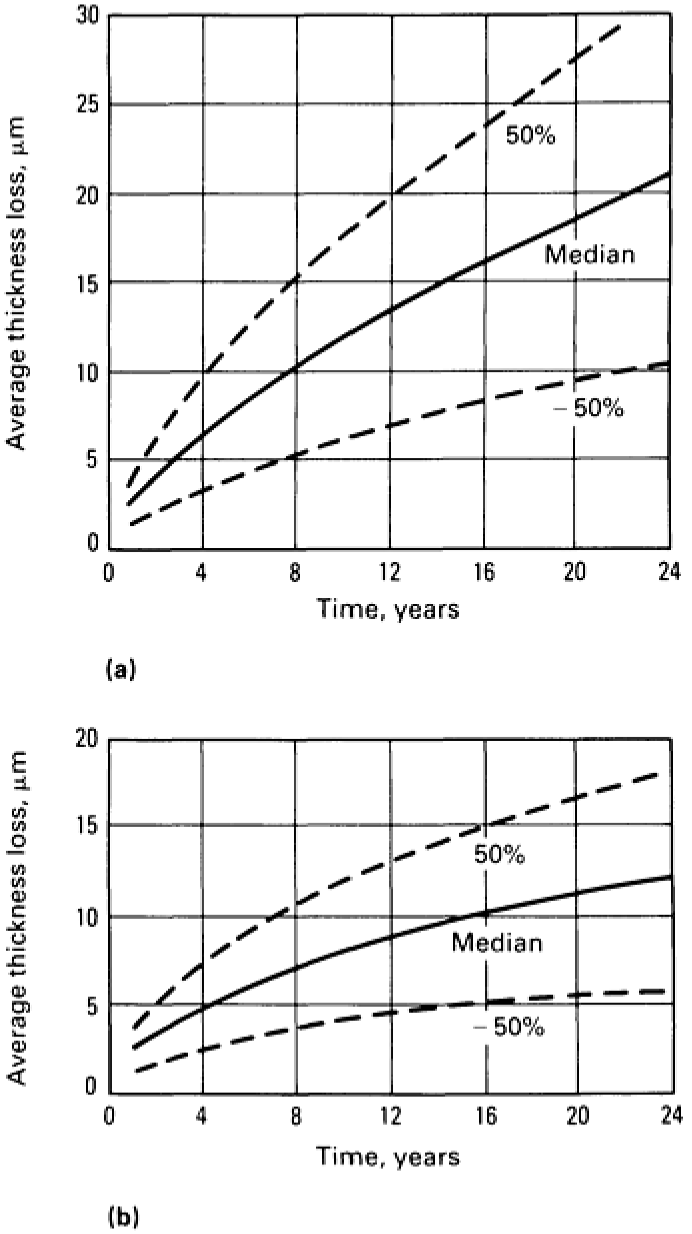

Fig. 3 Typical corrosion rates of representative copper alloys in a marine atmosphere. (a) Average data for copper, silicon bronze, and phosphor bronze. (b) Average data for brass, aluminum bronze, nickel silver, and copper-nickel

Environmental factors can cause this median thickness loss to vary by as much as 50% or more in a few extreme cases. Figure 3 shows the extent of this variation as a pair of dashed lines forming an envelope around the median. Those environmental factors that tend to accelerate metal loss include high humidity, high temperatures (either ambient or due to solar radiation), proximity to the ocean, long times of wetness, and the presence of pollutants in the atmosphere. The converse of these conditions would tend to retard metal loss.

Metallurgical factors can also affect metal loss. Within a given alloy family, those with a higher alloy content tend to corrode at a lower rate. Surface finish also plays a role in that a highly polished metal will corrode slower than one with a rougher surface. Finally, design details can affect corrosion behavior. For example, designs that allow the collection and stagnation of rainwater will often exhibit wastage rates in the puddle areas that are more typical of those encountered in seawater immersions.

Certain copper alloys are susceptible to various types of localized corrosion that can greatly affect their utility in a marine atmosphere. Brasses and nickel silvers containing more than 15% Zn can suffer from dealloying. The extent of this attack is greater on alloys that contain higher proportions of zinc. In addition, these same alloys are subject to SCC in the presence of small quantities of NH_3 or other gaseous pollutants. Inhibited grades of these alloys are available that resist dealloying but are susceptible to SCC.

Alloys containing large amounts of manganese tend to be somewhat prone to pitting in marine atmospheres, as are the cobalt-containing beryllium-coppers. A tendency toward intergranular corrosion has been observed in silicon bronzes and aluminum brass, but its occurrence is somewhat sporadic.

On the whole, however, even under somewhat adverse conditions, the average thickness losses for copper alloys in a marine atmosphere tend to be very slight, typically under 50 μm (Fig. 3). Thus, copper alloys can be safely specified for applications requiring long-term durability in a marine atmosphere. Design considerations for the atmospheric use of copper alloys include allowance for free drainage of structures, the possibility of staining from runoff water, and the use of smooth or polished surfaces.

Soils and Groundwater

Copper, zinc, lead, and iron are the metals most commonly used in underground construction. Data compiled by the National Bureau of Standards (NBS) compare the behavior of these materials in soils of the following four types: well-aerated acid soils low in soluble salts (Cecil clay loam), poorly aerated soils (Lake Charles clay), alkaline soils high in soluble salts (Docas clay), and soils high in sulfides (Rifle peat).

Corrosion data as a function of time for copper, iron, lead, and zinc exposed to these four types of soil are given in Fig. 4. Copper exhibits high resistance to corrosion by these soils, which are representative of most soils found in the United States. Where local soil conditions are unusually corrosive, it may be necessary to use some means of protection, such as cathodic protection, neutralizing backfill (limestone, for example), protective coating, or wrapping.

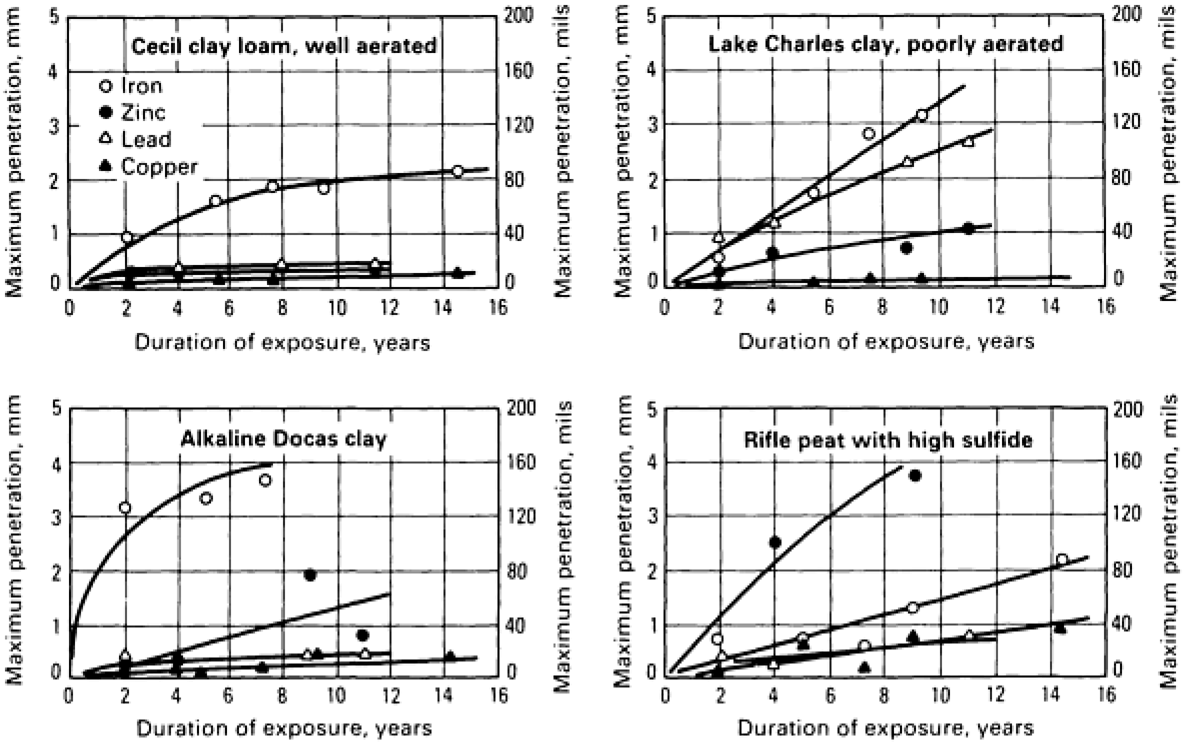

Fig. 4 Corrosion of copper, iron, lead and zinc in four different soils

For many years, NBS has conducted studies on the corrosion of underground structures to determine the specific behavior of metals and alloys when exposed for long periods in a wide range of soils. Results indicate that tough pitch coppers,

deoxidized coppers, silicon bronzes, and low-zinc brasses behave essentially alike. Soils containing cinders with high concentrations of sulfides, chlorides, or hydrogen ions (H^+) corrode these materials. In this type of contaminated soil, the corrosion rates of copper-zinc alloys containing more than about 22% Zn increase with zinc content. Corrosion generally results from dezincification. In soils that contain only sulfides, corrosion rates of the copper-zinc alloys decrease with increasing zinc content, and no dezincification occurs. Although not included in these tests, inhibited admiralty metals would offer significant resistance to dezincification.

Electric cables that contain copper are often buried underground. A recent study investigated the corrosion behavior of phosphorus-deoxidized copper (C12200) in four soil types: gravel, salt marsh, swamp, and clay (Ref 8). After 3 years of exposure, uniform corrosion rates were found to vary between 1.3 and 8.8 μm/yr (0.05 to 0.35 mil/yr). No pitting attack was observed. In general, the corrosion rate was highest for soils of lowest resistivity.

The possibility of disposing of nuclear waste in copper containers buried deep underground is currently under investigation. Except for the mining and oil industries, underground construction is usually limited to the first few tens of meters from the surface; an underground waste disposal vault would probably be located at a depth of 500 to 1000 m (1640 to 3280 ft) in stable bedrock. At these depths, the environment differs in several respects from that nearer the surface. With increasing depth, the natural groundwaters tend to become more saline and less oxidizing. In addition, the pressures exerted by hydrostatic and lithostatic forces become greater. These aspects affect the design and corrosion behavior of any metallic structure buried at such great depths.

A copper nuclear waste disposal container would be surrounded by a compacted claylike material. This serves a dual purpose: first it acts as a physical barrier, reducing the rate of transport of species to and from the container, and second, it provides some chemical buffering effects and effectively increases the pH of the environment. Both of these properties are beneficial in terms of the corrosion resistance of copper.

The clay most likely to be used is a montmorillonite clay, such as sodium bentonite. In the compacted form, this clay swells when wet and would effectively seal all cracks in the surrounding rock. The low permeability of the clay ensures that there would be no mass flow of groundwater and that transport of dissolved species would occur by diffusion only. The rate of diffusion in the clay is perhaps 100 times slower than in free solution. This slow rate of diffusion applies not only to the transport of oxidants, such as dissolved oxygen (O^2) or sulfide ions (S^{2-}), to the copper surface but also to the diffusion of soluble corrosion products away from the surface. The net effect is reduction in the corrosion rate of copper compared with that in free solution. One study suggests that under such conditions uniform corrosion of oxygen-free electronic copper (C10100) would only amount to 1.1 mm (43.4 mils) in 10^6 years (Ref 9). Experimental results indicate that the clay may reduce the corrosion rate by about a factor of ten over that in bulk solution, although these results suggest a corrosion rate of about 1 μm/yr (0.04 mils/yr) (Ref 10).

Naturally occurring saline waters are also found deep underground. Although the composition and concentration of these groundwaters vary from site to site, the concentration of dissolved species generally increases with depth (Ref 11). Such groundwaters are encountered in mines, during oil drilling, and in deep boreholes. The waters have a complex composition, often being mixtures of sodium (Na^+), calcium (Ca^{2+}), magnesium (Mg^{2+}), chloride (Cl^-) sulfate (SO_4^{2-}) and bicarbonate (HCO_3^-) ions as well as trace amounts of other ions. Iron minerals in the bedrock react with dissolved oxygen in the groundwater and produce less oxidizing conditions than are found in waters nearer the surface. Additional information on the corrosion of nuclear waste containment materials is available in the section "Corrosion of Containment Materials for Radioactive Waste" of the article "Corrosion in the Nuclear Power Industry" in this Volume.

The corrosion rate of copper in quiescent groundwaters tends to decrease with time. This is due to the formation of a protective film, an example of which is shown in Fig. 5. The underlying layer consists of species from the groundwater as well as copper. This layer is brittle and is extensively cracked, permitting continued dissolution of copper ions into solution. In Fig. 5, some of these copper ions have precipitated on the underlying layer in the form of cupric hydroxychloride [$CuCl_2 \cdot 3(Cu(OH)_2)$] and copper oxide crystals. The corrosion layer is not truly passivating, and corrosion will continue, although at a reduced rate.

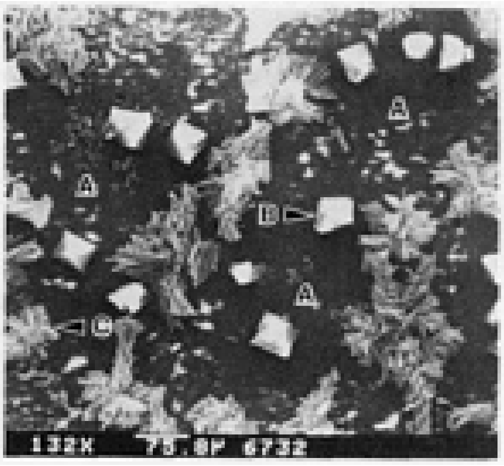

Fig. 5 Scanning electron micrograph of the corrosion product formed on C10100 in complex groundwater at 150 °C (300 °F). A, underlying film containing copper, silicon, calcium, chlorine, and magnesium; B, crystals of $CuCl_2$-3($Cu(OH)_2$); C, crystals of CuO or Cu_2O. Courtesy of F. King and C.D. Litke

For both copper and copper alloys, corrosion rate depends strongly on the amount of dissolved oxygen present. The data in Table 8 illustrate this point for both pure copper and Cu-10Ni in various synthetic groundwaters. These data are derived from experiments lasting from 2 to 4 weeks; therefore, they include the high initial rates of corrosion and do not represent long-term corrosion rates. However, they do not serve to show that deoxygenation of the solution results in at least an order of magnitude decrease in the short-term corrosion rate. It is also apparent from these data that, in aerated solutions at least, the addition of nickel decreases the uniform corrosion rate of copper. This is due to the formation of a more highly protective surface film.

Table 8 Short-term corrosion rates of copper alloys in saline groundwaters

Alloy	Type of groundwater	Oxygen concentration, μg/g	Temperature		Corrosion rate		Ref
			°C	**°F**	**μm/yr**	**mils/yr**	
C10100	Synthetic 55 g/L TDS[a]	<0.1	150	300	15	0.6	[b]

		1750	250	480	5000	197	

	600	250	480	400	15.7	12
Seawater	<0.1	250	480	70	2.8	

(a) TDS, total dissolved solids.

(b) F. King and C.D. Litke, unpublished research, 1985

The effects of salinity and temperature are less well understood. In general, increasing the total salinity of these groundwaters tends to increase their corrosiveness. However, it is not clear whether this is due to the sum effect of all the dissolved ions or of some of the species in particular. In open systems, it is difficult to distinguish the effect of temperature from that of dissolved oxygen, because the solubility of oxygen decreases with increasing temperature. The combination of these two opposing effects can lead to an apparent maximum in the corrosion rate at some intermediate temperature. Consequently, it is important that the rates refer to a constant dissolved-oxygen concentration when considering the effects of temperature.

Water

Freshwater. Copper is extensively used for handling freshwater. Copper tubing in the K-gage range with flared fittings was designed for underground water service and, along with type L tubing, has now become standard for this application. The largest single application of copper tubing is for hot-and cold-water distribution lines in homes and other buildings, although considerable quantities are also used in heating lines (including radiant heating lines for homes), drain tubes, and fire safety systems.

Copper. Minerals in water combine with dissolved CO_2 and oxygen and react with copper to form a protective film. Therefore, the corrosion rate is low (5 to 25 μm/yr, or 0.2 to 1.0 mil/yr) in most exposures. In distilled water or very soft water, protective films are less likely to form; therefore, the corrosion rate may vary from less than 2.5 to 125 μm/yr (0.1 to 5 mils/yr) or more, depending on oxygen and CO_2 contents.

Copper-Zinc Alloys. The corrosion resistance of the brasses is good in unpolluted freshwater--normally 2.5 to 25 μm/yr (0.1 to 1.0 mil/yr). Corrosion rates are somewhat higher in nonscaling water containing CO_2 and oxygen. Uninhibited brasses of high zinc content (35 to 40% Zn) are subject to dezincification when used with stagnant or slowly moving brackish or slightly acid waters. On the other hand, inhibited admiralty metals and brasses containing 15% Zn or less are highly resistant to dezincification and are used very successfully in these waters. Inhibited yellow brasses are widely used in Europe and are gaining acceptance in North America. Alloy C68700 (arsenical aluminum brass, an inhibited 77Cu-21Zn-2Al alloy) has been successfully used for condenser and heat-exchanger tubes.

Copper nickels generally have corrosion rates under 25 μm/yr (1 mil/yr) in unpolluted water. They are sometimes used to resist impingement attack where severe velocity and entrained-air conditions cannot be overcome by changes in operating conditions or equipment design.

Copper-silicon alloys (silicon bronzes) also have excellent corrosion resistance, and for these alloys, the amount of dissolved oxygen in the water does not influence corrosion significantly. If CO_2 is also present, the corrosion rate will increase (but not excessively), particularly at temperatures above 60 °C (140 °F). Corrosion rates for silicon bronzes are similar to those for copper.

Copper-Aluminum Alloys. The aluminum bronzes have been used in many waters, from potable water to brackish water to seawater. Softened waters are usually more corrosive to these materials than hard waters. Alloys C61300 and C63200 are used in cooling tower hardware in which the makeup water is sewage effluent. Aluminum bronzes resist oxidation and impingement corrosion because of the aluminum in the surface film.

Steam. Copper and copper alloys resist attack by pure steam, but if much CO_2, oxygen, or NH_3 is present, the condensate is corrosive. Even though wet steam at high velocities can cause severe impingement attack, copper alloys are extensively used in condensers and heat exchangers. Copper alloys are also used for feedwater heaters, although their use in such applications is somewhat limited because of their rapid decline in strength and creep resistance at moderately elevated temperatures. Copper nickels are the preferred copper alloys for the higher temperatures and pressures.

Use of copper in systems handling hot water and steam is limited by the working pressures of tubes and joints. For example, copper tubing of 6.4 to 25 mm ($\frac{1}{4}$ to 1 in.) nominal diameter joined with 50Sn-50Pb solder can be used at temperatures to 120 °C (250 °F) and pressures to 585 kPa (85 psi). The working pressure at this temperature in tubing of the same size can be increased to 1380 kPa (200 psi) when the system is joined with 95Sn-5Sb solder. When the joining material is a silver-base brazing alloy with a melting point above 540 °C (1000 °F), the working pressure at 120 °C (250 °F) for tubing in this size range can be increased to 2070 kPa (300 psi). A few copper alloys have shown a tendency to fail by SCC when they are highly stressed and exposed to steam. Alpha aluminum bronzes that do not contain tin are among the susceptible alloys.

Steam condensate that has been properly treated so that it is relatively free of noncondensate gases, as in a power-generating station, is relatively noncorrosive to copper and copper alloys. Rates of attack in most such exposures are less than 2.5 μm/yr (0.1 mil/yr). Copper and its alloys are not attacked by condensate that contains a significant amount of oil, such as condensate from a reciprocating steam engine.

Dissolved CO_2, oxygen, or both significantly increase the rate of attack. For example, condensate with 4.6 ppm O, and 14 ppm CO_2 and a pH of 5.5 at 68 °C (155 °F) caused an average penetration of 175 to 350 μm/yr (6.9 to 13.8 mils/yr) when in contact with C12200 (phosphorus-deoxidized copper), C14200 (arsenical copper), C23000 (red brass), C44300 to C44500 (admiralty metal), and C71000 (copper nickel, 20%). Steel tested under the same conditions was penetrated at about twice the rate given for the copper alloys listed above, but tin-coated copper proved to be much more resistant and was attacked at a rate of less than 25 μm/yr (1 mil/yr). To attain the optimum service life in condensate systems, it is necessary to ensure that the tubes are installed with enough slope to allow proper drainage, to reduce the quantity of corrosive agents (usually CO_2 and oxygen) at the source by mechanical or chemical treatment of the feedwater, or to treat the steam chemically.

Modern power utility boiler feedwater treatments commonly include the additional of organic amines to inhibit the corrosion of iron components of the system by scavenging oxygen and increasing the pH of the feedwater. These chemicals, such as morpholine, and hydrazine, decompose in service to yield NH_3, which can be quite corrosive toward some copper alloys. In the main body of well-monitored operating condensers, oxygen and NH_3 levels are quite low, and corrosion is usually mild. More aggressive conditions exist in the air removal section. Abnormal operating conditions, tube leakage, and shutdown-startup cycles may also increase the corrosivity of the steam-side environment by raising the oxygen concentration. The corrosion resistance in laboratory tests of a number of copper alloys and low-carbon steel in both aerated (8 to 12 ppm O_2) and deaerated (100 to 200 ppb O_2) NH_3 solutions are illustrated in Fig. 6 and 7. In these tests, NH_3 enhanced the corrosion resistance of the copper-nickel alloys, modifying surface oxides by increasing nickel content. Elevated oxygen levels are generally more deleterious than elevated NH_3 levels. However, C71500 was minimally affected by the elevated oxygen content. These laboratory data correlate well with field corrosion data from operating power plants (Table 9). Additional information on corrosion in power plant applications is available in the article "Corrosion of Fossil Fuel Power Plants" in this Volume.

Salt Water. An important use of copper alloys is in handling seawater in ships and tidewater power stations. Copper itself, although fairly useful, is usually less resistant to general corrosion than C44300 to C44500, C61300, C68700, C70600, or C71500. The superior performance of these alloys results from the combination of insolubility in seawater, erosion resistance, and biofouling resistance. The corrosion rates of copper and its alloys in relatively quiescent seawater are typically less than 50 μm/yr (2 mils/yr).

In the laboratory and in service, copper-nickel alloys C70600, C71500, C72200, and C71640 exhibit excellent corrosion resistance in seawater. Average corrosion rates for both C70600 and C71500 were shown to range from 2 to 12 μm/yr (0.08 to 0.5 mils/yr) (Ref 15). The long-term evaluations illustrated in Fig. 8 and 9 revealed corrosion rates under 2.5 μm/yr (0.1 mil/yr) for both alloys after 14 years of exposure to quiescent and low-velocity seawater (Ref 16). Sixteen-year tests confirmed this same low corrosion rate (Ref 17).

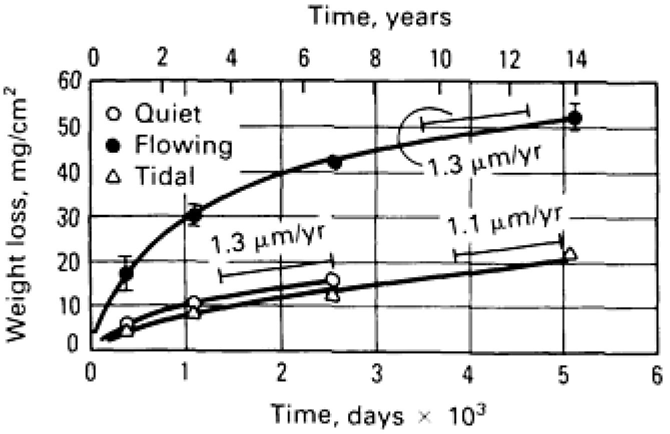

Fig. 8 Chronogravimetric curves for C70600 in quiet, flowing, and tidal seawater. Source: Ref 16

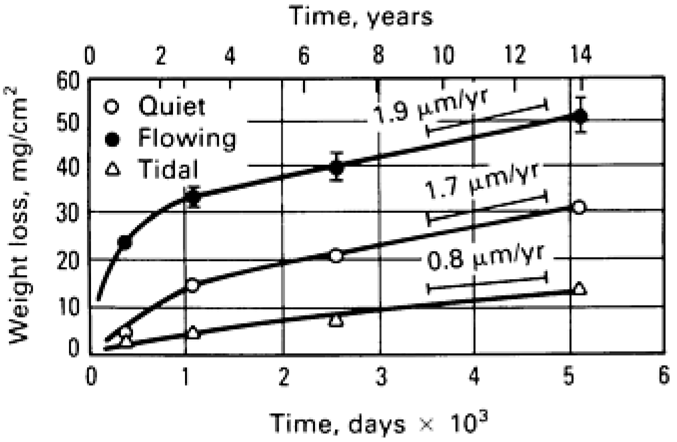

Fig. 9 Chronogravimetric curves for C71500 in quiet, flowing, and tidal seawater. Source: Ref 16

Pitting Resistance. Alloys C70600 and C71500 both display excellent resistance to pitting in seawater. The average depth of the 20 deepest pits in C71500 observed at the end of the 16-year tests was less than 127 μm (5 mils) (Ref 17). Chromium-modified copper-nickel alloys, developed for resistance to high-velocity seawater, were evaluated in both low- and high-velocity conditions. The quiescent and low-velocity performances of C72200, C70600, and C71500 were compared (Ref 18, 19); results showed uniform corrosion (5 to 25 μm/yr, or 0.2 to 1 mil/yr) on all three alloys. The chromium containing alloys, however, were slightly more susceptible to localized attack in quiet seawater. Another study reported that the pitting behavior of C72200 is influenced by the presence of iron and chromium in or out of solid solution (Ref 20). The fraction of iron plus chromium in solution in C72200 must be kept higher than 0.7 to avoid pitting corrosion.

Velocity Effects. The corrosion resistance of copper alloys in flowing seawater depends on the growth and maintenance of a protective film or corrosion product layers. These alloys typically exhibit velocity-dependent corrosion rates. The more adherent and protective the film on a particular alloy, the higher its breakaway velocity (the velocity at

which there is a transition from low to high corrosion rate) and the greater its resistance to impingement attack or erosion-corrosion.

Some of the earliest work on copper-nickel alloys demonstrated the beneficial effects of iron additions on seawater impingement resistance. The graphical summary of the effects of iron shown in Fig. 10 qualitatively illustrates the balance between pitting resistance and impingement resistance that defines the optimum iron content for 90Cu-10Ni and 70Cu-30Ni at 1.5 and 0.5% Fe, respectively. The effects of manganese level in association with iron in copper-nickel alloys are also addressed in Ref 21. The relative beneficial effects of 2% Fe and 2% Mn in a 70Cu-30Ni alloy (C71640) are shown in Fig. 11, which indicates that the C71640 and C72200 alloys are markedly more resistant to erosion-corrosion than C70600 at velocities up to 9 m/s (30 ft/s). The chromium-modified copper-nickel alloys also provide increased resistance to impingement attack compared to copper-nickel-iron alloys. In jet impingement tests (Ref 19) on several copper-base alloys at impingement velocities as high as 10 m/s (33 ft/s), no measurable impingement attack was observed on alloys C72200 and C71900 at 4.6 m/s (15 ft/s) (Table 10).

The behaviors of several copper-nickel alloys, including C71640 and C72200, have been characterized under conditions simulating partial blockage of a condenser tube (Ref 22). In the 1-year natural seawater tests, enhanced erosion-corrosion resistance was observed for the C71640 and C72200 alloys as compared to C70600 and C71500. Some localized pitting and/or crevice corrosion associated with the nonmetallic blockage device was noted for C71640 and C72200, with no

such attack occurring for the C70600 and C71500 alloys. Superior performance of the modified copper-nickel alloys C72200 and C71640 was also observed under severely erosive conditions in seawater containing entrained sand (Ref 23).

The combined results of laboratory impingement studies and service performance have produced maximum acceptable design velocities for condenser tube materials (Table 11). Erosion-corrosion was recently studied on the basis of fluid dynamics (Ref 24, 25, 26). Instead of defining the critical velocity of a material, which is difficult to relate to service conditions and which is specific to tubing diameter, the use of critical surface shear stress was advocated. This shear stress in a dynamic fluid system is a measure of the force applied by the moving fluid to the surface with which it interacts. It takes into account the changes in fluid density and kinematic viscosity with variations in temperature, specific gravity, and hydrodynamic parameters. Values of critical surface shear stress for several copper-base alloys are shown in Table 12.

Galvanic Effects. In general, the copper-base alloys are galvanically compatible with one another in seawater. The copper-nickel alloys are slightly cathodic (noble) to the nickel-free copper-base alloys, but the small differences in corrosion potential generally do not lead to serious galvanic effects unless unusually adverse anodic/cathodic area ratios are involved.

The data given in Table 13 demonstrate the increased attack of less noble carbon steel coupled to copper-nickel alloys, the increased attack on the copper-nickel alloys when coupled to more noble titanium, and the general compatibility of copper-nickel alloys with aluminum bronze. Coupling copper-nickel alloys to less noble materials affords protection to the copper-nickel that effectively reduces its corrosion rate, thus inhibiting the natural fouling resistance of the alloy.

Table 13 Galvanic couple data for C70600 and C71500 with other materials in flowing seawater

2-year exposures of equal area couples at a velocity of 0.6 m/s (2 ft/s)

Results of short-term galvanic couple tests between C70600 and several cast copper-base and ferrous alloys are listed in Table 14. The corrosion rate of cast 70Cu-30Ni was unaffected by coupling with an equal area of C70600, but some increased corrosion of other cast copper-base alloys was noted. Corrosion rates of cast stainless steels were reduced, with a resultant increase in the corrosion of C70600. Gray iron displayed the largest galvanic effect, while the corrosion rates of Ni-Resist cast irons nominally doubled. Although some caution should be exercised in using absolute values from any short-term tests, the relative degree of acceleration of corrosion from galvanic coupling was shown to be unaffected by extending some tests with Ni-Resist/C70600 couples to 1 year.

Effect of Oxygen, Depth, and Temperature. The corrosion of copper and copper-base alloys in clean seawater is cathodically controlled by oxygen reduction, with H^+ reduction being thermodynamically unfavorable. Dissolved oxygen retards corrosion by the promotion of a protective film on the copper alloy surface, but increases the rate of corrosion by depolarizing cathodic sites and oxidizing Cu^+ ions to more aggressive Cu^{2+} ions. Other factors, such as velocity, temperature, salinity, and ocean depth, affect the dissolved oxygen content of seawater, thus influencing the corrosion rate. In general, oxygen concentration decreases with increasing salinity, temperature, and depth. These factors can vary with depth in a complex manner and also vary from location to location in the oceans of the world (Ref 27.)

Although cathodic control by oxygen reduction suggests a strong dependence of corrosion rate on dissolved oxygen concentration, the growth of a protective oxide film on copper-nickel alloys minimizes the influence within the normally observed range of oxygen content found in seawater. Deep-ocean testing indicated that the corrosion rates of copper and copper-nickel alloys do not change significantly for dissloved oxygen contents between 1 and 6 mL/L of seawater and consequently were not significantly affected by variations in depth of exposure (Ref 27).

Short-term laboratory tests indicated only a small increase in corrosion rate with increasing temperature up to 30 °C (85 °F) (Ref 28). Long-term corrosion rate data from tests conducted at a coastal site near Panama (Ref 17) agree very well with long-term data for exposures in Wrightsville Beach, NC (Ref 16), where the seasonal temperature variation is 5 to 30 °C (40 to 85 °F). Final steady-state corrosion rates at both locations for C71500 ranged from 1 to 3 μm/yr (0.04 to 0.12 mils/yr).

Studies performed at higher temperatures relative to those in desalination plant environments show considerable disagreement in results (Ref 29, 30, 31, 32, 33, 34). From 60 to 107 °C (140 to 225 °F), temperature may increase, decrease, or have no significant effect on the corrosion rate of copper-nickel alloys. Lower corrosion rates for C70600 over an intermediate temperature range were reported in seawater corrosion tests between 32 and 107 °C (90 and 225 °F) with controlled seawater chemistry; bicarbonate alkalinity, dissolved oxygen, and pH were noted as critical factors controlling corrosion (Ref 33). Other studies confirmed lower average corrosion rates at 40 °C (105 °F) than at lower temperatures (Ref 35). The variation in results reported in the literature can perhaps be explained by variations in seawater chemistry between test sites and/or control of operating conditions in desalination plants.

Effect of Chlorine. Coastal power plants that use seawater as a coolant have long used chlorine to control fouling and slime formation. The effect of chlorination, both continuous and intermittent, on the corrosion of copper-nickel alloys was studied (Ref 36, 37). Continuous chlorine additions increased the corrosion rate of C70600 by a factor of two. Intermittent chlorination at a higher level controlled fouling, yet had no apparent effect on corrosion rates. A net reduction was noted in the corrosion rate of C71500 with continuous and most intermittent chlorine additions.

Seawater impingement tests were conducted on C70600, C71500, and C71640 with continuous additions of chlorine (and iron) (Ref 38). Additions of 0.5 to 4.0 mg/L of chlorine caused increased susceptibility to impingement attack on C70600 at a velocity of 9 m/s (30ft/s). Addition of chlorine up to 4.0 mg/L had little effect on the impingement resistance of C71500. Figure 12 summarizes the results of these tests.

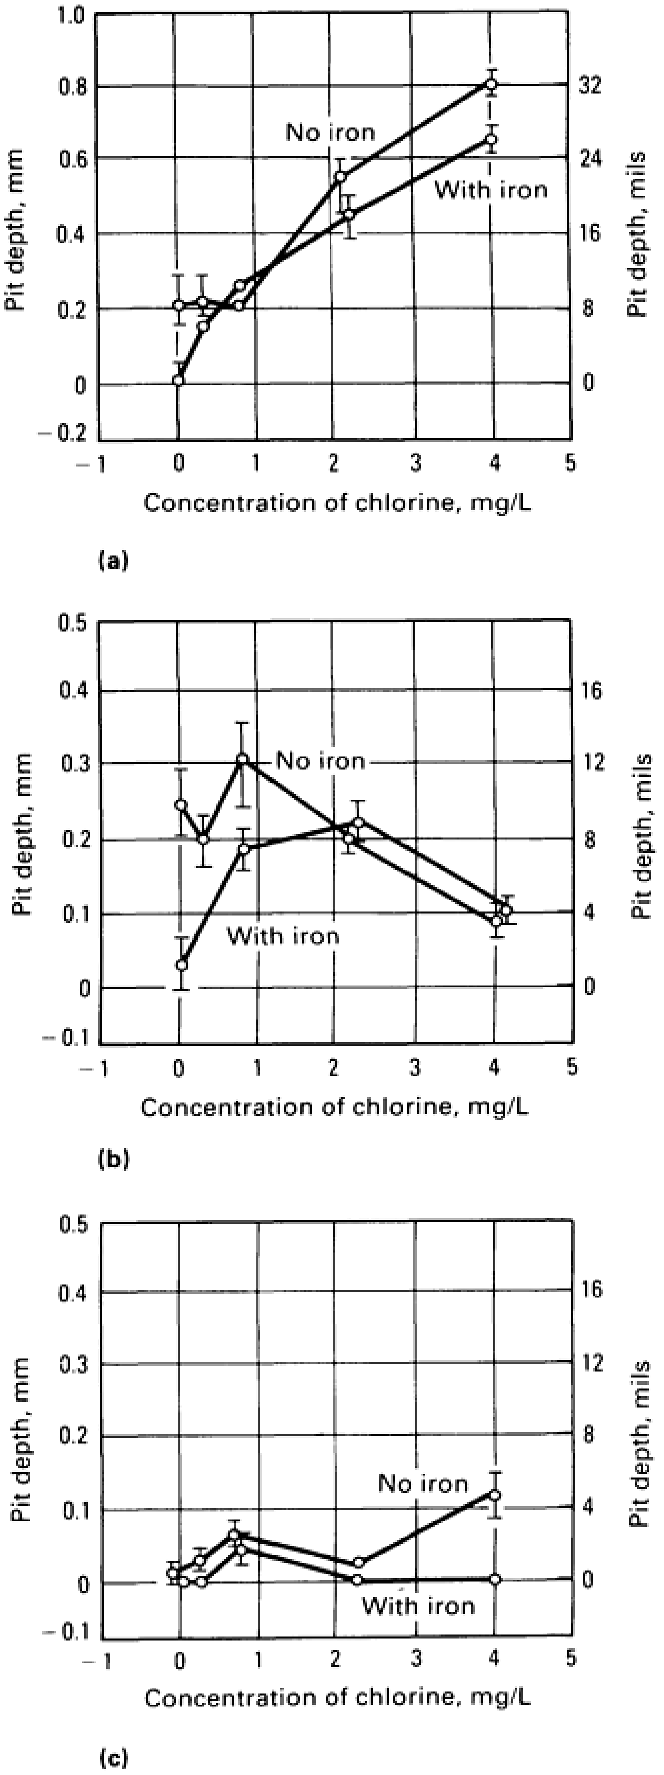

Fig. 12 Impingement attack versus chlorine levels for three copper alloys. (a) C70600. (b) C71500. (c) C71640

Polluted cooling waters, particularly in coastal harbors and estuaries, reportedly cause numerous premature failures of power station and shipboard condensers using copper-base alloys, including the copper-nickels. During the early 1950s, polluted waters were identified as the most important contributing factor in the failure of condenser tubes (Ref 39). Although enforcement of strict pollution standards has dramatically reduced pollution in many harbors in recent years, accelerated attack of condenser tubes and seawater piping materials by polluted waters is still reported.

The attack of copper-containing materials by polluted seawater has been addressed in numerous test programs. The primary causes of accelerated attack of copper-base alloys in polluted seawater are (1) the action of sulfate-reducing bacteria, under anaerobic conditions (for example, in bottom muds or sediments), on the natural sulfates present in seawater and (2) the putrefaction of organic sulfur compounds from decaying plant and animal matter within seawater systems during periods of extended shutdown (Ref 40). Partial putrefaction of organic sulfur compounds may also result in the formation of organic sulfides, such as cystine or glutathione, which can cause pitting of copper alloys in seawater (Ref 41).

Alloy C70600 has been found to be susceptible to sulfide-induced attack in aerated seawater containing sulfide concentrations as low as 0.01 mg/L (Ref 42). Recent work has demonstrated that, although the presence of 0.01 mg/L sulfide in aerated seawater can accelerate corrosion of copper-nickel alloys, the influence of seawater velocity is more significant (Ref 43). Figure 13 shows the rate of accelerated corrosion for C70600 as a function of sulfide and velocity.

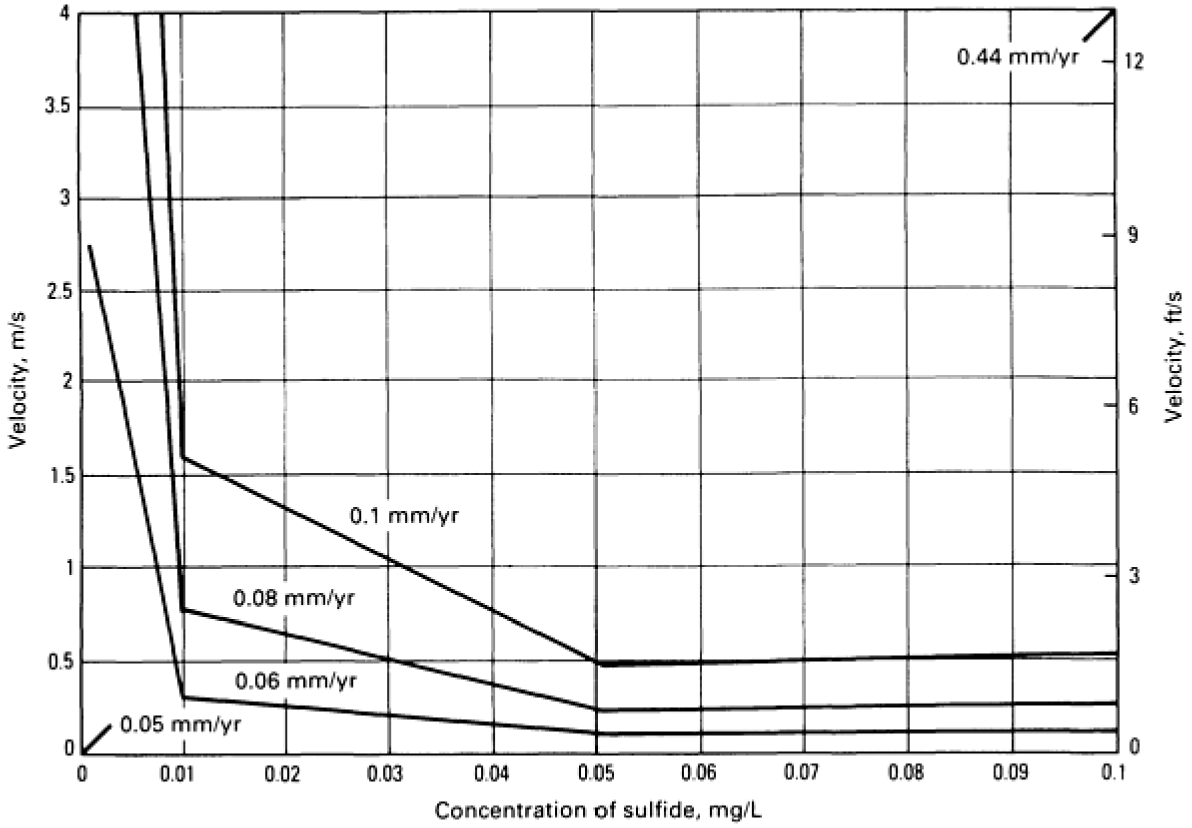

Fig. 13 Corrosion rates of C70600 as a function of seawater velocity and sulfide content

Inhibition of Corrosion. In some applications, the corrosion resistance of copper alloys is further enhanced by adding iron to the seawater. This iron is introduced either through the addition of ferrous sulfate ($FeSO_4$) or by direct oxidation of a sacrificial iron anode either with or without an externally applied current.

The effectiveness of environmental iron additions against sulfide corrosion of copper-nickel alloys was evaluated (Ref 44, 45). Iron added continuously at a level of 0.2 mg/L by a stimulated iron anode was effective against low level (0.01 mg/L) sulfide corrosion of both C70600 and C71500, although some attack was still observed. Corrosion, already actively proceeding, was significantly reduced, and the effects of additional low-level sulfide exposure were nullified by ferrous ion (Fe^{2+}) treatment. Intermittent injection of $FeSO_4$ for 2 h per day at 1.0 to 5.0 mg/L was not found effective against

high sulfide levels (0.2 mg/L), but was effective in reducing corrosion at lower sulfide levels (0.01 to 0.04 mg/L). Additional work demonstrated that continuous low-level additions of $FeSO_4$ could counteract sulfide-accelerated corrosion of copper-nickel alloys (Fig. 14).

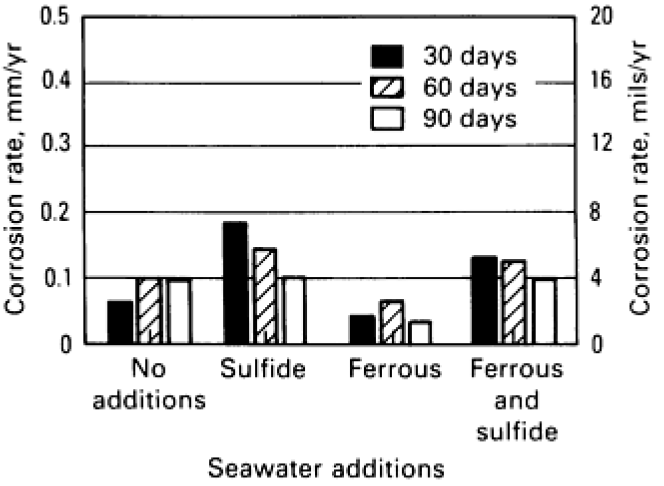

Fig. 14 Corrosion rates for C70600 exposed to seawater with additions of sulfide (0.05 mg/L) and/or Fe^{2+} (0.01 mg/L) ions. Source: Ref 46

In the use of $FeSO_4$ or stimulated iron anodes to counteract sulfide-induced corrosion, it should also be considered that iron additions affect heat-exchanger efficiency. The continued use of iron additions can result in a significant buildup of scale on the tube surface. At high enough levels of iron addition, sufficient sludge or precipitate may develop to result in complete blockage of the heat-exchanger tubes. At lower levels of iron addition, a bulky deposit will develop on the tube surface that may also interfere with heat transfer. In study of the increase in deposit formation and loss of heat transfer for aluminum brass in seawater with both intermittent and continuous Fe^{2+} ion dosing, it was recommended that some consideration be given to gradual reduction in dosing levels after the initial film formation (Ref 47).

Other preventive measures can be taken to minimize the deleterious effects of sulfides (Ref 48, 49, 50). Elimination of decaying plant and animal life from inlet pipes and channels can alleviate the effects of sulfate-reducing bacteria. Initial design or operational procedures, such as eliminating stagnant legs in a piping system or careful use of screening and filtration systems, can yield a valuable return on investment. Aeration of the seawater, such as by the use of cooling towers or cascading systems, also helps to displace any dissolved hydrogen sulfide (H_2S). In one study, impingement tests were performed on C71500 in seawater containing 10 mg/L cystine (an organic sulfur compound) and varying amounts of an inhibitor, sodium dimethyldithiocarbamate (Ref 50). The results indicated a reduction in the depth of impingement attack. It was noted, however, that a 0.10% solution would be cost prohibitive on a once-through basis, but would be cost effective if circulated through the shipboard piping system upon first flooding and upon shutting down. It was further noted that inhibitor injection is necessary only when the cooling water source is polluted estuarine seawater.

Biofouling. Copper alloys, including the copper-nickels, have long been recognized for their inherent resistance to marine fouling. This fouling resistance is usually associated with macrobiological fouling, such as barnacles, mussels and marine invertebrates of corresponding size. Service experience with shrimp trawlers and private yachts fabricated with C70600 or C71500 hulls has demonstrated excellent resistance to hard-shell fouling and an accompanying reduction in hull maintenance costs (Ref 49). Copper-nickel alloys have also performed successfully as seawater intake screens by virtue of their mechanical strength, corrosion resistance, and resistance to biofouling (Ref 50).

Research demonstrated that fouling was not observed on copper-nickel alloys containing 80% or more copper and that only incipient fouling was noted on the 70Cu-30Ni alloy (Ref 51, 52). More recent evaluations indicated approximately equivalent fouling resistance for C70600 and C71500 in 14 and 5-year exposures, respectively (Ref 16, 53). One investigation concluded that the fouling resistances of pure copper, C70600, and C71500 were virtually identical (Ref 53).

Studies of copper-nickel alloys found that some minimum copper solution rate from the corrosion process is required to prevent fouling (Ref 52). It was not established whether the effect was due to toxicity of copper ions released from the

metal surface or to a continual sloughing off of corrosion products. Fouling was minimal on C71500 exposed for 14 years, during which time the corrosion rate approached 1.0 μm/yr (0.04 mils/yr) (Ref 16). It was further demonstrated that copper ions released from a bare C70600 surface offered no fouling protection to an adjacent painted surface (Ref 53). This work concluded that the duplex nature of corrosion products on copper alloy surfaces is responsible for fouling resistance. The initial film formed on copper alloys exposed to seawater is Cu_2O. This inherently fouling-resistant material subsequently oxidizes to $CuCl_2 \cdot 3(Cu(OH)_2)$, which does not appear to be as toxic to marine organisms. The $CuCl_2 \cdot 3(Cu(OH)_2)$ periodically sloughs off from the material surface, carrying with it many marine organisms that may have attached. This reexposes the adherent, toxic Cu_2O film and renews fouling resistance.

Whatever the mechanism, the resistance to fouling is a result of corrosion of the alloy. If this is suppressed by galvanic effects or impressed cathodic protection, fouling will not be prevented.

Biofouling growth was studied on titanium and C70600 at 27 °C (80 °F) and at various velocities (Ref 54). Results (Fig. 15) indicated that the major fouling problem on titanium in the tests was silt particles bound by organic growths, while C70600 is fouled both by silt and corrosion products. Increasing velocity removes more of the silt and binding organisms, but not the corrosion products. Because titanium does not produce corrosion products, the change in the fouling rate with increasing velocity was more dramatic. The behavior of C70600 suggested the periodic sloughing off of portions of the fouling layer previously noted (Ref 53). At sufficient velocities (1.8 and 2.4 m/s, or 6 to 8 ft/s), macroorganisms did not adhere to the C70600 surface, and heat transfer resistance was due to corrosion products and entrapped particles. Fouling rates decrease by a factor of ten on titanium with an increase in velocity from 0.6 to 2.4 m/s (2 to 8 ft/s) and decrease by a factor of five on C70600 for the same velocity range.

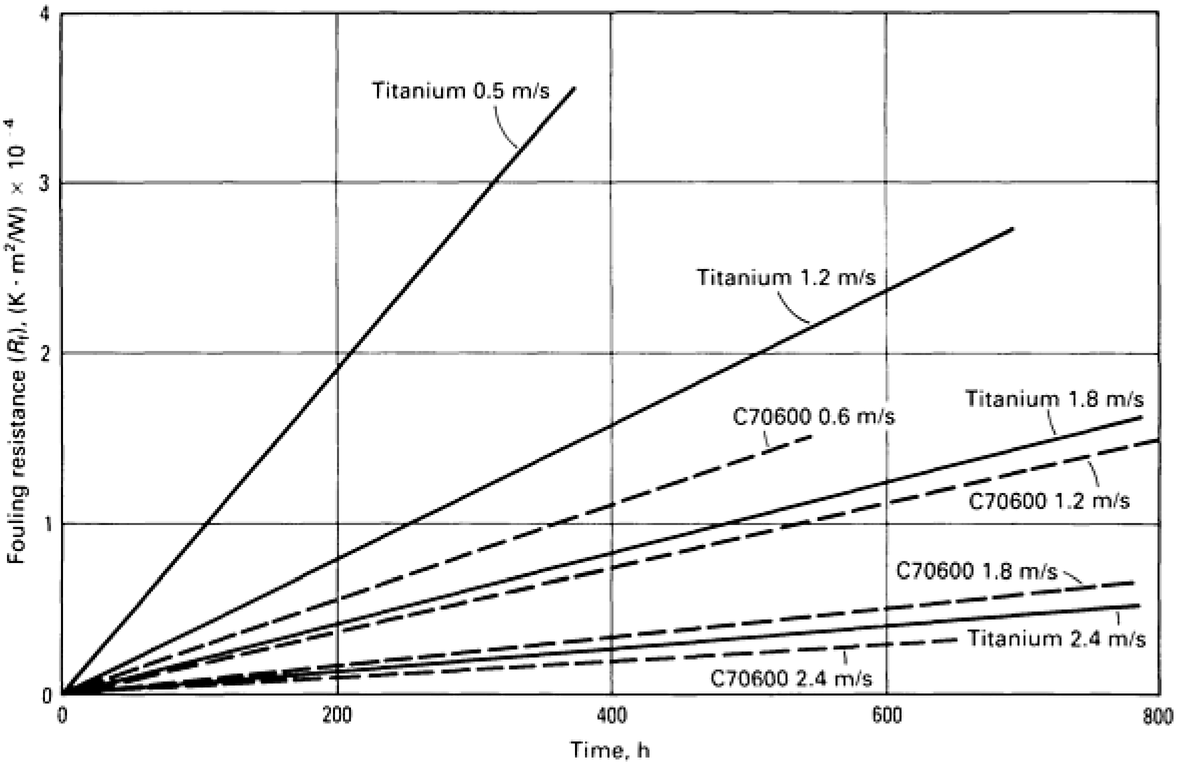

Fig. 15 Fouling rates of C70600 and titanium as a function of seawater velocity. Source: Ref 54

Other studies demonstrated the excellent resistance to fouling and resulting retention of heat transfer efficiency in natural seawater of the copper alloys (Ref 55, 56). Figure 16 shows corrosion data for C70600 specimens. The relatively infrequent sponge ball mechanical cleaning did not increase corrosion of the C70600 compared to uncleaned controls. Mechanical cleaning was required much more frequently for the titanium in order to maintain a given level of heat transfer efficiency. Intermittent chlorination did increase the initial corrosion rates, although the rates were comparable to uncleaned controls after approximately 90 days. By contrast, in other tests in which excessive mechanical cleaning was

used in natural seawater, a significant acceleration of corrosion occurred with daily sponge ball cleaning at a rate of 12 passes/h (Ref 57).

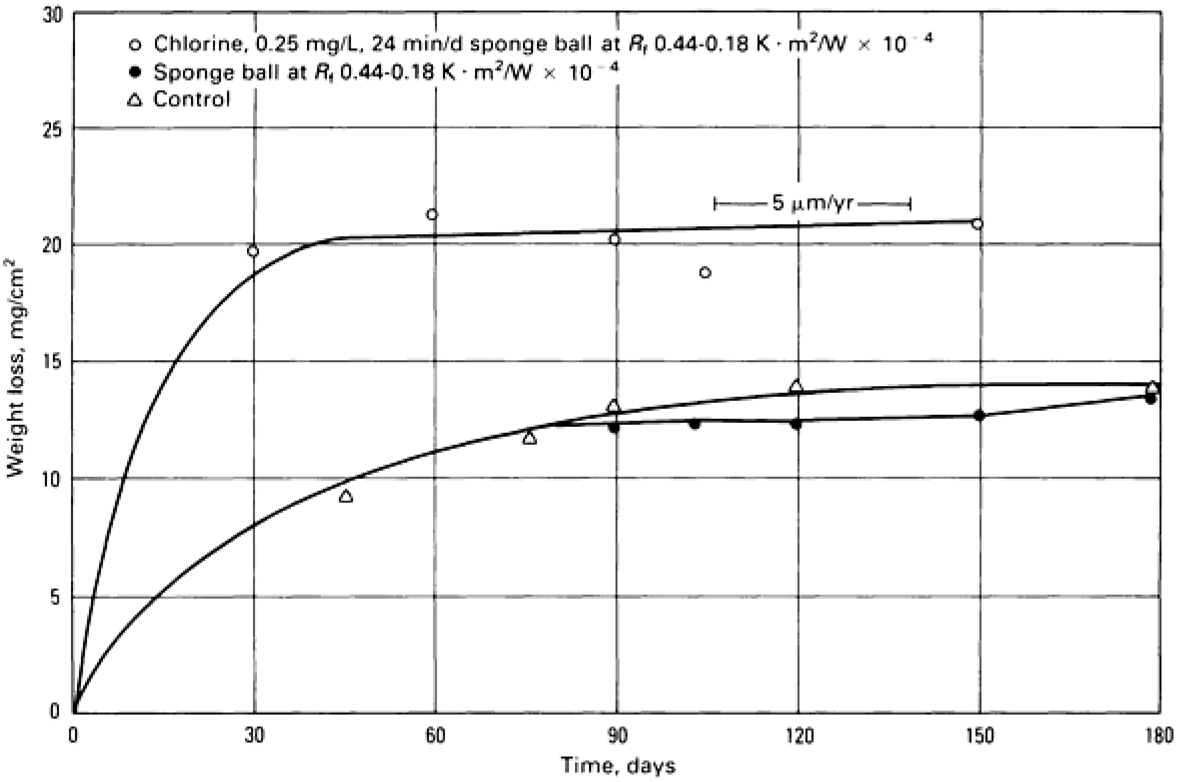

Fig. 16 Weight loss/corrosion data for C70600 cleaned by chlorinated sponge ball and sponge ball without chlorination

Heat Exchangers and Condensers. The selection of material for condenser and heat-exchanger tubes necessitates a survey of service conditions, an examination of tubes previously used and evaluation of its service life, and a review of the type, form, and location of corrosion experienced in the unit or in similar units. Types of water and operating conditions vary widely, and any estimate of probable tube performance must be based on specific operating factors. The tubes of the various alloys discussed in this section provide satisfactory and economical performance for the services described.

Inhibited admiralty metal (C44300, C44400, and C44500) has good corrosion resistance and is extensively used for tubing in various services, especially steam condensers cooled with fresh, salt, or brackish water. Admiralty metal tubes are also used for heat exchangers in oil refineries, in which corrosion from sulfur compounds and contaminated water may be very severe, and for feedwater heaters and heat-exchanger equipment as well as other industrial processes. Admiralty metal tubes are often used in equipment operating at temperatures of 200 °C (400 °F) or higher. Small amounts of phosphorus (0.02 to 0.06%) added to admiralty metal markedly increase dezincification resistance.

Inhibited aluminum brass (C68700) resists the action of high-velocity salt and brackish water and is commonly used for condenser tubes. The outstanding characteristic of C68700 is its high resistance to impingement attack. Tubes of this alloy are frequently recommended for use in marine and land power stations, in which cooling water velocities are high and inhibited admiralty metal tubes have failed because of impingement attack.

Aluminum Bronzes. Tube sheets made of C61300 and C63200 have been specified for coastal power station condensers. Alloy C61300 is also used for emergency raw seawater cooling system piping in coastal nuclear power plants. The aluminum bronzes of C61300, C63000, and C63200 in wrought form and C95400, C95500, and C95800 in cast form are extensively used in salt water environments. They are used in Navy seawater systems and submarine systems in pumps, valves, heat exchangers, and structural components for mounting electronic gear and propulsion units and are even more widely used in minesweepers, for which their nonmagnetic characteristics are important. They are used

in cast or wrought form for tube sheets and water boxes in saltwater evaporators and in seawater cooling loops in fossil and nuclear power plants. Corrosion rates are of the order of 10 to 50 μm/yr (0.4 to 2 mils/yr) depending on temperature and velocity, and generally decrease with time. Temper annealing is particularly important in the cast forms of these alloys when used in seawater.

Copper nickel, 10% (C70600) exhibits excellent resistance to impingement attack; it appears to be inferior only to copper nickel, 30%. It is also highly resistant to SCC. This alloy is suitable for marine condenser tube installations in place of aluminum brass, especially where higher water velocities are encountered.

Copper nickel, 30% (C71500) has, in general, the best resistance of any of the copper alloys to impingement attack and to corrosion by most acids and waters. It is being used in increasing quantities under severely corrosive conditions for which service lives longer than those of other copper alloys are desired. It is used by the United States Navy for most shipboard condensers and heat exchangers.

Phosphorus-deoxidized coppers (C12000 to C12300) are extensively used in sugar refineries for condensers and evaporators. Deoxidized copper and standard materials in the refrigeration industry and for transferring heat from steam to water or air, because of their excellent resistance to corrosion by freshwater and their high thermal conductivities.

Bimetal tubes are sometimes used to meet sever corrosion problems not handled adequately by tubes of a single metal or alloy. Two tubes of different alloys, one inside the other, form one integral tube. Copper may be the inner or outer layer, depending on the application.

Drain Tubes. Copper is used for waste and vent lines in drains. The first such installations were made in the mid-1930s, and since then, many municipalities have approved the use of copper drain lines. Development of Sovent fittings now enables construction of a single-stack drain system in high-rise buildings instead of the two-stack system formerly used.

Corrosion in Acids

Copper is widely employed for industrial equipment used to handle acid solutions. A fairly definite separation exists between those acids that can be handled by copper and those that cannot. In general, copper alloys are successfully used with nonoxidizing acids, such as CH_3COOH, H_2SO_4, HCl, and H_3PO_4, as long as the concentration of oxidizing agents, such as dissolved oxygen (air) and ferric (Fe^{3+}) or dichromate ions, is low. Broadly speaking, a thoroughly agitated or stirred solution or one into which a stream of air has been bubbled approaches air saturation and is therefore not a suitable acid medium for copper. Acids that are oxidizing agents in themselves, such as HNO_3; sulfurous (H_2SO_3); hot, concentrated H_2SO_4; and acids carrying such oxidizing agents as Fe^{3+} salts, dichromate ions, or permanganate (MnO_4^-) ions, cannot be handled in equipment made of copper or its alloys.

The corrosive action of a dilute (up to 1% acid) nonoxidizing acid on copper is relatively low; corrosion rates are usually less than 6 $g/m^2/d$ (equivalent penetration rate: 250 μm/yr, or 10 mils/yr). This is true only of oxidizing acids when the concentration does not exceed 0.01%. At such low acid concentrations, aeration has little effect in either oxidizing or nonoxidizing acids.

Nonoxodizing acids with near-zero aeration have virtually no corrosive effect. Rates in 1.2 *N* H_2SO_4, HCl, and CH_3COOH are less than 0.1 $g/m^2/d$ (4 μm/yr, or 0.15 mils/yr) in the absence of air. Figure 17 shows the general effect of various concentrations of oxygen on the corrosion rate of copper in these acids.

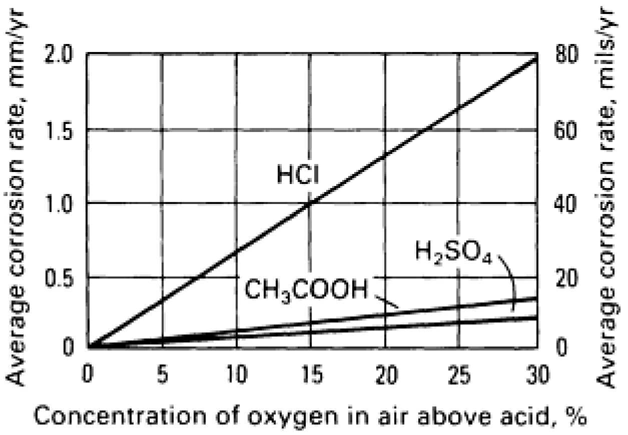

Fig. 17 Effect of oxygen on corrosion rates for copper in 1.2 *N* solutions of nonoxidizing acids. Specimens are immersed for 24 h at 24 °C (75 °F). Oxygen content of the solutions varied from test to test, depending on the concentration of oxygen in the atmosphere above the solutions.

Except for HCl, nonoxidizing acids that contain as much air as is absorbed in quiet contact with the atmosphere are weakly corrosive. Rates generally range from 0.5 to 6 $g/m^2/d$ (approximately 20 to 250 μm/yr, or 0.8 to 10 mils/yr).

Air-saturated solutions of nonoxidizing acids are likely to be strongly corrosive, with corrosion rates of 5 to 30 $g/m^2/d$ (0.2 to 1.25 mm/yr, or 8 to 50 mils/yr). This rate is higher for HCl. The actual corrosion in any aerated acid depends on acid concentration, temperature, and other factors that are difficult to classify. Except in very dilute solutions, oxidizing acids corrode copper rapidly--usually at rates above 50 $g/m^2/d$ (2.1 mm/yr, or 85 mils/yr). The reaction is independent of aeration.

The corrosion rates of three common acids are compared below (temperature and aeration are not specified):

Acid	Corrosion rate		
	$g/m^2/d$	**mm/yr**	**mils/yr**
32% HNO_3	5700	240	9450
Concentrated HCl	18	0.75	30

Phosphoric, CH_3COOH, tartaric, formic, oxalic, malic, and similar acids normally react comparably to H_2SO_4. Many of the copper alloys can be brazed with brazing rod of the same composition, which provides a joint that is about as corrosion resistant in acids as the base metal.

Factors that may accelerate corrosion vary from one plant to another, and it is advisable to conduct preliminary service or field tests under actual operating conditions before purchasing large quantities of an alloy. Corrosion-accelerating factors can then be evaluated. Selection of the most suitable material for use in a chemical process depends not only on corrosion

resistance but also on such factors as continuing availability of the alloy in the desired form and size (which should be ensured before any alloy is given serious consideration).

The following corrosion data were obtained in tests made under various conditions for handling different acids and acid solutions. Because of the variety of factors affecting all chemical reactions, that values shown cannot be taken as absolute and should be considered only as trends.

Sulfuric Acid. The corrosion rate of C65500 (3% silicon bronze) in H_2SO_4 indicates that this alloy can be successfully used with solutions of 3 to 70% H_2SO_4 (by weight) at temperatures of 25 to 70 °C (75 to 160 °F). Laboratory test results are shown in Fig. 18.

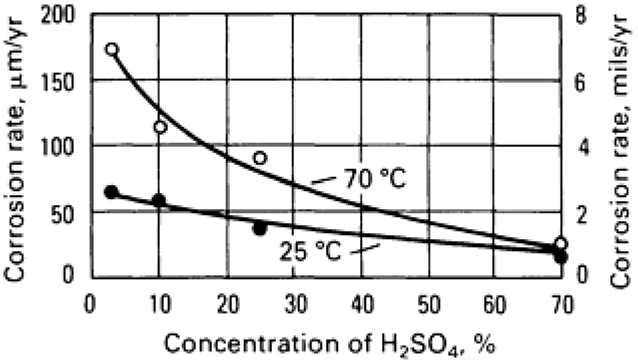

Fig. 18 Corrosion of C65500 in H_2SO_4 solutions. Specimens were immersed for 48 h at the indicated temperatures. The solution was not agitated or intentionally aerated.

Rate of attack by H_2SO_4 varies with concentration (Table 15). The presence of copper or iron salts in acid solutions accelerates the corrosion rate of copper (Table 16).

Aluminum bronze C61300 (wrought), as well as C95200 and C95800 (cast), were used extensively in dilute (10 to 20%) H_2SO_4 service, particularly in steel-pickling acids. Because these alloys have good corrosion resistance and high mechanical properties, thinner sections can withstand the required loads. In general, the copper alloys are quite resistant to the environment, but when in contact with the steel being pickled, they are galvanically protected and in turn accelerate the cleaning action of the acid on the steels. In time, the iron salts are changed from Fe^{2+} to Fe^{3+} (oxidizing) form, and there is increased corrosion; therefore, filtering or elimination of the salts is beneficial. Also, open tanks made of copper for this medium will have a higher corrosion rate at the liquid level line because of higher oxygen concentration. Hydrochloric acid added to H_2SO_4 greatly increases the corrosion rate of copper alloys compared to that in either acid individually.

Phosphoric Acid. Copper and copper alloys are used in heat-exchanger tubes, pipes, and fittings for handling H_3PO_4, although the corrosion rates of some of these alloys may be comparatively high. Laboratory tests were performed on eight groups of copper alloys in aerated and unaerated acid, with specimens at the water line, in quiet immersion and totally submerged. Acid concentrations ranged from 5 to 90%, and temperatures ranged from 20 to 85 °C (70 to 185 °F) except for the copper-aluminum-silicon alloy, which was tested only in 6.5% H_3PO_4 at 20 °C (70 °F) with specimens at the water line and in quiet immersion. Corrosion rates for the eight alloy groups were as follows:

Alloy type	Corrosion rate	
	mm/yr	**mils/yr**
Copper	0.55-3.7	22-148
Copper-zinc (70% Cu min)	0.13-7.0	5-280
Copper-tin	0.025-1.30	1-52
Copper-nickel	0.025-0.63	1-25
Copper-silicon	0.13-0.93	5-37
Copper-aluminum-iron	0.13-0.25	5-10

In general, copper and copper alloys provide satisfactory service in handling pure H_3PO_4 solutions in various concentrations. The acid concentration seems to have less effect on the corrosion rate than the amount of impurities. The

impure H_3PO_4 produced by the H_2SO_4 process may contain a markedly higher concentration of Fe^{3+}, (SO_4^{2-}), sulfite (SO_3^{2-}), Cl^-, and fluoride (F^-) ions than acid produced by the electric furnace process. These ions increase the corrosion rate up to 150 times, which limits the service lives of copper alloys.

Pure H_3PO_4 produced by the electric furnace process contains only small quantities of impurities and is therefore only slightly corrosive to copper and its alloys. Inhibited admiralty meals C44300, C44400, and C44500 are suggested for solutions of pure H_3PO_4.

Accumulation of corrosion products on metal surfaces may also increase both the rate of corrosion and the possibility of pitting. Low-copper alloys, such as C46400 (naval brass), appear to form thin, adherent films of corrosion products. Copper, copper-silicon alloys, and other high-copper alloys form more voluminous, porous films or scales beneath which roughened or pitted surfaces are likely to be found.

The H_3PO_4 vapors that condense in electrostatic precipitators at about 120 °C (250 °F) are noticeably more corrosive than solution of pure H_3PO_4 at the same or lower temperatures. The corrosion rates encountered in precipitators are so high that copper alloy wires will not give satisfactory service as electrodes. The high rate of corrosion is probably caused by an abundant supply of oxygen.

Although the corrosion rates of copper cooling tubes in H_3PO_4 condensation chambers are high (about 10 mm/yr, or 400 mils/yr), the rates are lower than those of some other materials. Therefore, the use of copper tubes is feasible for this application.

The above discussion on the effect of H_3PO_4 on copper and its alloys emphasizes the value of keeping service records. Such records are valuable for anticipating repairs, making changes to minimize the effect of various factors, and selecting materials for replacement parts.

Hydrochloric acid is one of the most corrosive of the nonoxidizing acids when in contact with copper and its alloys and is successfully handled only in dilute concentrations. The rates for C65800 in HCl of various concentration are listed in Table 17. The corrosion rates for two nonstandard silicon bronzes were about the same as those for C65800.

Table 17 Corrosion of C65800 totally submerged in HCl

Size of specimens, 50 × 25 × 1.3 mm (2 × 1 × 0.050 in.); surface condition, pickled; velocity of solution, natural convection; aeration, none; duration of test, 48 h

3	18.3	780	30.7
10	13.7	508	20.0
20	23.8	102	40.1
35	160.8	6860	270.1

The corrosion rate of copper nickels in 2 *N* HCl at 25 °C (75 °F) may range from 2.3 to 7.6 mm/yr (90 to 300 mils/yr), depending on the degree of aeration and other factors. Specimens of C71000 (copper nickel, 20%) in stagnant 1% HCl solutions at room temperature corrode at a rate of 305 μm/yr (12 mils/yr); in 10% HCl, 790 μm/yr (31 mils/yr).

Hydrofluoric acid (HF) is less corrosive than HCl and can be successfully handled by C71500 (copper nickel, 30%), which has good resistance to both aqueous and anhydrous HF. Unlike some other copper alloys, C71500 is not sensitive to velocity effects. The data given in Table 18 were generated from laboratory tests in conjunction with the HF alkylation process in anhydrous acid.

Table 18 Corrosion of wrought copper alloys in anhydrous HF

		C51000		**C44400**		**C71500**	
°C	**°F**	**μm/yr**	**mils/yr**	**μm/yr**	**mils/yr**	**μm/yr**	**mils/yr**
16-27	60-80	510	20	255	10	180	7
27-38	80-100	480	18.8	480	18.8	. . .	. . .

(a) These values are representative of results on copper alloys having high copper content, such as copper, aluminum bronze, silicon bronze, and inhibited admiralty metal. Corrosion rates for C23000 are between those for C44400 and C51000.

Acetic Acid and Acetic Anhydride [$(CH_3CO)_2O$]. Copper and copper alloys are successfully used in commercial processes involving exposure to CH_3COOH and related chemical compounds or in the manufacture of this acid. One plant kept records concerning the corrosion rate of C11000 used in two different CH_3COOH still systems. One still operated at 115 to 140 °C (240 to 285 °F) and handled a solution containing 50% CH_3COOH and about 50% $(CH_3CO)_2O$, with some esters also present. After operating for 663 h, the kettle showed an average penetration rate of 210 μm/yr (8.4 mils/yr). The rate was lower (60 μm/yr, or 2.4 mils/yr) for the bottom column and was lower yet (30 μm/yr, or 1.2 mils/yr) for the middle and top columns. A second still operating at 60 to 140 °C (140 to 285 °F) contained a 70% solution of CH_3COOH, the remainder being anhydride, esters, and ketones. After 1464 h, the kettle showed a corrosion rate of 120 μm/yr (4.8 mils/yr). The rate was only 30 μm/yr (1.2 mils/yr) for the middle and top columns.

In another field test, C11000 and C65500 coupons were placed in an CH_3COOH storage tank at ambient temperature. The stored solution contained 27% CH_3COOH, 1% butyl acetate, 70% H_2O, and small amounts of acetates, aldehydes, and other acids. During the 3984-h exposure, the specimens were immersed in the liquid phase 80% of the time and were in

the vapor phase 20% of the time. The C11000 specimens showed a corrosion rate of 38 to 53 μm/yr (1.5 to 2.1 mils/yr); the C65500 specimens, 30 to 45 μm/yr (1.2 to 1.8 mils/yr).

The results of other field tests for C11000 and C65500 exposed in CH_3COOH mixtures are given in Tables 19, 20, and 21. Test conditions involved various temperatures, concentrations, exposure times, locations in equipment as well as the presence of other chemicals.

Table 19 Corrosion of copper in $CH_3COOH-(CH_3CO)_2O$ mixtures

Copper alloy	Exposure time, h	Test conditions	Average penetration rate	
			μm/yr	**mils/yr**

(a) Test specimens were exposed in stills separating CH_3COOH from $(CH_3CO)_2O$.

(b) Top of column.

(c) Kettle.

(d) Test specimens were exposed in cycle feed lines at 30-50 °C (85-120 °F).

(e) Joint brazed with BCuP-5 filler metal.

(f) BAg filler metal.

(g) Test specimens were exposed in the CH_3COOH recovery column, in which concentration of the acetic acid was 45% max.

(h) Test specimens were exposed to crude by-product CH_3COOH (approximately 25% concentration) in pump suction line from storage tank.

In laboratory tests at room temperature, C61300 and C62300 exhibited typical corrosion rates of 65 to 80 μm/yr (2.5 to 3.2 mils/yr) in 10 to 40% CH_3COOH. The copper-aluminum alloys are suitable for use in CH_3COOH and the range of aliphatic and aromatic organic acids. The addition of chlorine atoms to the organic molecule will not increase the tendency toward pitting or crevice corrosion. Alloy C61300 is extensively used for pressure and valve castings.

Hydrocyanic acid (HCN) can be successfully handled by copper and copper alloys. Results of field tests for C11000 and C65500 are given in Tables 22 and 23.

Fatty Acids. Under severe service conditions, fatty acids attack copper alloys at somewhat higher rates than other organic acids, such as CH_3COOH or citric. Tests were conducted for 400 h in a copper-lined wooded splitting tank containing a mixture of about 60% fatty acids, 39% H_2O, and 1.17% H_2SO_4 heated to 100 °C (212 °F) and agitated violently with an open steam jet. Specimens of C71000 (copper nickel, 20%) showed a corrosion rate of 64 μm/yr (2.6 mils/yr); specimens of C71500 (cooper nickel, 30%), 59 μm/yr (2.4 mils/yr) when submerge just below the liquid level in the tank. Similar specimens submerged 150 mm (6 in.) from the bottom of the tank showed corrosion rates of 178 and 185 μm/yr (7.0 and 7.3 mils/yr) for C71000 and C71500, respectively.

Oleic Acid. Copper and copper-zinc alloys are highly resistant to attack by pure oleic acid. However, oleic acid will attack these alloys when air and water are present. Temperature also influences the rate of attack. Copper and several copper alloys were tested in oleic acid at 25 °C (75 °F); C51000 and C61300 corroded at less than 50 μm/yr (2 mils/yr) compared with about 500 μm/yr (20 mils/yr) for C26000 and C65500.

Stearic acid, like all other fatty acids, attacks copper and copper alloys when moisture and air are present. Temperature and impurities also influence the rate of attack. Tests made at 25 to 100 °C (75 to 212 °F) in stearic acid showed corrosion rates of C11000, C26000, and C65500 to be in the range of 500 to 1250 μm/yr (20 to 50 mils/yr).

Tartaric Acid. Copper and its alloys corrode rather slowly when exposed to various concentrations of tartaric acid, as indicated by the laboratory test data given in Table 24.

Table 24 Corrosion of copper alloys in contact with tartaric acid at 25 °C (75 °F)

Corrosion in Alkalies

Copper and its alloys resist alkaline solutions, except those containing NH_4OH or compounds that hydrolyze to NH_4OH or cyanides. Ammonium hydroxide reacts with copper to form soluble complex copper cations, but the cyanides react to form soluble complex copper anions. The rate of attack for copper-zinc alloys exposed to alkalies other than those

specified above is about 50 to 500 μm/yr (2 to 20 mils/yr) at room temperature under stagnant conditions, but is about 500 to 1750 μm/yr (20 to 70 mils/yr) in aerated boiling solutions.

Alloy C71500 corrodes at less than 5 μm/yr (0.2 mil/yr) in 1 *N* to 2 *N* NaOH solutions at room temperature, and the degree of aeration usually has no significant effect. This rate is two to three times as great as the rate in boiling solutions. Copper-tin alloys (phosphor bronzes) corrode at less than 250 μm/yr (10 mils/yr) in 1 *N* to 2 *N* NaOH solutions at room temperature and are apparently unaffected by aeration.

Copper and two grades of silicon bronze were tested in a 50% NaOH solution at 60 °C (140 °F) for 4 weeks. The specimens were bright rolled and degreased sheet measuring about 25 × 50 × 1.3 mm (1 × 2 × 0.05 in.). The solution was exposed to air (no additional aeration), and velocity was limited to natural convection. Alloy C11000 showed a corrosion rate of 1.7 g/m^2/d (70 μm/yr, or 2.8 mils/yr); C65100, 1.5 g/m^2/d (63 μm/yr, or 2.5 mils/yr); and C65500, 1.1 g/m^2/d (47 μm/yr, or 1.85 mils/yr).

Ammonium Hydroxide. Strong NH_4OH solutions attack copper and copper alloys rapidly, as compared with the rates of attack by metallic hydroxides because of the formation of a soluble complex copper-ammonium compound. However, in some applications, the corrosion of copper exposed to dilute solutions of NH_4OH is low. For example, copper specimens submerged in 0.01 *N* NH_4OH solution at room temperature for 1 week experienced weight loss of 1.5 m/m^2/d (60 μm/yr, or 2.5 mils/yr).

Ammonium hydroxide solutions also attack copper-zinc alloys. Alloys containing more than 15% Zn are susceptible to SCC when exposed to NH_4OH. The stress may be due to applied service loads or to unrelieved residual stresses. In quiescent 2 *N* NH_4OH solutions at room temperature, copper-zinc alloys corrode at 1.8 to 6.6 mm/yr (70 to 260 mils/yr), copper-nickel alloys at 0.25 to 0.50 mm/yr (10 to 20 mils/yr), copper-tin alloys at 1.3 to 2.5 mm/yr (50 to 100 mils/yr), and copper silicon alloys at 0.75 to 5 mm/yr (30 to 200 mils/yr).

Anhydrous NH_3. Copper and its alloys are suitable for handling anhydrous NH_3 if the NH_3 remains anhydrous and is not contaminated with water and oxygen. In one test conducted for 1200 h, C11200 and C26000 each showed an average penetration of 5 μm/yr (0.2 mil/yr) in contact with anhydrous NH_3 at atmospheric temperature and pressure. Tests showed the rates of corrosion to be low in the presence of small amounts of water, but oxygen was probably excluded. Table 25 lists data on exposure for 1600 h. For any new installation, tests simulating the expected conditions are recommended.

Table 25 Corrosion of copper and brass in NH_3

Alloy	Average penetration rate[(a)]			
	Liquid		**Vapor**	
	μm/yr	**mils/yr**	**μm/yr**	**mils/yr**
Anhydrous NH_3				
C11000	2.5	0.1	<2.5	<0.1
C26000	<2.5	<0.1	<2.5	<0.1
Anhydrous NH_3 plus 1% H_2O[(b)]				

C26000	2.5	0.1	<2.5	<0.1
Anhydrous NH_3 plus 2% H_2O[(b)]				
C11000	2.5	0.1	2.5	0.1
C26000	5.0	0.2	2.5	0.1

(a) Atmospheric temperature and pressure of 345 to 1035 kPa (50 to 150 psi) for 1600-h exposure. Specimens were placed at the top and bottom of 2-L bombs that were charged with NH_3. Pressure varied throughout the test, depending on temperature. Water was added to two of the bombs before charging with NH_3.

(b) Any air present was probably depleted rapidly during initial stages of test.

Corrosion in Salts

Copper metals are widely used in equipment for handling saline solutions of various kinds, particularly those that are nearly neutral. Among these are the nitrates, sulfates, and chlorides of sodium and potassium. Chlorides are usually more corrosive than the other salts, especially in strongly agitated, aerated solutions.

The nonoxidizing acid salts, such as the alums and certain metal chlorides (magnesium and calcium chlorides) that hydrolyze in water to produce an acidic pH, exhibit essentially the same behavior as dilute solutions of the corresponding acids. Corrosion rates generally range from 2.5 to 1500 μm/yr (0.1 to 60 mils/yr) at room temperature, depending on the degree of aeration and the acidity. Table 26 lists test data for corrosion of copper in 30% calcium chloride ($CaCl_2$) refrigeration brine with and without inhibitors.

Table 26 Corrosion of C11000 in 30% $CaCl_2$ refrigeration brine

Inhibitors	Corrosion rate	
	μm/yr	**mils/yr**
None[(a)]	10	0.4
$K_2Cr_2O_7$[(b)]	6	0.23
Aluminum foil[(c)]	119	4.7

(a) Exposed for 325 days at -12 °C (10 °F).

(b) Exposed for 372 days, cold.

(c) Exposed for 50 days with slight agitation in brine with a pH of 9

Neutral saline solutions can be successfully handled by copper alloys. Consequently, these alloys are used in heat-exchanger and condenser equipment exposed to seawater. Corrosion rates of copper in NaCl brine are given in Table 27. These rates are not necessarily the same as those in seawater.

Table 27 Corrosion of C11000 in a NaCl brine refrigeration system

Field test; 98 days at -15 °C (4 °F)

Location in equipment	Corrosion rate	
	μm/yr	**mils/yr**
With $Na_2Cr_2O_7$ inhibitor; pH 6.0 to 6.5		
Brine tank for near main outlet	5	0.2
Top of brine pump, high agitation	10	0.4
Inside cooler tube	15	0.6
Return line to storage tank	2.5	0.1
Brine tank near agitator	2.5	0.1
Without inhibitor; pH 10.5		
Open brine tank	160	6.3
Brine cooler outlet, rapid flow	360	14.2
Cooler inlet	157	6.2
Cooler outlet	250	9.8

Such alkaline salts as sodium silicate (Na_2SiO_3), sodium phosphate (Na_3PO_4), and sodium carbonate (Na_2CO_3) attack copper alloys at low but different rates at room temperature. On the other hand, alkali cyanide is aggressive and attacks copper alloys fairly rapidly because it forms a soluble complex copper anion. Table 28 provides specific corrosion rates.

Table 28 Corrosion of copper alloys in alkaline saline solutions

Alloy family	Common name	Corrosion rate	
		μm/yr	**mils/yr**
Na_2SiO_3, Na_3PO_4, or Na_2CO_3			
Copper-zinc	Brasses	50-125	2-5
Copper-tin	Phosphorus bronzes	<50	<2
Copper-nickel	Copper nickels	2.5-40	0.1-1.5
NaCN			
Copper-zinc	Brasses	250-500	10-20
Copper-tin	Phosphorus bronzes	875	35
Copper-nickel	Copper nickels	500-2500	20-100

Oxidizing salts corrode copper and copper alloys rapidly; therefore, copper metals should not be used with oxidizing saline solutions except those that are very dilute. Aqueous sodium dichromate ($Na_2Cr_2O_7$) solutions can be safely handled by copper alloys, but the presence of a highly ionized acid, such as H_2CrO_4 or H_2SO_4, may increase the corrosion rate several hundred times, because the dichromate acts as an oxidizing agent in acidic solutions. In one test, a copper-nickel corroded at 2.5 to 250 μm/yr (0.1 to 10 mils/yr) and a copper-tin alloy (phosphor bronze) at 5 μm/yr (0.2 mil/yr) when handling an aqueous $Na_2Cr_2O_7$ solution. The rate increased 200 to 300 times for both metals when H_2CrO_4 was added to the solution. In solutions containing Fe^{3+}, mercuric (Hg^{2+}) or stannic (Sn^{4+}) ions, a copper-nickel showed a corrosion rate of 27.4 mm/yr (1080 mils/yr), while copper-zinc an copper-tin alloys showed a still greater rate of 228 mm/yr (8980 mils/yr).

Salts of metals more noble than copper, such as the nitrates of mercury and silver, corrode copper alloys rapidly, simultaneously plating out the noble metal on the copper surface. Temperature and acidity influence the rate of attack. A film of mercury on high-zinc brass (more than 15% Zn) may cause intergranular cracking by liquid-metal embrittlement (LME) if the alloy is under tensile stress, either residual of applied.

Corrosion in Organic Compounds

Copper and many of its alloys resist corrosive attack by most organic solvents and by organic compounds, such as amines, alkanolamines, esters, glycols, ethers, ketones, alcohols, aldehydes, naphtha, and gasoline. Although the corrosion rates of copper and copper alloys in pure alkanolamines and amines are low, they can be significantly increased if these compounds are contaminated with water, acids, alkalies, salts, or combinations of these impurities, particularly at high temperatures. Tables 29, 30, 31, 32, 33, 34, and 35 list the results of corrosion testing of copper and a limited but representative variety of copper alloys in contact with various organic compounds under many conditions.

Table 29 Corrosion of copper alloys in amine system service

Alloy	Exposure time, h	Test conditions	Average rate	penetration
			μm/yr	**mils/yr**

Gasoline, naphtha, and other related hydrocarbons in pure form will not attack copper or any of the copper alloys. However, in the manufacture of hydrocarbon materials, process streams are likely to be contaminated with one or more of such substances as water, sulfides, acids, and various organic compounds. These contaminants attack copper and its alloys. Corrosion rates for C44300 and C71500 exposed to gasoline are low (Table 36), and these two alloys are successfully used in equipment for refining gasoline. Table 37 lists corrosion rates for copper and for alloys exposed to contaminated naphtha in two different environments.

Table 36 Corrosion of C44300 and C71500 exposed to gasoline in a refinery

Service condition[(a)]	Temperature		Average penetration rate	
	°C	**°F**	**m/yr**	**mils/yr**
C44300				
Straight-run (untreated)				
Tower liquid[(b)]	121	250	1270 min	50 min
Storage[(c)]	4-27	40-80	63	2.5
Distilled tops from straight-run gasoline[(d)]	35	95	1270	50
Cracked gasoline (top tray in tower)[(e)]	204	400	15	0.6
Sweet gasoline vapor[(f)]	177	350	7.5	0.3
C71500				
Straight-run (untreated)				
Tower liquid[(b)]	121	250	180	7
Storage[(c)]	4-27	40-80	180	7
Distilled tops from straight-run gasoline[(d)]	35	95	1140	45
Cracked gasoline (top tray in tower)[(e)]	204	400	200	8
Sweet gasoline vapor[(f)]	177	350	10	0.4

Aviation gasoline (top of column)	121	250	2.5	0.1

(a) Gasoline or related hydrocarbons will not attack copper or its alloys. Attack depends on the type and amount of impurities in the gasoline, such as water, sulfides, mercaptans, aliphatic acids, naphthenic acids, phenols, nitrogen bases, and dissolved gases.

(b) 100 lb of H_2S present per 1000 bbl of gasoline.

(c) 0.02-0.03 g H_2S per liter of gasoline.

(d) pH controlled by NH_3.

(e) H_2S and HCl present.

(f) Vacuum operation

Table 37 Corrosion of copper alloys in contaminated naphtha

Alloy	Corrosion rate	
	m/yr	**mils/yr**
At 21 °C (70 °F)[a]		
C23000	230	9
C46400	50	2
C28000	75	3
C44200	200	8
C11000	1270	50
At 177 °C (350 °F[b]		
C23000	2030	80
C46400	10	0.4
C28000	10	0.4

C44200	200	8

(a) The naphtha contained H_2S, H_2O, and HCl.

(b) The naphtha contained H_2S, mercaptans, and naphthenic acids

Creosote. Copper and copper alloys are generally suitable for use with creosote, although creosote attacks some high-zinc brasses. Alloys C11000, C23000, C26000, C51000, and C65500 typically corrode at rates less than 500 m/yr (20 mils/yr) when exposed to creosote at 25 °C (75 °F).

Linseed Oil. Copper and its alloys are fairly resistant to corrosion by linseed oil. All of the alloys show some attack, but none exhibits corrosion severe enough to make it unsuitable for this application. Alloys C11000, C51000, and C65500 showed corrosion rates less than 500 m/yr (20 mils/yr) in linseed oil at 25 °C (75 °F). Alloy C26000 had a rate of 500 to 1250 m/yr (20 to 50 mils/yr).

Benzol and Benzene. Alloys C11000, C23000, C26000, C51000, and C65500 tested in these materials at 25 °C (75 °F) had corrosion rates under 500 m/yr (20 mils/yr).

Sugar. Copper is successfully used for vacuum-pan heating coils, evaporators, and juice extractors in the manufacture of both cane and beet sugar. Inhibited admiralty metals, aluminum brass, aluminum bronzes, and copper nickels are also used for tubes in juice heaters and evaporators. Bimetal tubes of copper and steel have been used by manufacturers of beet sugar to counteract SCC of copper tubes caused by NH_3 from beets grown in fertilized soil. Table 38 lists the results of tests conducted on copper and copper alloys in a beet-sugar refinery.

Table 38 Corrosion of copper alloys in beet-sugar solution

Alloy	Decrease in tensile strength, %, for test rack number[a]			
	1	**2**	**3**	**4**
C11000	0	4.0	3.5	0
C44300	2.0	9.5	11.5	2.5
C44400	0	3.0	6.0	0
C44500	4.5	9.0	12.5	5.5
C71000	1.0	4.5	7.0	0

(a) Corrosion specimens (0.8-mm, or 0.032-in., thick strips) were exposed in contact with beet-sugar solution for 100 days in normal refinery operations. Test racks 1 and 4 were at the finishing pan containing Steffen's filtrate; rack 2 was in the first-effect thin-juice evaporator; rack 3 was at the third body of the triple-effect evaporator.

Beer. Copper is extensively used in the brewing of beer. In one installation, the wall thickness of copper kettles thinned from an original thickness of 16 mm ($\frac{5}{8}$ in.) to 10 mm ($\frac{3}{8}$ in.) in a 30-year period. Brazing with BAg (copper-silver) filler metals eliminates the possibility that the alkaline compounds used for cleaning copper equipment will destroy joints by attacking tin-lead solders. Steam coils require more frequent replacement than any other component in brewery equipment. They have service lives of 15 to 20 years. The service lives of other copper items exposed to process streams in a brewery range from 30 to 40 years. Additional information on metals and alloys for this application is available in the article "Corrosion in the Brewery Industry" in this Volume.

Sulfur compounds free to react with copper, such as H_2S, sodium sulfide (Na_2S), or potassium sulfide (K_2S), form CuS. Reaction rates depend on alloy composition; the alloys of highest resistance are those of high zinc content.

Strip tensile specimens of seven copper alloys were exposed in a fractionating tower in which oil containing 1.4% S was being processed. The results of this accelerated test are given in Table 39. These data show the suitability of the higher-zinc alloys for use with sulfur-bearing compounds. Alloy C28000 (60Cu-40Zn) showed good corrosion resistance, but C23000 (85Cu-15Zn) was completely destroyed.

Table 39 Corrosion of selected copper alloys in cracked oil containing 1.4% S

Alloy type	UNS number	Exposure time, days	Loss in tensile strength[(a)], %			
			360 °C (680 °F)	**315 °C (600 °F)**	**285 °C (545 °F)**	**255 °C (490 °F)**
Red brass, 85%	C23000	27	100[(b)]	100[(c)]	100	100

Silicon bronze, 3%	. . .	34	. . .	100	100	100

(a) Specimens 0.8 × 13 mm (0.032 × 0.50 in.) in cross section were exposed at different locations within a high-pressure fractionating column, each location having a characteristic average temperature.

(b) 115-day exposure.

(c) 26-day exposure.

(d) Length of exposure unavailable

Inhibited admiralty metals are also excellent alloys for use in heat exchangers and condensers that handle sulfur-bearing petroleum products and use water as the coolant. Alloys C44300, C44400, and C44500, which are inhibited toward dezincification by the addition of arsenic, antimony, or phosphorus to the basic 70Cu-29Zn-1Sn composition, offer good resistance to corrosion from sulfur as well as excellent resistance to the water side of the heat exchanger.

Corrosion in Gases

Carbon dioxide and carbon monoxide (CO) in dry forms are usually inert to copper and its alloys, but some corrosion takes place when moisure is present. The rate of reaction depends on the amount of moisture. Because some alloy steels are attacked by CO, the high-pressure equipment used to handle this gas is often lined with copper or copper alloys.

Sulfur Dioxide (SO_2). Gases containing SO_2 attack copper in a manner similar to oxygen. The dry gas does not corrode copper or copper alloys, but the moist gas reacts to produce a mixture of oxide and sulfide scale. Table 40 lists the corrosion rates of some copper alloys in hot paper mill vapor that contains SO_2.

Table 40 Corrosion of copper alloys in hot paper mill vapor containing SO_2

Temperature, 200-220 °C (390-430 °F), atmosphere, 17-18% SO_2 plus 1-2% O_2; test duration, mainly 30 days, but some longer

Alloy type	UNS number	Weight loss, $g/m^2/d$
Bronze (90Cu-10Sn)	. . .	22.0

Nickel silver, 65-18	C75200	67.4
Nickel bronze (88.5 Cu-5Sn-5Ni-1.5Si)	. . .	70.5

Hydrogen Sulfide. Moist H_2S gas reacts with copper and copper-zinc alloys to form CuS. Alloys containing more than 20% Zn have considerably better resistance than lower-zinc alloys or copper. Hot, wet H_2S vapors corrode C26000, C28000, or C44300 at a rate of only 50 to 75 m/yr (2 to 3 mils/yr), but the rate for C11000 and C23000 under the same conditions is 1250 to 1625 m/yr (50 to 65 mils/yr).

Halogen Gases. When they are dry, fluorine, chlorine, bromine, and their hydrogen compounds are not corrosive to copper and its alloys. However, they are aggressive when moisture is present. The corrosion rates of copper metals in wet hydrogen compounds are comparable to those given for HF and HCl in Tables 17 and 18.

Hydrogen. Copper and its alloys are not susceptible to attack by hydrogen unless they contain copper oxide. Tough pitch coppers, such as C11000, contain small quantities of Cu_2O. Deoxidized coppers with low residual deoxidizer contents--C12000, for example--may contain Cu_2O, but will contain less than tough pitch coppers. These deoxidized coppers are not immune to hydrogen embrittlement. Deoxidized coppers with high residual deoxidizer contents, however, are not susceptible to hydrogen embrittlement, because the oxygen is tied up in complex oxides that do not react appreciably with hydrogen.

When oxygen-bearing copper is heated in hydrogen or hydrogen-bearing gases, the hydrogen diffuses into the metal and reacts with the oxide to form water, which is converted to high-pressure steam if the temperature is above 375 °C (705 °F). The steam produces fissures, which decrease the ductility of the metal. This condition is generally known as hydrogen embrittlement. Any degree of embrittlement can lead to catastrophic failure and therefore should be avoided; there is no safe depth of attack.

Figure 19 shows the depth of damage, or embrittlement, of C11000 after it has been heated in hydrogen at about 600 °C (1100 °F) for varying times. The reaction is especially important when oxygen-containing copper is bright annealed in reducing atmospheres containing relatively small amounts of hydrogen (1 to 1.5%). Annealing of tough pitch coppers in such atmospheres at temperatures much above 475 °C (900 °F) may lead to severe embrittlement, especially when annealing times are long. In fact, tough pitch coppers should not be exposed to hydrogen at any temperature if they will subsequently be exposed to temperatures above 370 °C (700 °F).

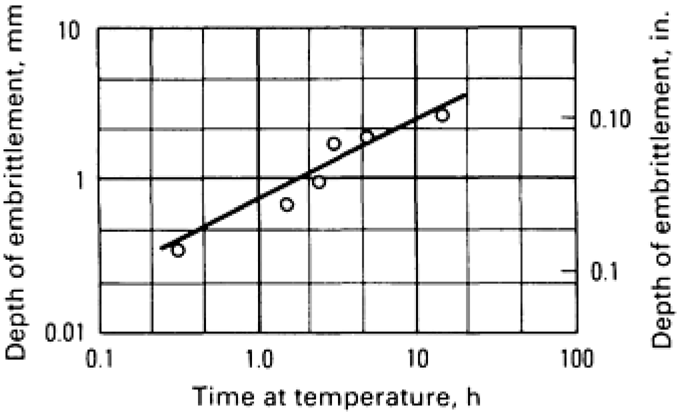

Fig. 19 Hydrogen embrittlement of tough pitch coppers heated in pure hydrogen at 600 °C (1100 °F)

When tough pitch coppers are welded or brazed, the possibility of hydrogen embrittlement must be anticipated, and hydrogen atmospheres must not be used. Where copper must be heated in hydrogen atmospheres, an oxygen-free copper or deoxidized copper with high residual deoxidizer content should be selected. No hydrogen embrittlement problems have been encountered with these materials. Additional information on hydrogen damage in metals is available in the section "Hydrogen Damage" of the article "Environmentally Induced Cracking" in this Volume.

Dry Oxygen. Copper and copper alloy tubing is used to convey oxygen at room temperature, as in hospital oxygen service systems. When heated in air, copper develops at Cu_2O film that exhibits a series of interference tints (temper colors) as it increases in thickness. The colors associated with different oxide film thicknesses are:

Color	Film thickness, nm
Dark brown	37-38
Very dark purple	45-46
Violet	48
Dark blue	50-52
Yellow	94-98
Orange	112-120
Red	124-126

Black cupric oxide (CuO) forms over the Cu_2O layer as the film thickness increases above the interference color range.

Scaling results when copper is used at high temperatures in air or oxygen. At low temperatures (up to 100 °C, or 212 °F), the oxide film increases in thickness logarithmically with time. Scaling rate increases irregularly with further increases in temperature and rises rapidly with pressure up to 1.6 kPa (12 torr). Above 20 kPa (150 torr) the rate of increase is steady. Beyond the interference color range, the growth rate of the oxide film is approximately defined by:

$$W^2 = kt \qquad \textbf{(Eq 4)}$$

where *W* is weight gain (or increase in equivalent thickness) per unit area, *t* is time, and *k* is a constant of proportionality. Values for *k* are given in Table 41. Different investigators report different oxidation rates, but those given in Ref 58 appear to be reliable.

Table 41 Values of rate constant for oxide growth on unalloyed copper

Temperature		Rate constant k[(a)]	
°C	**°F**	**Pure O_2**	**Air**
400	750	4.4×10^{-8}	. . .
500	950	4.4×10^{-7}	. . .
600	1100	3.24×10^{-6}	. . .
700	1300	1.6×10^{-5}	8.03×10^{-6}
800	1475	8.69×10^{-5}	7.97×10^{-5}
900	1650	3.49×10^{-4}	3.36×10^{-4}
950	1750	7.30×10^{-4}	. . .
1000	1850	1.78×10^{-3}	1.35×10^{-3}

(a) For calculation of weight gain in g/m^2 from Eq 4 when time is measured in seconds

Low concentrations of lead, oxygen, zinc, nickel, and phosphorus in copper have little influence on oxidation rate. Silicon, magnesium, beryllium, and aluminum form very thin insulating (nonconductive) oxide films on copper, which protect the metal surface and retard oxidation.

SCC of Copper Alloys in Specific Environments

Properly selected copper alloys possess excellent resistance to SCC in many industrial and chemical environments; nevertheless, cracking has been identified in a significant number of environments. In some cases, the conditions for cracking are very limited and exist only within a narrow range of pH values or a narrow range of potentials. In many cases, the experimental data are limited to a single alloy, and it is not known if the environment is generally deleterious to many copper alloys or to a restricted group of alloys. Data re summarized below for environments in which cracking has been recognized. Additional information is available in the references cited in this section; they should be consulted when selecting a copper alloy for a specific application.

Acetate Solution. Pure copper wire stressed beyond the yield strength was observed to crack in 0.05 *N* cupric acetate ($Cu(C_2H_3O_2)_2$) (Ref 59). Alloy C26000 is susceptible to cracking in the same solution, and the cracking rate under slow strain rate conditions is a function of both pH and applied potential (Ref 60).

Amines. Alloy C26000 is susceptible to cracking in solutions of methyl amine, ethylamine, and butyl amine when dissolved copper is present in the solution (Ref 61). Susceptibility is a maximum at a potential approximately 50 mV anodic from the rest potential. Tubing fabricated from C68700 exhibited cracks from the steam side of a condenser system after 3048 h of service in a desalination plant. The most likely cause of the cracking was an amine used as a water treatment chemical (Ref 62).

Ammonia. All copper-base alloys can be made to crack in NH_3 vapor, NH_3 solutions, ammonium ion (NH_4^+) solutions, and environments in which NH_3 is a reaction product. The rate at which cracks develop is critically dependent on many variables, including stress level, specific alloy, oxygen concentration in the liquid, pH, NH_3 or NH_4^+ concentration, copper ions concentration, and potential.

Early work on the stress corrosion of brass in NH_3 provided the following summary of findings (Ref 63):

- Stress-corrosion cracking occurs in a great variety of brasses that differ widely in composition, degree of purity, and microstructure
- Cracking occurs only in objects that are subjected to external or internal stresses
- Visible corrosion is frequently associated with the effect, but the corrosion may often be superficial
- Lacquer coatings do not offer complete protection against SCC
- Sufficient and continuous coatings of a metal, such as nickel, confer complete protection
- Highly stressed articles may be kept for years in a clean air atmosphere without developing cracks
- Ammonia and ammonium NH_4^+ salts induce cracking
- Surface defects which localize stresses, do not appear to contribute to the development of cracks in the absence of an essential corroding agent, such as NH_3
- Severe corrosion and pitting do not of themselves lead to cracking
- Cracks often follow an intercrystalline path
- Traces of NH_3 in the environment are an important agent in inducing SCC in atmospheric exposure
- Ammonia has a specific and selective action on the material in the grain boundaries of brass
- Cracking always begins in surface layers that are under tension
- The behavior of a copper alloy subjected to the combined effect of tensile stress and NH_3 is an index of susceptibility to SCC
- Susceptibility to SCC diminishes as the copper content of the brass is increased
- Protracted heating of 70Cu-30Zn brass at 100 °C (212 °F) does not develop cracks and does not reduce the internal stress appreciably

Table 42 provides a ranking of various copper alloys according to their relative SCC susceptibility in NH_3 environments.

Table 42 Relative susceptibility to SCC of some copper alloys in NH_3

Alloy	Susceptibility index[(a)]
C26000	1000
C35300	1000
C76200	300
C23000	200
C77000	175
C66400	100
C68800	75

C63800	50
C75200	40
C51000	20
C11000	0
C15100	0
C19400	0
C65400	0
C70600	0
C71500	0
C72200	0

(a) 0, essentially immune to SCC under normal service conditions; 1000, highly susceptible to SCC as typified by C26000

Atmosphere. Many natural environments contain pollutants that, in the presence of moisture, may cause stress-corrosion problems (Ref 64). Sulfur dioxide, oxides of nitrogen, and NH_3 are known to induce SCC of some copper alloys. Chlorides may also cause problems. Atmospheric-exposure test data are summarized in Table 43. In these tests, 150- × 13-mm (6- × $\frac{1}{2}$-in.) U-bend samples were stressed in the long-transverse direction. The bend was produced by bending around a 19-mm ($\frac{3}{4}$-in.) diam mandrel, and the legs of each specimen were held in nonconductive jigs during the test. The stress on the specimens was not determined. The stressed specimens were exposed in two industrial locations in New Haven, CT, and Brooklyn, NY, and in one marine location at Daytona Beach, FL.

Source: Ref 65

(a) I, intergranular; T, transgranular. Parentheses indicate minor mode.

(b) NF, no failures in time specified.

(c) NT, not tested.

(d) Heated at 205 °C (400 °F) for 30 min.

(e) Normal structure for this alloy.

Chlorate Solutions. Brass was observed to crack intergranularly and transgranularly when immersed in 0.1 to 5 *M* sodium chlorate ($NaClO_3$) solutions at pHs from 3.5 to 9.5 when subjected to slow straining (Ref 66). Crack velocities in 1 *N* $NaClO_3$ at pH 6.5 were 10^{-7} m/s at a crosshead speed of 10^{-4} cm/min (4 × 10^{-5} in./min) and 10^{-6} m/s at a crosshead speed of 10^{-3} cm/min (4 × 10^{-4} in./min).

Chloride Solutions. The service lives of copper alloys under cyclic stress are shorter in chloride solutions than in air. Slow strain rate experiments have also shown that C26000 (Ref 67) and C44300 (Ref 68) have lower fracture stresses in NaCl solutions when the metal is anodically polarized. The changes in fracture stress are insignificant relative to those in air in the absence of an applied potential.

Citrate Solutions. Alloy C72000 is sensitive to cracking in citrate solutions containing dissolved copper in the pH range of 7 to 11. The U-bend test specimens exhibited intergranular cracking (Ref 69).

Formate Solutions. Brass is susceptible to SCC in sodium formate ($NaCHO_2$) solutions at pHs exceeding 11 over a considerable range of applied potentials (Ref 60).

Hydroxide Solutions. Brass exhibits increased crack growth rates under slow strain rate conditions when it is exposed to NaOH at pHs of 12 and 13. The rate of crack growth is a function of the applied potential (Ref 60).

Mercury and Mercury Salt Solutions. Stressed alloys and alloys with internal stress crack readily when exposed to metallic mercury or mercury salt solutions that deposit mercury on the surface of the alloy. This high sensitivity to mercury is the basis of an industry test for the detection of internal stresses in which the alloy is immersed in a solution of mercurous nitrate. Cracking in mercury is the result of LME, not stress corrosion. It does not indicate the SCC susceptibility of an alloy.

Nitrate Solutions. Transgranular cracking was observed on C44300 specimens immersed in naturally aerated 1 *N* sodium nitrate ($NaNO_3$) at pH 8 and a potential of 0.15 V versus standard hydrogen electrode (SHE). The fracture stress relative to air was 0.34 (Ref 68).

Copper alloy (Cu-23Zn-12Ni) wires measuring 0.6 mm (0.023 in.) in diameter and normally under a 6-g load and a positive potential in telephone equipment were observed to undergo SCC within 2 years (Ref 70). Laboratory tests suggested that nitrate salts were the cause. The phenomenon was duplicated in the laboratory by exposing the wires to such nitrate salts as zinc nitrate ($Zn(NO_3)_2$), ammonium nitrate (NH_4NO_3, calcium nitrate ($Ca(NO_3)_2$), and cupric nitrate ($Cu(NO_3)_2$) at high humidity; a potential was applied such that the wires were anodic to the normal corrosion potential. The wires were tested under a constant load of 386 MPa (56 ksi). Cracking also occurred in the absence of an applied potential when the nitrate concentration of the surface was high. Cracking did not occur in the presence of $(NH_4)_2SO_4$ and ammonium chloride (NH_4Cl) salts. Wires of Cu-20Ni did not crack under similar conditions.

Nitrite Solutions. Copper, 99.9 and 99.996% pure, exhibited transgranular cracking when subjected to a strain rate of 10^{-6} s^{-1} while immersed in 1 *M* sodium nitrite ($NaNO_2$) at a pH of 8.2 (Ref 71). The 99.9% Cu tested in solution showed an ultimate tensile strength of 160 MPa (23 ksi) and 25% elongation, as opposed to the 196 MPa (28.5 ksi) and 55% elongation obtained in air. Cracking in 1 *M* $NaNO_2$ was also observed in C26000, Admiralty brasses, and C70600.

Solder. In one investigation of the susceptibility to cracking of copper alloys by various solders, a U-shaped tube was coated with solder at 400 °C (750 °F) and then immediately flattened between steel tools in a hand press (Ref 72). The sample was then examined for cracks. The data are given in Table 44.

Table 44 Susceptibility of copper alloy tubes to cracking by solder

Solder applied at 400 °C (750 °F); specimens were immediately deformed and examined for cracks.

Solder	Alloy		
	80Cu-20Ni	**97Cu-3Zn**	**70Cu-30Zn**
Lead	Shattered	Cracked	Cracked
97.5Pb-2.5Ag	Shattered	Uncracked	Cracked
95Pb-5Sn	Cracked	Uncracked	Cracked
80Pb-20Sn	Cracked	Uncracked	Uncracked
Grade B solder	Cracked	Uncracked	Uncracked
95Sn-5Sb	Uncracked	Uncracked	Uncracked

Sulfur Dioxide. Brass is susceptible to SCC in moist air containing 0.05 to 0.5 vol% SO_2. In addition, pre-exposure of the brass to a solution of benzotriazole inhibits the cracking (Ref 73).

Sulfate Solutions. Stress-corrosion cracking of C26000 was observed in a solution of 1 *N* sodium sulfate (Na_2SO_4) and 0.01 *N* H_2SO_4 when the alloy was polarized at a potential of 0.25 V versus SHE and subjected to a constant strain (Ref 74).

Sulfide Solutions. National Association of Corrosion Engineers (NACE) committee T-1F issued a report on the acceptability of various materials for valves for production and pipeline service (Ref 75). Bronze and other copper-base alloys are generally not acceptable for highly stressed parts in sour service. Some nickel-copper alloys are considered satisfactory.

Tungstate Solutions. Mild transgranular cracking of C44300 was observed in 1 *N* sodium tungstate (Na_2WO_4) at pH 9.4 and a corrosion potential of 0.080 V versus SHE. The fracture stress relative to that in air was 0.89, and the crack growth velocity was 2×10^{-9} m/s when a strain rate of 1.5×10^{-5} s^{-1} was used (Ref 68).

Water. Several cases of the SCC of admiralty brass heat-exchanger tubing are documented in Ref 76. The environments in which such SCC was observed included stagnant water, stagnant water contaminated with NH_3, and water accidentally contaminated with a nitrate. No cases were noted of SCC of the following alloys when used in heat-exchanger service: C70600, C71500, arsenical copper, C19400, and aluminum bronze.

Service data for various copper alloys used as condenser tubing are given in Ref 77. Information on six different alloys used in freshwater and in seawater service is summarized in Table 45.

Table 45 Experience with copper alloys in condenser tubing service

Medium	Alloy	Susceptibility to SCC
Freshwater	Admiralty brass	Very susceptible
	C70600	Resistant
	Arsenical Copper	Resistant
	C19400	Low Susceptibility
Seawater	C70600	Resistant
	C71500	Resistant
	Arsenic-aluminum brass bronze	Susceptible

An instance of the SCC of a Cu-7Al-2Si stud from an extraction pump exposed to wet steam is discussed in Ref 78. Also in Ref 78 are examples of SCC failures of copper alloys in marine service. These include tubing, a lifeboat keel pin, brass bolts and screws, a brass propeller, a flooding valve, and aluminum bronze valve parts. Some of the failures were attributed to bird excreta that provided a source of NH_3.

Protective Coatings

Copper metals resist corrosion in many environment because they react with one or more constituents of the environment upon initial exposure, thus forming an inert surface layer of protective reaction products. In certain applications, the corrosion resistance of copper metals may be increased by applying metallic or organic protective coatings. If the coating material is able to resist corrosion adequately, service life may depend on the impermeability, continuity, and adhesion to the basis metal of the coatings. The electropotential relationship of the coating to the basis metal may be important, especially with metallic coatings and at uncoated edges. Tin, lead, and solder, used extensively as coatings, are ordinarily applied by hot dipping. Electroplating is also used.

Tin arrests corrosion caused by sulfur; it is most effective as a coating for copper wire and cable insulated by rubber that contains sulfur. Lead-coated copper is primarily used for roofing applications, in which contact with flue gases or other products that contain dilute H_2SO_4 is likely. Tin or lead coatings are sometimes applied to copper intended for ordinary atmospheric exposure, but this is done primarily for architectural effect; the atmospheric-corrosion resistance of bare copper is excellent in rural, urban, marine, and most industrial locations. Additional information on the use of tin for corrosion resistance is available in the article "Corrosion of Tin and Tin Alloys" in this Volume.

Electroplated chromium is used for decoration, for improvement of wear resistance, or for reflectivity. Because it is somewhat porous, it is not effective for corrosion protection. Where corrosion protection is important, electroplated nickel is most often used as a protective coating under electroplated chromium. Additional information on the corrosion resistance of chromium plate is available in the article "Corrosion of Electroplated Hard Chromium" in this Volume.

Various organic coatings are applied to copper alloys to preserve a bright metallic appearance. These are discussed in detail in the section "Organic Coatings" of the article "Protective Coatings" in this Volume and in the articles "Painting" and "Surface Engineering of Copper and Copper Alloys" in *Surface Engineering*, Volume 5, *ASM Handbook*.

Corrosion and Stress-Corrosion Testing

Aqueous Corrosion Testing. As with other alloys, static tests are used to examine the corrosion behavior of copper alloys in both natural and artificial environments. Tests common to many alloys systems are described in the Section "Corrosion Testing and Evaluation" in this Volume. General procedures are discussed in Ref 79 and 80.

One specific procedure that has been applied to copper alloys in closed-container tests is the determination of the partitioning of the major alloying elements between the corrosion product and the solution (Ref 13, 81). In this procedure, the samples are exposed to the test solution for some time period, after which the sample is removed and the solution filtered to remove any particulate. The collected particulate is dissolved in an acidified solution and quantitatively analyzed for copper and other alloying elements of interest; a similar analysis is performed on the filtered solution. The corrosion product is then stripped from the copper alloy using an inhibited HCl solution and analyzed. The results indicate which alloying elements contribute to film formation and whether the element is more prone to go into solution rather than into the film. In addition, the amount of copper that has entered solution and the amount that is actually particulate that spalled off of the surface can be determined. These date are of significance with regard to heavy-metal ion contamination of water sources.

Dynamic Corrosion Tests. One of the major uses of copper alloys is the transport of aqueous solutions; consequently, a significant number of tests have been designed to examine the effects of dynamic conditions on the corrosion behavior of the materials in these environments. The tests, which range in complexity from simple recirculating loops to jet impingement apparatus, examine the effects of such variables as flow rate, heat transfer conditions, and blockages, as well as various solution conditions. Of the systems developed, the flow loop is probably the most widely used test because it is easily constructed, requiring only a pump, ducting, and valves, and can incorporate a wide variety of test variables. Because of their simplicity, flow loops can be constructed on-site and tapped into process flow systems so that the actual operating environment can be used as the test environment. Descriptions of test loops are available in Ref 24, 43, 82, 83, 84, and 85.

Tubular samples are the most easily tested in this system because they can be directly incorporated into the loop. As with any other corrosion test, the tube samples must be separated by insulating connectors to avoid galvanic effects; tube union fittings of plastic or flexible plastic hose clamped to the tubes are generally adequate. Flat samples can also be tested in flow loops by using special sample holders, such as those described in ASTM D 2688 (Ref 86) and in Ref 24, 82, 83 and 87.

A major variable that affects the corrosion behavior of copper alloys is solution velocity. The effect of flow rate on copper alloys has been examined by placing various diameters of the same tube material in series within a loop and pumping the solution through the loop at a constant pump speed (Ref 83). Velocity effects have also been studied in a parallel flow system with orifice size and header pressure controlled to produce various velocities simultaneously (Ref 24, 43). The effects of local velocity changes and crevices, conditions that arise in power plant condenser tubes because of lodged debris, have been examined by introducing artificial blockages into tubes (Ref 82). The blockage reduces the cross section of the tube, increasing local flow rate, and produces crevice corrosion conditions where it contacts the tube.

Heat transfer effects have been studied by running test tubes through small steam condensers to ovens and pumping the test solution through the tubes. It should be noted that the conditions provided by this type of test are unlike those obtained when the bulk solution is heated before pumping it through the tubes. Heating the bulk solution may change the concentration of components throughout the solution, such as decreasing the oxygen concentration or promoting precipitation. Under heat transfer conditions, these changes may only occur locally, resulting in different corrosion behavior. Corrosion behavior can also be affected by the temperature gradient that exists between the tube wall and the solution under heat transfer conditions, which is much larger than that of a heated solution passing through a tube surrounded by ambient air.

Loop tests are generally used to evaluate the corrosion rates of materials based on their weight loss over a period of time. Test duration depends in large measure on the aggressiveness of the solution and the sample thickness. However, for

copper alloys in most aqueous solutions, the test duration should be at least 120 days in order to ensure attainment of steady-state corrosion rates.

When evaluating the samples that have been exposed to flowing systems, more than just the weight loss should be considered. Evidence of erosion should be sought, especially at leading edges and obstructions, and the depth of erosion should be monitored with respect to time. Evidence of pitting should also be looked for, and the depth of pitting as a function of time should be determined. Depth of crevice attack should be noted in samples with crevices, for example, at clamp sites. With regard to crevice corrosion in copper alloys, the attack usually occurs adjacent to the contact site; therefore, the contact site will generally be at the original thickness and can be used as a reference point when measuring the depth of attack.

Each alloy should also be examined for evidence of dealloying. This can generally be determined by metallographic examination of the cross section to see if a copper-rich layer at the sample surface is present. The material can also be mechanically tested to determine whether the mechanical properties have deteriorated with respect to a control sample. This type of testing, however, is generally performed only on materials that have not suffered from severe corrosion, which would obviously degrade the properties of the material.

Other dynamic systems, in addition to flow loops, have been developed primarily to evaluate the maximum flow rate that materials can withstand before erosion-corrosion occurs (Ref 88). An example of such a system is the jet impingement test (Ref 89). In this test, a high-velocity stream of solution is sprayed onto the specimen for some period of time, after which the depth of attack and the amount of surface area attacked are determined. Based on this evaluation, the relative erosion-corrosion resistance of various materials can be ranked.

The spinning-disk test is used to define the velocity that causes erosion in a material (Ref 89, 90). In this test, a disk of the material is immersed in the solution and rotated at a specific rate around the disk axis perpendicular to the plane of the disk. At the conclusion of the test, the sample is examined to determine the distance from the center of the disk, and therefore the velocity, at which erosion occurs.

One other test is used to examine the relative resistance of various materials to erosion by entrained particles in solution (Ref 23). In this test, silica sand of controlled size is introduced to the solution in which L-shaped samples are mounted on the periphery of a rotating disk.

Although any solution an be used in these dynamic test systems, most tests are conducted with seawater or freshwater. Natural waters, such as from the sea, rivers, or lakes, are used as test solutions, but their use is generally restricted by the location of the test facility. In addition, the compositions of natural waters vary not only with location but also with time, making a standardized test procedure difficult. To circumvent this problem for seawaters, substitute seawater (Ref 91) and a 3.4% NaCl solution have both been used. In general, these solutions are slightly more aggressive than natural seawaters; as a result, predictions of corrosion lifetimes based on data from these solutions are generally conservative with respect to actual performance.

A significant amount of work has recently been done on the behavior of copper alloys in sulfide-contaminated seawaters. An extensive bibliography is given in Ref 92. Sulfides are added to the seawater by either bubbling H_2S gas through the solution or adding a Na_2S solution. In general, sulfide concentrations of the order of 1 ppm are sufficient to cause accelerated attack. For rapid corrosion to occur, the copper alloy must be exposed to a solution that contains oxygen as well as sulfide or must be alternately exposed to sulfide-bearing deaerated solutions, followed by exposure to sulfide-free aerated solutions.

Because of the transient nature of sulfides in water, it is necessary to monitor the sulfide level in solution with time. Titration techniques are available for measuring the sulfide concentration, but these are generally time consuming and tedious if continual monitoring is required. An alternative is the use of a sulfide-specific ion electrode, which provides accurate sulfide readings in substitute ocean water in much less time.

Another environment of interest is the freshwater cooling water tower environment typically found in power plant applications. A simulated cooling tower water environment has been developed based on the analysis of Ohio River water for its major constituents and their concentrations. The solution (Table 46) corresponds to a sixfold concentration of typical river water chemistry, simulating the concentrating effect of the cooling tower. Other cooling water solutions have also been used (Ref 93).

Table 46 Composition of simulated cooling tower water

Component	Concentration, mg/L
CuO	700
$MgSO_4$(anhydrous)	693
NaCl	614
KCl	59
KNO_3	24
Na_2CO_3	167
$SiO_2 \cdot XH_2O$	21
H_2SO_4	0.75 mL/L

Atmospheric Testing. In a variety of applications, such as electrical and architectural components, the behavior of copper alloys when fully immersed in solution is not relevant with regard to their performance under various atmospheric conditions. Constant humidity and temperature chambers are used to evaluate the relative atmospheric behavior of the materials. The design and typical test environments are described in Ref 94, 95, 96. As with aqueous tests under artificial conditions, the corrosion behavior determined in these tests generally cannot be used to ensure the behavior of the material in the actual service environment. This is the case primarily because many variables in the service environment cannot be incorporated into the test or are overlooked and because the environment changes constantly. Such tests do, however, provide approximate data and allow ranking of the test materials.

Evaluation of tested specimens involves typical corrosion parameters, such as weight loss, depth of pitting, and crevice corrosion. In addition, patina (oxide film formation) is evaluated with regard to color, continuity, and film tenacity. After the specimen has been cleaned, evidence of dealloying should also be sought by examination of a metallographic cross section or by loss of mechanical properties (as compared to an untested control sample). In Military Standard 853C Method 1009.4 for electronic materials, materials exposed to the salt fog test are evaluated to determine the amount of corrosion over the surface and to determine whether pitting or corrosion contributed to failure of the bend test. Materials are also evaluated with regard to the effect to the oxide film on solderability and the corrosion resistance of the solder base metal.

Other environmental tests are Military Standard 202 Method 2080, in which candidate materials are aged in the steam from boiling distilled water and then solder dipped to evaluate their solderability. Ammonium sulfide ($(NH_4)_2S$) is used to determine the effectiveness of tarnish inhibitors in protecting the material. In this test, the specimen is held for a short period of time (usually 30 s) over an open beaker containing $(NH_4)_2S$ solution and then examined. If the surface has become blackened, the protective layer is considered to be inadequate.

Atmospheric testing of copper alloys in natural environments is conducted to evaluate the behavior of the materials in industrial, rural, and marine atmospheres. The procedure most widely used is given in Ref 97, which describes sample preparation, types of test racks, typical locations and orientation. This long-term test may last up to 20 years or more and therefore requires careful recordkeeping.

Stress-Corrosion Testing. Much of the early knowledge of the SCC tendencies of copper alloys was based on service experience. Such data were assimilated at laboratories involved in the development of copper alloys and were used to design alloys with greater resistance to SCC in specific environment. Some of this information reached the open literature. In other cases, researchers concerned with specific objectives, such as designing a desalination plant or operating power station, occasionally wrote summary articles in which they cited their experience with different alloy compositions. Such information is useful but qualitative, and the environmental constituents or conditions that led to the cracking are unknown.

In the past several decades, the study of SCC has been greatly accelerated, and the causes and mechanisms for the behavior have been addressed by materials scientists, physicists, chemists, metallurgists, and mechanical engineers. Laboratory studies under controlled conditions have been expanded, ASTM has developed standardized tests, and laboratories have compared data. As a result, considerable quantitative information is now available in the literature. In some cases, this information is obtained with full knowledge of fracture mechanics principles. The methods of generating SCC data are numerous and include both static and dynamic tests.

In the static tests, the sample is put under tension by bending and restraining the sample or by mounting it in a tensile-testing machine. The data thus generated include time to first crack, time to fracture, or time to relax to a certain fraction (for example, 50 or 80%) of the unrestrained distance between the ends of the bent specimen. The data generated in this fashion allow comparison among different alloys, among different pretreatments, and among other experimental variables. The data are comparative within one data set but yield no absolute information.

Various NH_3 environments are widely used to test copper alloys, the most common being Mattsson's solution of pH 4.0, 7.2, and 10. Two other NH_3-base environments that produce very aggressive stress-corrosion conditions are a NH_3-0.5 *M* copper solution of pH 14, and a moist NH_3 test. The pH 14 solution is made by dissolving 3.18 g of copper powder in 1 L of 29.5% NH_4OH solution (typical reagent-strength NH_4OH). The moist NH_3 test requires the construction of a chamber in which 100% relative humidity and a constant NH_3 gas concentration are maintained (Ref 98).

One of the simplest laboratory stress-corrosion tests that provides a significant amount of information is the U-bend test, in which the springback of the sample is measured over time in the test solution. Two sample sets of each material are produced in a manner similar to that described in Ref 99. One is placed in the test solution, and the other remains in the room environment as a control. A variety of test jigs are described in Ref 99; however, the legs of the jig must be compressed the same distance when the sample is removed and then replaced in the jig. A typical example of this type of jig is given in Ref 99.

The samples are placed in the jig, removed, and the springback between the legs measured; this is also done for the control samples. The samples are reinserted in the test jig and placed in the test solution. At periodic intervals, the samples are removed from the solution, taken from the jig, and the springback distance between the legs remeasured. Similar measurements are made on the air control samples. The test continues until either physical failure occurs--that is, if the sample breaks or if it no longer has enough tension to hold it in the jig--or some predetermined performance criteria are met, for example, 1000 h elapsed time or springback reduction to 80% of its initial value. At the conclusion of the test, the average change in percent springback for each material at each time is determined, taking into account the loss in springback that occurred as a result of stress relaxation based on springback measurements of the air control samples.

A constant percent springback versus time indicates that the material is not susceptible to SCC in the test solution over that time period. A decrease in percent springback with time indicates the SCC has occurred. This should be verified by optical examination for cracking as well as metallographic examination of the sample to determine the mode of cracking. An increase in percent springback indicates that the tension side of the sample dissolved at a faster rate than the compressive side due to stress-assisted dissolution. Examination will reveal that the specimen has thinned and that failure occurred because of overload, not cracking. This result indicates that the solution is too aggressive for SCC to occur and that another solution should be used to compare stress-corrosion behavior.

Dynamic Tests. During the past decade, there has been a major swing toward the use of dynamic tests, which yield values that can be quantitatively applied to the proposed mechanisms of SCC. Primary among these is the slow strain rate technique. The application of this technique to the understanding of SCC began in the early 1960s (Ref 100). An excellent summary of the slow strain rate technique and its applications to SCC is given in Ref 101.

This method uses tensile-test specimens mounted in stiff-frame machines and strained at the rate of 10^{-7} to 10^{-5} s^{-1} in the presence of a specific environment. Strain rates in this range promote SCC, but the absence of cracking is no assurance of

immunity to SCC. Various methods are used to assess the results when SCC is observed. These include the area under the stress-elongation curve, time to failure, crack velocity, and ratio of fracture stress in a medium to fracture stress in air.

Characteristics of Nickel and Nickel-Base Alloys

D.L. Klarstrom, Haynes International, Inc.

NICKEL AND NICKEL-BASE ALLOYS are vitally important to modern industry because of their ability to withstand a wide variety of severe operating conditions involving corrosive environments, high temperatures, high stresses, and combinations of these factors. There are several reasons for these capabilities. Pure nickel is ductile and tough because it possesses a face-centered cubic (fcc) crystal structure up to its melting point. Therefore, nickel and its alloys are readily fabricated by conventional methods, and they offer freedom from the ductile-to-brittle behavior of most body-centered cubic (bcc) and noncubic metals. Nickel has good resistance to corrosion in the normal atmosphere, in natural freshwaters and in deaerated nonoxidizing acids, and it has excellent resistance to corrosion by caustic alkalies (Ref 1). Therefore, nickel offers very useful corrosion resistance itself and it is an excellent base on which to develop specialized alloys. Its atomic size and nearly complete 3*d* electron shell enable it to receive large amounts of alloying additions before encountering phase instabilities (Ref 2). This allows a wide variety of alloys to be fashioned in a manner that can adequately capitalize on the unique properties of specific alloying elements. Finally, unique inter-metallic phases can form between nickel and some of its alloying elements; this enables the formulation of very high strength alloys for both low- and high-temperature service. These and other important characteristics of the nickel alloy family will be discussed below.

Effects of Major Alloying Elements

The roles of the major alloying elements used to promote corrosion resistance in nickel-base alloys can be summarized as follows.

Copper. Additions of copper provide improvement in the resistance of nickel to nonoxidizing acids (Ref 3). In particular, alloys containing 30 to 40% Cu offer useful resistance to nonaerated sulfuric acid (H_2SO_4) and offer excellent resistance to all concentrations of nonaerated hydrofluoric acid (HF). Additions of 2 to 3% Cu to nickel-chromium-molybdenum-iron alloys have also been found to improve resistance to hydrochloric acid (HCl), H_2SO_4, and phosphoric acid (H_3PO_4) (Ref 4).

Chromium additions impart improved resistance to oxidizing media such as nitric (HNO_3) and chromic (H_2CrO_4) acids (Ref 3). Improved resistance to hot H_3PO_4 has also been shown (Ref 5). Chromium also improves resistance to high-temperature oxidation and to attack by hot sulfur-bearing gases (Ref 1). Although alloys have been formulated containing up to 50% Cr, alloying additions are usually in the range of 15 to 30%.

Iron is typically used in nickel-base alloys to reduce costs, not to promote corrosion resistance. However, iron does provide nickel with improved resistance to H_2SO_4 in concentrations above 50% (Ref 1). Iron also increases the solubility of carbon in nickel; this improves resistance to high-temperature carburizing environments (Ref 6).

Molybdenum in nickel substantially improves resistance to nonoxidizing acids (Ref 1, 3). Commercial alloys containing up to 28% Mo have been developed for service in nonoxidizing solutions of HCl, H_3PO_4, and HF, as well as in H_2SO_4 in concentrations below 60% (Ref 1, 7), Molybdenum also markedly improves the pitting and crevice corrosion resistance of nickel-base alloys (Ref 8). In addition, it is an important alloying element for imparting strength in metallic materials designed for high-temperature service (Ref 2).

Tungsten behaves similarly to molybdenum in providing improved resistance to nonoxidizing acids and to localized corrosion (Ref 9). However, because of its atomic weight, approximately twice as much tungsten as molybdenum must be added by weight to achieve atomically equivalent effects. Because of the negative impact this would have on alloy density and because of the typically higher cost and lower availability of tungsten, additions of molybdenum are generally preferred. However, additions of tungsten of the order of 3 to 4% in combination with 13 to 16% Mo in a nickel-chromium base result in alloys with outstanding resistance to localized corrosion (Ref 10).

Silicon is typically present only in minor amounts in most nickel-base alloys as a residual element from deoxidation practices or as an intentional addition to promote high-temperature oxidation resistance. In alloys containing significant amounts of iron, cobalt, molybdenum, tungsten, or other refractory elements, the level of silicon must be carefully controlled because it can stabilize carbides and harmful intermetallic phases. On the other hand, the use of silicon as a major alloying element has been found to improve greatly the resistance of nickel to hot, concentrated H_2SO_4 (Ref 9). Alloys containing 9 to 11% Si are produced for such service in the form of castings.

Cobalt. The corrosion resistance of cobalt is similar to that of nickel in most environments (Ref 9). Because of this and because of its higher cost and lower availability, cobalt is not generally used as a primary alloying element in materials designed for aqueous corrosion resistance. On the other hand, cobalt imparts unique strengthening characteristics to alloys designed for high-temperature service (Ref 2). Cobalt, like iron, increases the solubility of carbon in nickel-base alloys, and this increases resistance to carburization. Further, the melting point of cobalt sulfide is higher than that of nickel sulfide; therefore, alloying with cobalt also tends to improve high-temperature sulfidation resistance.

Niobium and Tantalum. In corrosion-resistant alloys, both niobium and tantalum were originally added as stabilizing elements to tie up carbon and prevent intergranular corrosion attack due to grain-boundary carbide precipitation (Ref 1, 4). However, the advent of argon-oxygen decarburization melting technology made it possible to achieve very low levels of residual carbon, and such additions of niobium and tantalum are no longer necessary. In high-temperature alloys, both elements are used to promote high-temperature strength through solid-solution and precipitation-hardening mechanisms (Ref 2). Additions of these elements are also considered to be beneficial in reducing the tendency of nickel-base alloys toward hot cracking during welding (Ref 11).

Aluminum and titanium are often used in minor amounts in corrosion-resistant alloys for the purpose of deoxidation or to tie up carbon and/or nitrogen, respectively (Ref 1). When added together, these elements enable the formulation of age-hardenable high-strength alloys for low- and elevated-temperature service. Additions of aluminum can also be used to promote the formation of a tightly adherent alumina scale at high temperature that resists attack by oxidation, carburization, and chlorination (Ref 12).

Carbon and Carbides. There is evidence that nickel forms a carbide of the formula Ni_3C at elevated temperatures, but it is unstable and decomposes into a mixture of nickel and graphite at low temperatures (Ref 13). Because this phase mixture tends to have low ductility, low-carbon forms of nickel are usually preferred in corrosion-resistant applications. This problem is also alleviated to some extent when nickel is alloyed with copper (Ref 1). In other nickel alloys, the carbides that form depend on the specific alloying elements present, their amounts, and the level of carbon present.

In corrosion-resistant alloys, many types of carbides are considered harmful because they can precipitate at grain boundaries during heat treatment or weld fabrication and subsequently promote intergranular corrosion or cracking in service. This results from the depletion of matrix elements essential to corrosion resistance during the carbide precipitation process. In high-temperature alloys, the presence of carbides is generally desired to control grain size and to enhance elevated-temperature strength and ductility. However, careful attention must be paid to the carbide types and morphologies after solution heat treatment or postfabrication heat treatment in order to avoid cracking during component manufacture or loss of strength and/or ductility in service.

In discussing carbides, it is necessary to distinguish between primary and secondary types. Primary carbides form during the solidification process. They are interdendritic and form from the last liquid to freeze, which is generally enriched in alloying elements. These carbides are typically metastable and would dissolve if given sufficient time at elevated temperatures. However, during metal manufacture, this is usually not the case; therefore, they can persist in the final product as stringers in the direction of predominant metal flow. Some level of carbide stringers usually must be tolerated because they cannot be economically avoided in complex alloy systems. However, large amounts of such stringers should be avoided, because they can adversely affect formability, weld fabrication, and service performance characteristics.

Secondary carbides are those that precipitate as the result of thermal exposures during metal manufacture and component fabrication operations or during component service life. These carbides precipitate preferentially on grain boundaries and internal structural defects, such as twin boundaries and dislocations. The quantity of secondary carbides that precipitate depends on the amount of carbon in solution, the exposure temperature, and the time at temperature. Therefore, conditions that generate a supersaturated solution of carbon followed by slow cooling or thermal arrests below carbide solvus temperatures will produce heavy secondary carbide precipitation. It is also possible to generate aligned or stringer-type structures of secondary carbides. This can occur if an alloy with secondary precipitates is mechanically worked and annealed below the solvus temperature. Heavy secondary carbide precipitation generally reduces ductility and toughness, and this adversely affects fabrication and service performance.

The carbide types occurring in nickel-base alloys can be separated into two broad categories: those that are chromium rich and those that are rich in refractory alloying elements. The chromium-rich carbides are of the forms Cr_7C_3 and $M_{23}C_6$. The Cr_7C_3 carbide forms only in a few simple alloys that are low in chromium as well as reactive and refractory alloying elements (Ref 14). It occurs as a blocky, intergranular precipitate, and it is stable only at temperatures of the order of 1050 to 1150 °C (1920 to 2100 °F) (Ref 15). It decomposes into $M_{23}C_6$ at lower temperatures.

The $M_{23}C_6$ carbide can range in chemistry from $Cr_{23}C_6$ in simple nickel-chromium alloys to $Cr_{21}(Mo, W)_2C_6$ in alloys containing molybdenum and tungsten (Ref 14). Other elements, such as nickel, iron, and cobalt, can partially substitute for chromium. The $M_{23}C_6$ carbide can assume a variety of morphologies, such as discrete, globular particles, continuous grain-boundary films, or a cellular grain-boundary structure. In some alloys, the latter two forms can seriously reduce ductility. Depending on alloy chemistry, $M_{23}C_6$ carbides can be stable to temperatures of 1150 °C (2100 °F) or above. Precipitation kinetics are particularly rapid in the temperature range of 760 to 980 °C (1400 to 1800 °F), which may be encountered during heat treatment or in-service exposure.

The common refractory metal carbides take on the forms of MC, M_6C, and $M_{12}C$. The MC carbides are formed by the reactive metal elements, such as titanium, zirconium, and hafnium, and by the refractory metal elements, such as vanadium, niobium, and tantalum. The MC carbides can contain mixtures of these elements (for example. (Ti, Nb)C) as well as less refractory elements, such as molybdenum and tungsten (for example, (Ti Mo)C) (Ref 14). If nitrogen is present in the alloy, carbonitride forms, such as Nb(C,N), are also possible. When present, these carbonitrides exhibit yellow to orange coloration as opposed to the steel gray appearance of the simple monocarbide. The MC carbides are usually formed as primary carbides. In wrought alloys, they are present as discrete, angularly shaped particles within grains and at grain boundaries. In cast alloys, they are usually present in a script morphology at interdendritic locations. The MC carbides are extremely stable and do not break down easily unless weakened by molybdenum or tungsten substitution (Ref 13). Decomposition of the MC carbide can yield the $M_{23}C_6$ or M_6C carbide forms.

The M_6C carbides, also known as the eta (η) carbides, are usually formed between the refractory elements molybdenum and tungsten and the major matrix elements of nickel, iron, cobalt, and chromium. Carbide chemistries can vary widely from forms such as $(Ni,Co)_3Mo_3C$ to $(Ni,Co)_2W_4C$, and carbon contents may range above and below that required for stoichiometry (Ref 14, 16). Silicon is also known to enter the carbide in large amounts (Ref 14). The M_6C carbides can form both as primary and secondary precipitates in a globular morphology. Their solvus temperatures are high, typically of the order of 1175 °C (2150 °F) or higher. In the temperature range of 760 to 980 °C (1400 to 1800 °F), they can decompose into the $M_{23}C_6$ or $M_{12}C$ carbide forms, depending on the alloy system.

The $M_{12}C$ carbides are closely related to the M_6C carbides. They usually form between the refractory elements molybdenum and tungsten and the matrix elements nickel, iron, cobalt, and chromium. However, unlike M_6C, the $M_{12}C$ carbides exhibit a very narrow chemistry range, with a composition such as Ni_6Mo_6C representing a typical example (Ref 16). Silicon is also known to enter the carbide preferentially in large quantities (Ref 17). The $M_{12}C$ carbide is usually observed as a secondary carbide after the dissolution or decomposition of primary M_6C carbides. Once formed, the $M_{12}C$ carbides are very stable, with solvus temperatures of 1175 °C (2150 °F) and above.

Intermetallic Phases

The occurrence of intermetallic phases in nickel-base alloys carries both good and bad connotations. On the positive side, the nickel-base system has been the most widely and successfully exploited of any alloy base in the development of high-strength high-temperature alloys because of the occurrence of unique intermetallic phases. On the negative side, the precipitation of certain intermetallic phases can seriously degrade ductility and corrosion resistance. This latter effect results from the fact that intermetallics, like carbides, can rob the matrix of elements vital to service performance.

In the case of corrosion-resistant alloys, especially the solid-solution type, the formulation of alloy chemistry to avoid intermetallic precipitation altogether is not necessary, because service temperatures are usually well below those at which precipitation kinetics become important. In such cases, it is necessary only to restrict alloy composition sufficiently to ensure successful manufacturing, fabrication, and use capabilities. For high-temperature alloys, the precipitation of undesired intermetallics can be a major concern, especially for applications requiring a long service life or ease of repair. Therefore, must effort has been devoted to understanding intermetallics and their effects on properties and to determining how to avoid their occurrence through alloy design.

Most high-strength nickel-base alloys depend on the precipitation of an A_3B-type compound known as gamma prime (γ'). In simple alloys, it takes on the form $Ni_3(Al,Ti)$. In complex alloys, other elements can substitute for nickel on the "A"

side or for aluminum and titanium on the "B" side. This compound has an ordered fee derivative, Ll_2, crystal structure. Its low lattice mismatch (0 to 1%) allows the precipitate to nucleate homogeneously with low surface energy and long-term stability (Ref 14). The γ' phase is unique in a number of ways (Ref 2):

- Because it is an ordered compound, its antiphase boundary energy contributes to alloy strengthening
- It possesses the unusual characteristic of having increased strength with increasing temperature
- It is inherently ductile, unlike most other intermetallic compounds

The strength of γ' alloys can be increased by increasing the Al + Ti content to obtain a higher γ' volume fraction. However, alloys with high Al + Ti levels are difficult to manufacture in wrought forms and to fabricate, and they are best exploited as castings. Additions of refractory metals can also be used to increase strength by altering lattice mismatch and antiphase boundary energy and by solid-solution strengthening γ' and the matrix (Ref 2). Additions of cobalt are also effective by increasing the γ' solvus temperature (Ref 2).

Another important intermetallic phase that can be used to strengthen nickel-base alloys is a metastable form of Ni_3Nb known as gamma double prime (γ"). For the most part, it has been exploited in alloys containing significant amounts of iron (Ref 18). Gamma double prime has a body-centered tetragonal crystal structure and usually precipitates in the form of a disk. At temperatures of 705 °C (1300 °F) and above, it overages rapidly and transforms into the orthorhombic form of Ni_3Nb (Ref 19). Because of the sluggish nature of the precipitation reaction, alloys strengthened by γ" can possess excellent weldability (Ref 11).

The most common harmful intermetallic phases that occur in nickel-base alloys are the topologically closed-packed (tcp) phases: sigma (σ), mu (μ), and Laves. These are complex layered structure phases that often nucleate at grain-boundary carbides (Ref 14). The σ phase has a complex tetragonal structure that can exist over a broad range of compositions involving the common transition alloying elements (Ref 20). In nickel-base alloys, σ is typically rich in chromium and often contains molybdenum and/or tungsten. It usually nucleates on $M_{23}C_6$ carbides that contain these elements and that are structurally related to σ through a slight shift in atomic arrangements (Ref 21). Typically, σ occurs in a platelike morphology that gives rise to a needle-shaped appearance when viewed two dimensionally (Ref 21).

The μ phases are complex rhombohedral compounds involving molybdenum and/or tungsten and the matrix elements nickel, chromium, iron, and cobalt. They occur in binary systems of iron and cobalt in forms such as Fe_7Mo_6, but they do not occur in nickel binary systems. However, a μ phase does form in the nickel-chromium-molybdenum ternary system (Ref 20). The μ phase tends to nucleate on M_6C or $M_{12}C$ carbides that have a compositional and structural similarity; this is analogous to σ-phase precipitation on $M_{23}C_6$ carbides (Ref 21, 22). The μ phase also occurs with a platelike morphology that is very distinctively faulted when observed by transmission electron microscopy.

The Laves phases are complex hexagonal compounds that, in nickel-base alloys, generally involve iron and the refractory elements molybdenum, tungsten, niobium, and tantalum. The chemical form is A_2B with iron on the "A" side. Laves phases occur because of atomic size effects; in contrast, the σ and μ phases form because of electronic effects. Unlike σ and μ, the Laves phases are not known to nucleate at carbide particles (Ref 21). However, their morphology is also platelike.

Because of the detrimental effects on properties produced by the tcp phases, much effort has been devoted to finding ways to avoid their occurrence. The early work of Beck and others led to the development of the electron vacancy (Nv) theory, which was based on Pauling's analysis of the transition metal 3*d* electronic structure (Ref 21). This eventually resulted in a computerized calculation known as PHACOMP (phase computation), which makes a prediction for tcp phase precipitation after taking into account the matrix element depletion caused by the precipitation of γ', borides, and carbides (Ref 2, 21). Another approach is based on the computer calculation of phase diagrams called SIGMA-SAFE (Ref 23). Finally, an approach based on theoretical electronic structure calculations has also been proposed (Ref 24). Thus, powerful tools are available for designing new alloy chemistries that are free of tcp phases.

Behavior of Nickel-Base Alloys in Corrosive Environments

Narasi Sridhar, Haynes International, Inc.

Nickel and its alloys, like the stainless steels, offer a wide range of corrosion resistance. However, nickel can accommodate larger amounts of alloying elements, chiefly chromium, molybdenum, and tungsten, in solid solution than iron. Therefore, nickel-base alloys, in general, can be used in more severe environments than the stainless steels. In fact, because nickel is used to stabilize the austenite (fcc) phase of some of the highly alloyed stainless steels, the boundary between these and nickel-base alloys is rather diffuse. The nickel-base alloys range in composition from commercially pure nickel to complex alloys containing many alloying elements.

A distinction is usually made between those alloys that are primarily used for high-temperature strength, commonly referred to as superalloys, and those that are primarily used for corrosion resistance. Again, the distinction is not sharp, because of some of the former class of alloys are used in corrosion service and some of the latter in high-treatment service. Many of the alloys that have high-temperature strength are multiphase alloys with precipitation-strengthening elements such as aluminum, titanium, and niobium. They also have higher carbon levels. Most of the corrosion-resistant alloys are primarily single-phase alloys that can be strengthened mainly by cold working. However, in applications in which geometry or size prevents strengthening by cold work, precipitation-strengthened alloys are used. A partial list of nickel-base alloys and their compositions is given in Table 1. The corrosion applications that are the topic of this section involve both aqueous and nonaqueous environments at relatively low temperatures (<260 °C, or 500 °F). High-temperature applications of nickel-base alloys involving hot gases or molten salts are discussed in the articles "Corrosion of Metal Processing Equipment," "Corrosion in Fossil Fuel Power Plants," and "Corrosion in the Nuclear Power Industry" in this Volume.

Table 1 Nominal chemical compositions of some typical nickel-base alloys

(a) Maximum

The types of corrosion of greatest importance in the nickel-base alloys system are uniform corrosion, pitting and crevice corrosion, intergranular corrosion, and galvanic corrosion (Ref 25). Stress-corrosion cracking (SCC), corrosion fatigue, and hydrogen embrittlement are also of great importance and are discussed in another section of this article. In order to estimate the performance of a set of alloys in any environment, it is of paramount importance to ascertain the composition and, for liquid environments, the electrochemical interaction of the environment with an alloy. A case in point is the nickel-molybdenum alloy B-2. The alloy performs exceptionally well in pure, deaerated H_2SO_4 and HCl, but it deteriorates rapidly when oxidizing impurities, such as oxygen (air) and ferric ions (Fe^{3+}), are present.

Electrochemical Interaction and Corrosion

This discussion will introduce some basic concepts necessary for understanding the corrosion behavior of metals. Although the electrochemical response of a metal in an electrolyte is a vast and complex subject, many of the corrosion phenomena observed in nickel-base alloys can be qualitatively understood in terms of the schematic diagram shown in Fig. 1. Generally, two types of behavior are exhibited by metals in solution:

- Type I, in which the corrosion or anodic current increases monotonically with potential
- Type II, in which the anodic current initially increases with potential (active behavior), then decreases to a small constant value (passive behavior), and finally increases again (transpassive)

These two types of behavior are not intrinsic properties of an alloy, such as the modulus of elasticity, but are the result of the interaction of the alloy with a given environment. Thus, alloy B-2, which exhibits Type I behavior in dilute H_2SO_4 and HCl, exhibits Type II behavior in concentrated H_2SO_4.

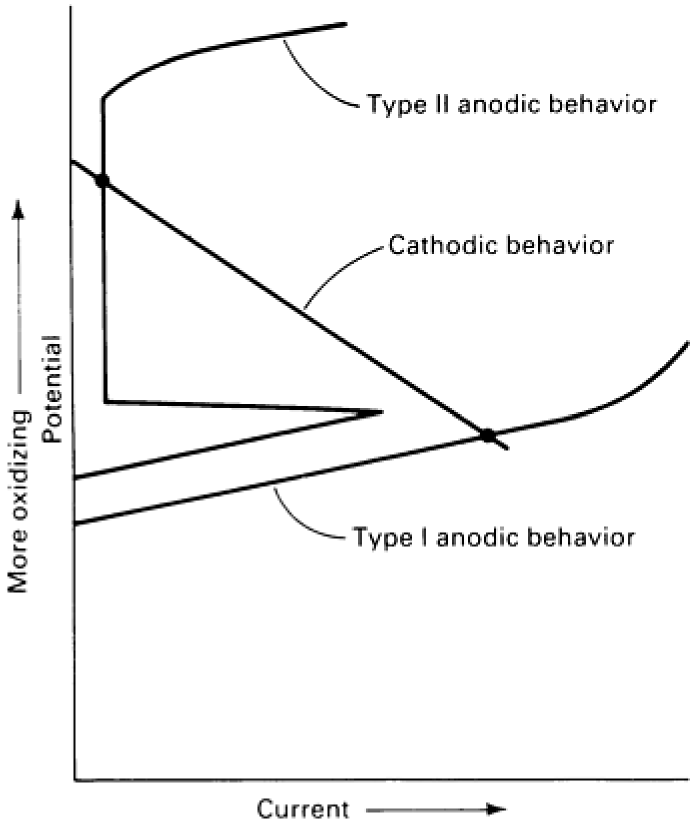

Fig. 1 Schematic showing the two basic types (Type I and Type II) of electrochemical response exhibited by nickel-base alloys. These responses are not intrinsic properties, but are interactions between alloys and environments.

The potential of a metal in an environment is influenced by the balance of reduction-oxidation processes taking place at the solution/metal interface. Thus, in dilute H_2SO_4, the reduction (also termed cathodic) reaction is the conversion of hydrogen ion to hydrogen gas ($H^+ + e^- \rightarrow \frac{1}{2}H_2$). In a ferric chloride ($FeCl_3$) solution, the cathodic reaction is the conversion of Fe^{3+} to ferrous (Fe^{2+}) ion ($Fe^{3+} + e^- \rightarrow Fe^{2+}$). These cathodic reactions are represented by a downward-sloping line in Fig. 1, indicating that, as the potential is reduced, the reduction reaction takes place at a faster rate. Because no net current flows when a metal is dipped in a solution, the metal attains a potential that is the intersection of the cathodic and anodic lines. The higher the cathodic line, the greater the oxidizing power of the solution. For example, the reaction $Fe^{3+} + e^- \rightarrow Fe^{2+}$ has a potential that is more positive than the reaction $H^+ + e^- \rightarrow \frac{1}{2}H_2$. Thus, in a more oxidizing solution, the resultant potential of the metal is higher. The absolute metal-solution potential cannot, in theory, be measured, but a relative potential with respect to an unchanging reference potential can be measured.

With regard to the corrosion behavior of alloys, if an alloy exhibits Type I behavior, increasing the corrosion potential will result in an increased corrosion rate. Alloy B-2 in dilute, deaerated H_2SO_4 exhibits a low corrosion rate (Type I behavior) because the corrosion potential determined by the hydrogen reduction reaction is low. If Fe^{3+} impurities are present in the acid (this is quite common in acid streams that contact steel parts elsewhere in the system), the corrosion potential, and thus the corrosion rate, is increased (Fig. 2). The presence of oxygen can result in a similar behavior. In contrast, a high-chromium alloy such as alloy G-30 exhibits Type II behavior, and the presence of Fe^{3+} shifts the potential into the passive region, which results in a low corrosion rate.

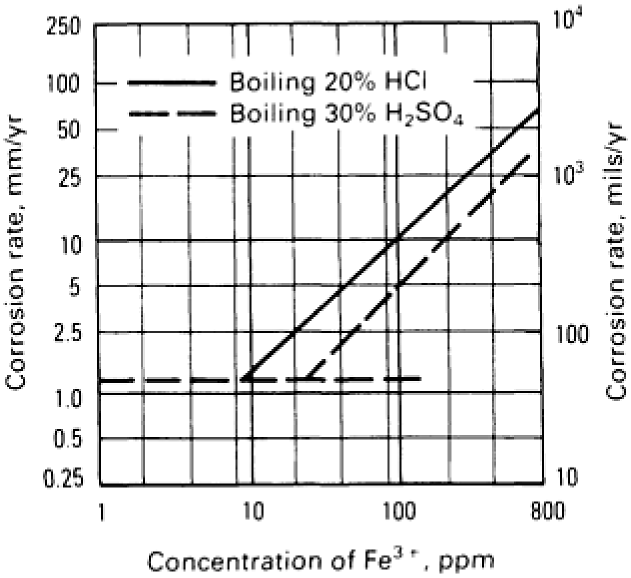

Fig. 2 Effect of Fe^{3+} in boiling H_2SO_4 and HCl on the corrosion rate of alloy B-2

A third possibility is that the solution is oxidizing enough to shift the potential into the transpassive region. In some solutions, this can lead to pitting corrosion.

Corrosion Resistance of Nickel-Base Alloys in Acid Media

Sulfuric acid is the most ubiquitous environment in the chemical industry. The electrochemical nature of the acid varies a great deal, depending on the concentration of the acid and the impurity content (Ref 25). The pure acid is considered to be a nonoxidizing acid up to a concentration of about 50 to 60% by weight, beyond which it is generally considered to be oxidizing (Ref 25, 26). The corrosion rates of nickel-base alloys, in general, increase with acid concentration up to about 90% weight. Higher concentrations of the acid are generally less corrosive.

A broad view of the relative performance of various alloys in reagent grade H_2SO_4 is illustrated in Fig. 3. In this graph, the temperatures at which the corrosion rate of an alloy in a given concentration of the acid exceeds 0.5 mm/yr (20 mils/yr) are plotted as isocorrosion curves. At low acid concentrations, the nickel-chromium-molybdenum alloys show a significantly higher resistance than type 316 stainless steel. Alloy 20, a high-nickel stainless steel, shows similar behavior. These high-nickel-chromium-molybdenum alloys can be used only to moderate temperatures in the intermediate and high concentrations of H_2SO_4. The nickel-molybdenum alloys B and B-2 can be used to higher temperatures for all concentrations of acid. However, in the presence of oxidizing species and in aqueous acid systems, alloys B and B-2 suffer serious corrosion. This effect is shown in Fig. 2 for alloy B-2.

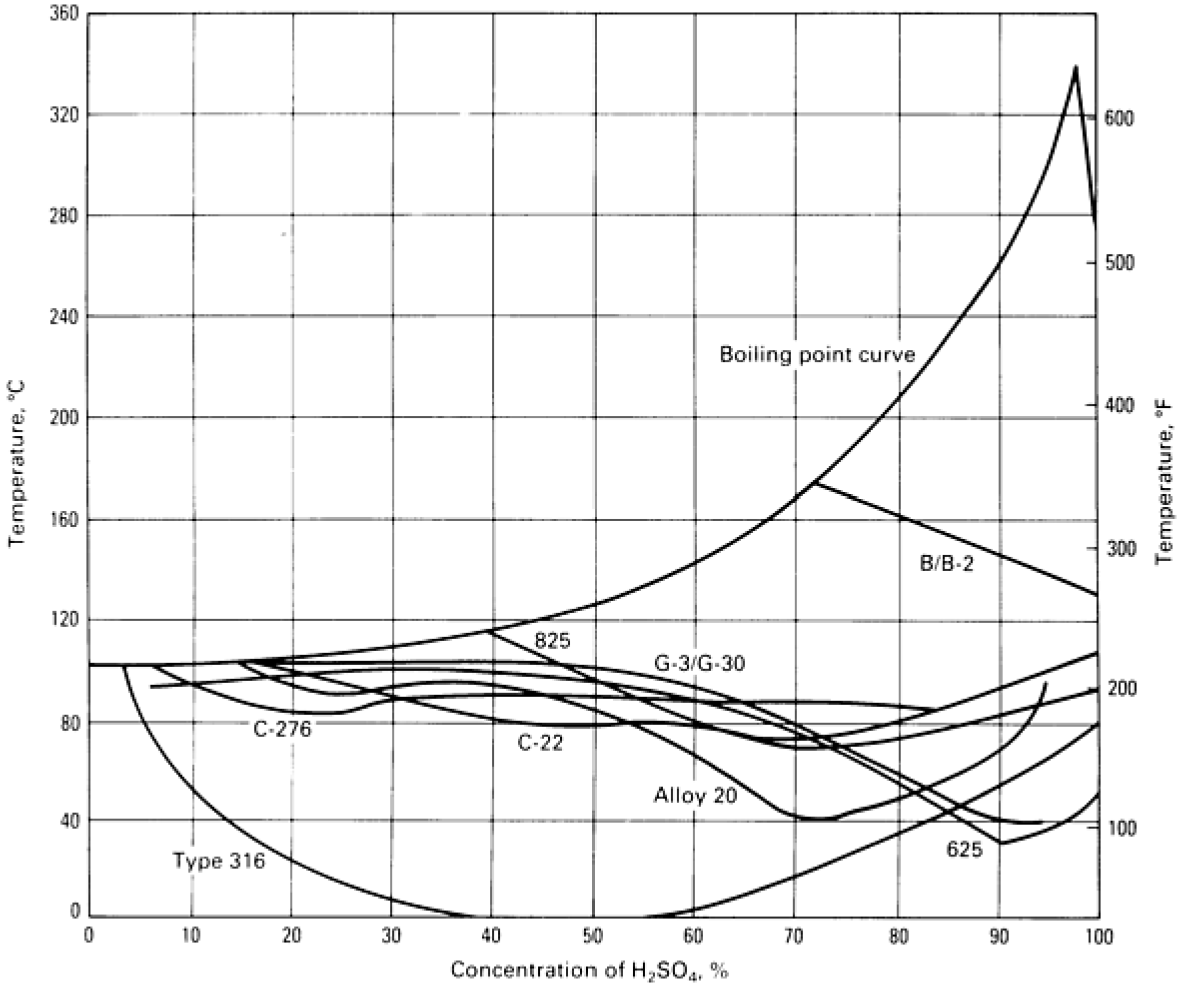

Fig. 3 Comparative behavior of several nickel-base alloys in pure H_2SO_4. The isocorrosion lines indicate a corrosion rate of 0.5 mm/yr (20 mils/yr). Source: Ref 27, 28, and 29

The presence of oxidizing impurities can be beneficial to nickel-chromium-molybdenum alloys shown in Fig. 3 because these impurities can aid in the formation of passive films that retard corrosion. Another important consideration is the presence of chlorides (Cl^-). Chlorides generally accelerate the attack; the extent of acceleration differs for various alloys. This is shown in Fig. 4 in terms of the 0.13-mm/yr (5-mils/yr) isocorrosion curves for alloys C-276 and G.

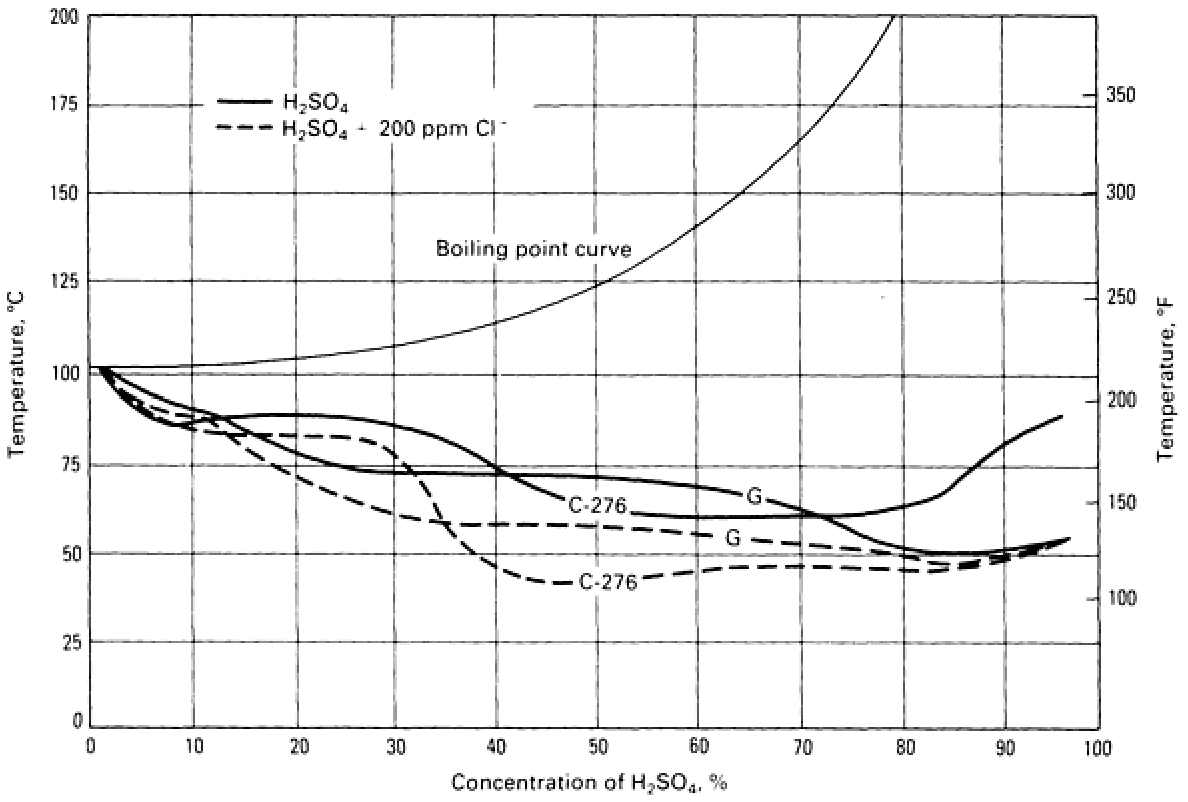

Fig. 4 Effect of dissolved chlorides on the corrosion resistance of nickel-base alloys in H_2SO_4. The isocorrosion lines indicate a corrosion rate of 0.13 mm/yr (5 mils/yr).

Hydrochloric Acid. The corrosion resistance of several nickel-base alloys in HCl and related environments is reviewed in Ref 30. Commercially pure nickel (200 and 201) and nickel-copper alloys (alloy 400) have room-temperature corrosion rates below 0.25 mm/yr (10 mils/yr) in air-free HCl at concentrations up to 10%. In HCl concentrations of less than 0.5%, these alloys have been used at temperatures up to about 200 °C (390 °F) (Ref 30). Oxidizing agents, such as cupric (Cu^{2+}), Fe^{3+}, and chromate (CrO_4^{2-}) ions or aeration, raise the corrosion rate considerably. Under these conditions nickel-chromium-molybdenum alloys such as 625 or C-276 offer better corrosion resistance. They can be passivated by the presence of oxidizing agents.

The nickel-chromium-molybdenum alloys also show higher resistance to uncontaminated HCl (Fig. 5). For example, alloys C-276, 625, and C-22 show very good resistance to dilute HCl at elevated temperatures and to a wide range of HCl concentrations at ambient temperature. The corrosion resistance of these alloys depends on the molybdenum content. The alloy with the highest molybdenum content--Hastelloy alloy B-2--shows the highest resistance in HCl of all the nickel-base alloys. Accordingly, this alloy is used in a variety of processes involving hot HCl or nonoxidizing chloride salts hydrolyzing to produce HCl. In Fig. 5, alloy B-2 shows two isocorrosion curves--one at high temperatures near the boiling point and one at low temperature. This is due to variations in the oxygen content of the solutions. At the higher temperatures, the oxygen solubility is lower, and therefore the corrosion rate is lower. The major weakness of the alloy is that its corrosion resistance decreases dramatically under oxidizing conditions (Fig. 2). Chromium-containing alloys such as C-276 or 625 can be passivated when oxidizers are present, and thus display much lower corrosion rates.

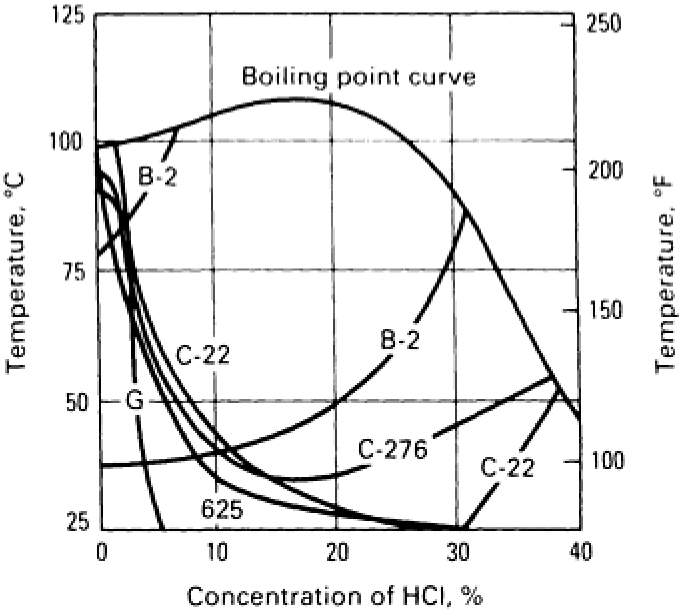

Fig. 5 Comparative isocorrosion plots of various nickel-base alloys in HCl. The lines indicate a corrosion rate of 0.13 mm/yr (5 mils/yr).

Pitting Corrosion in Chloride Environments. The nickel-chromium-molybdenum alloys, such as alloys C-276, 625, ALLCORR, and C-22, exhibit very high resistance to pitting in oxidizing chloride environments. The critical pitting temperatures of various nickel-chromium-molybdenum alloys in an oxidizing chloride solution are shown in Table 2. Pitting corrosion is most prevalent in chloride-containing environments, although other halides and sometimes sulfides have been known to cause pitting. There are several techniques that can be used to evaluate resistance to pitting (Ref 31, 32). Critical pitting potential and pitting protection potential indicate the electrochemical potentials at which pitting can be initiated and at which a propagating pit can be stopped, respectively. These values are functions of the solution concentration, pH, and temperature for a given alloy; the higher the potentials, the better the alloy. The critical pitting temperature (below which pitting does not initiate) is often used as an indicator of resistance to pitting, especially in the case of highly corrosion-resistant alloys (Table 2). Chromium and molybdenum have been shown to be extremely beneficialto pitting resistance (Ref 8).

Table 2 Critical pitting temperatures for nickel alloys evaluated in 6% $FeCl_3$ for 24-h periods

Alloy	Critical pitting temperature	
	°C	**°F**

C-22	70.0, 70.0	158, 158

Source: Ref 33

Nitric Acid. Chromium is an essential alloying element for corrosion resistance in HNO_3 environments because it readily forms a passive film in these environments (Ref 33). Thus, the higher chromium alloys show better resistance in HNO_3 (Fig. 6). In these types of environments, the highest chromium alloys. G-30 and 690, seem to show the highest corrosion resistance. Molybdenum is generally detrimental to corrosion resistance in HNO_3. For example, alloy C-22 (with 13% Mo) is not as good as alloy G-3 (with 7% Mo). In pure HNO_3 stainless steels find the greatest application. In concentrated (98%) HNO_3, stainless steels containing both chromium and silicon are finding greater use (Ref 34). Because of its oxidizing nature, HNO_3 streams are too severe for nickel-molybdenum alloys. The behavior of nickel-silicon alloys in HNO_3 seems to depend on their microstructure and composition (Ref 9). Cast Hastelloy alloy D, which consists of two phases (the nickel-silicon solid solution and the eutectic), does not show good resistance to any concentration of HNO_3. The Ni-9.5Si-2.5Cu-3Mo-2.75Ti cast alloy, which consists of a single phase, showed high resistance to boiling concentrated HNO_3 above 60% and to fuming (99%) HNO_3, up to 80 °C (175 °F). However, the corrosion rates in more dilute acid were very high.

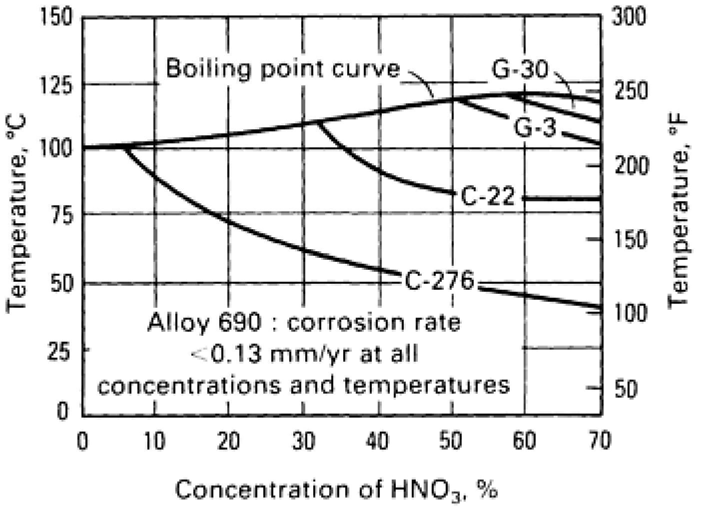

Fig. 6 Comparative behavior of nickel-base alloys in HNO_3. Isocorrosion curves indicate a corrosion rate of 0.13 mm/yr (5 mils/yr).

Phosphoric acid is obtained by two difficult routes. The wet-process acid is obtained by reacting phosphate rock with concentrated H_2SO_4 and concentrating the resulting dilute acid by evaporation. The furnace acid is obtained by calcining the phosphate rock to produce elemental phosphorus, which is then oxidized and reacted with water to produce H_3PO_4. This latter acid is very pure and is used as reagent grade. The wet-process acid is used to make phosphoric fertilizers and usually contains a number of impurities, such as HF, H_2SO_4, and SiO_2. The percentage of these impurities depends on the source of the rock, the process of reaction with H_2SO_4, and the stage of concentration of the H_3PO_4.

The corrosion rates of various alloys in pure and wet-process acids are compared in Table 3. It is interesting to note the variation in corrosion rate of the same alloy in wet-process acid from two different manufacturers. Because of these differences, it is imperative that any comparison between alloys in this type of acid be made from tests conducted in the same batch of acid from the same source. It can also be seen that the wet-process acid can be considerably more corrosive than the reagent grade acid. It has been shown that in wet-process acid a high chromium content, such as in alloy G-30, is beneficial (Ref 35). In addition, Cl^- is inevitably present in these acids; therefore, molybdenum and tungsten additions are beneficial.

Table 3 Corrosion of various alloys in reagent grade and wet-process H_3PO_4

Alloy	Corrosion rate					
	Reagent grade 75% H_3PO_4, 115 °C (240 °F)		**Wet process 75% H_3PO_4 (54% P_2O_5), 115 °C (240 °F)**

The plant test results shown in Table 4 indicate that alloys 20Cb3, 825, and C have the highest corrosion resistance in dilute H_3PO_4 process solutions. In very high-concentration H_3PO_4 at high temperatures, alloy B-2 shows the highest resistance (Table 5). The corrosion resistance in these acids seems to depend on molybdenum content.

Table 4 Results of plant corrosion test in a H_3PO_4 evaporator

Specimens were exposed for 42 days to 53% H_3PO_4 containing 1 to 2% H_2SO_4 and 1.2 to 1.5% fluoride at 120 °C (250 °F). No pitting was observed.

Hydrofluoric acid is commercially available in concentrations ranging from 30 to 70% and as anhydrous HF. Plain carbon steel can withstand the anhydrous acid and is extensively used and rail cars carrying anhydrous HF. Of the nickel-base alloys, alloy 400 has been the most extensively examined (Ref 37). The alloy possesses good corrosion resistance in all concentrations of HF up to a temperature of about 120 °C (250 °F). However, the presence of oxygen in the solution is detrimental (Table 6).

Table 6 Effect of oxygen on corrosion of alloy 400 in HF solutions

The acids were purged with nitrogen containing various amounts of oxygen.

Concentration of oxygen in purge gas, ppm	Corrosion rate							
	Boiling (112 °C, or 234 °F) 38% HF				**Boiling (108 °C, or 226 °F) 48% HF**

In another investigation, alloy 400 showed transgranular SCC in the vapor phase of dilute HF solutions (up to 0.5% HF) at temperatures up to 95 °C (200 °F) (Ref 38). The cracking susceptibility did not depend on the presence of oxygen, and no cracking was found in the liquid phase. The nickel-molybdenum alloys B and B-2 show good corrosion resistance at low temperatures. However, in one case, increasing the temperature from 25 to 95 °C (75 to 200 °F) in a 0.5% HF solution resulted in an increase in the corrosion rate of alloy B from 0.025 to 0.05 mm/yr (1 to 2 mils/yr) to 7.1 mm/yr (280 mils/yr). Alloy C-276 showed a low corrosion rate at all temperatures in HF up to 0.5% (Ref 38). The corrosion

resistance of a variety of nickel-base alloys in various concentrations of HF is shown in Table 7. No control of aeration was attempted in these tests. The presence of aeration may be detrimental to the corrosion resistance of alloy C-276, as shown in Table 8 for 70% HF solution.

Table 7 Corrosion of various nickel-base alloys in HF

The organic acids are generally not as corrosive as the mineral acids because of their lower acidity. Of the organic acids, acetic and formic acids form the bulk of the corrosion data on nickel-base alloys. Corrosion data on other organic acids can be found in Ref 39 and 40.

Acetic Acid. The corrosion rates of Nickel 200, alloy 400, and alloy 600 are shown in Table 9. The detrimental effects of aeration can be seen for alloy 400 and Nickel 200. The corrosion rates of a variety of alloys in boiling 10 and 99% acetic acids are given in Tables 10 and 11. No deliberate aeration or deaeration was done in these tests. The corrosion rates of all the alloys are quite low in these environments. Even though pure acetic acid is not very aggressive, the addition of contaminants can increase the corrosion rates. This is shown for Nickel 200 and alloy 400 in Table 12. The detrimental effects of aeration and oxidizing ions are indicated, especially in the dilute acid.

(a) Added as acetate.

Formic acid is generally more corrosive than acetic acid. This is partly because the dielectric constant of formic acid (56.1 at 25 °C, or 75 °F) is higher than that of acetic acid (6.2 at the same temperature); therefore, the ionic dissociation is higher in the former. Formic acid is also much more acidic than acetic acid. The corrosion rates of a variety of nickel-base alloys in boiling 40 and 88% formic acid are given in Tables 13 and 14. Among the nickel-chromium-molybdenum-iron alloys, the higher-molybdenum alloys generally tended to show higher resistance to corrosion. The isocorrosion curves for alloys C-276, B, and 400 and AISI type 316 stainless steel are shown in Fig. 7. For alloys 400 and B, the data shown in Fig. 7 and in boiling acids (Tables 13 and 14) do not agree. It is possible that these discrepancies are due to differences in aeration, because boiling acids are expected to have low aeration after a certain period of time.

Propionic Acid. The corrosion rates of several alloys in boiling propionic acid are shown in Fig. 8. Lowering the temperature from the boiling point can increase the corrosion rates of those alloys that are sensitive to the degree of aeration (Table 15).

Table 15 Effect of test temperature on corrosion of various nickel-base alloys in propionic acid

Other Organic Acids. The higher organic acids, such as acrylic acid, and the fatty acids, such as lauric and stearic acids, are generally not very corrosive to nickel-base alloys (Ref 39). The corrosion rates in these acids, as in other organic acids, are determined by the inorganic impurities present in the acids (for example, chlorides and oxidizing salts).

Corrosion in Acid Mixtures. In many processes, mixtures of several acids or acids and salts are encountered. Corrosion resistance in these types of environments is sometimes predictable qualitatively. In some cases, anomalous effects can be produced. Although it is impossible to list the corrosion rates of alloys in a wide range of acid mixtures within the constraints of this section, an attempt will be made to present those mixtures that are of greatest importance or that show surprising features.

Sulfuric + Nitric Acid Mixtures. In alloys that contain chromium and exhibit active-passive behavior, addition of HNO_3 or nitrates to H_2SO_4 will reduce the corrosion rate (Fig. 9). In nonchromium-containing alloys (for example, alloys B-2 or 400), addition of HNO_3 will increase the corrosion rates. The nitrate reduction reaction increases the redox potential in H_2SO_4 solution; the redox potential of H_2SO_4 solution is normally controlled by the H^+ reduction reaction. In nonpassivating alloys, for example, alloy B-2, in which the corrosion current increases monotonically with potential, an increase in potential will increase the corrosion rate. In passivating alloys, an increase in potential can move the alloy from the active state to the passive state, thus reducing the corrosion rate. For high nitrate concentrations, the passive current density itself can increase, or the corrosion potential can move into the transpassive region, which results in an increase in corrosion rate. In the case of alloy C-276 in Fig. 9, only an increase in corrosion rate is observed with the HNO_3 addition. It is possible that for lower concentrations (<10%) of HNO_3 a decrease in corrosion rate could have been observed.

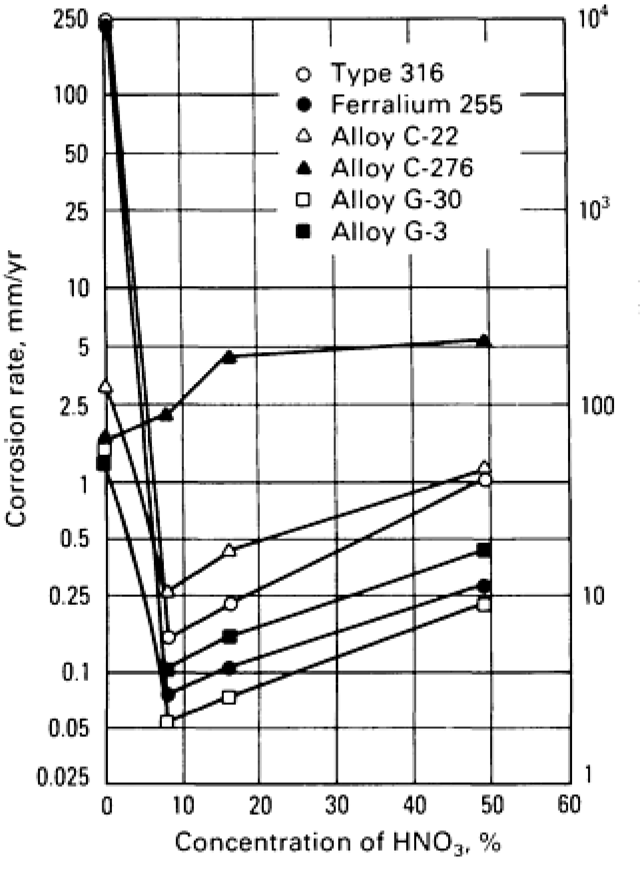

Fig. 9 Effect of HNO_3 on the corrosion of various alloys in a boiling 30% H_2SO_4 solution. Source: Ref 25

Sulfuric + Hydrochloric (or chloride) Mixtures. The addition of alkali chloride salts or HCl to H_2SO_4 increases the corrosion rates of all alloys. The behavior of three of the nickel-base alloys is shown in Fig. 4 and Fig. 10. For deaerated conditions, alloys B and B-2 are the most versatile, with alloys C-276 and C-22 following in that order. Generally, the higher the molybdenum, the better the performance of the alloy in H_2SO_4 + HCl mixtures.

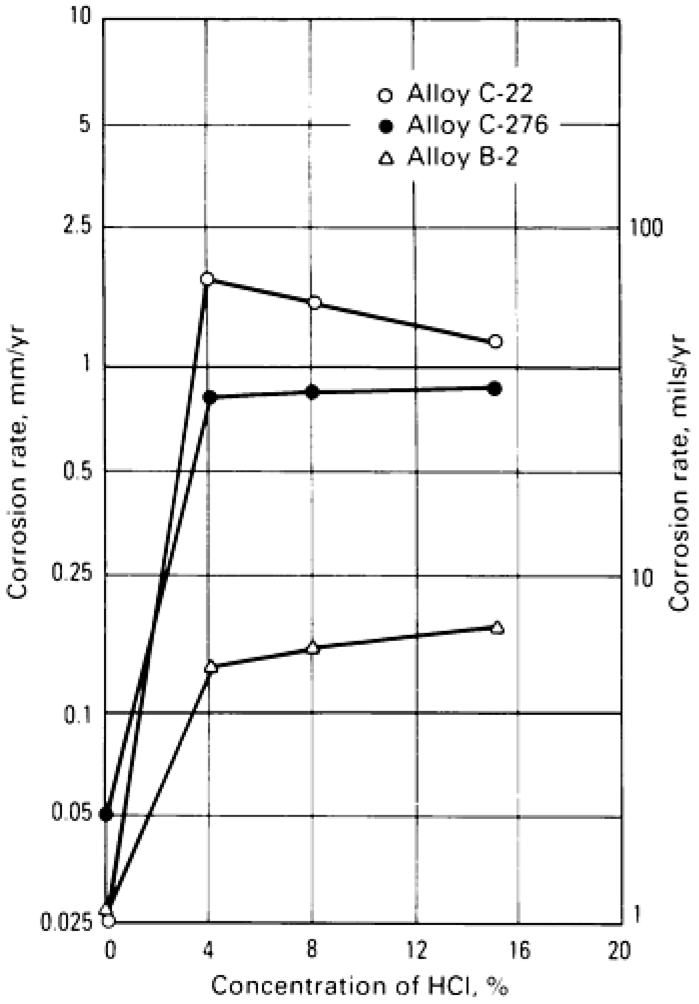

Fig. 10 Effect of HCl on the corrosion of various alloys in 15% H_2SO_4 at 80 °C (175 °F). Source: Ref 25

Nitric + Hydrochloric Acid Mixtures. The effects of HNO_3 additions to HCl are similar to the effects of HNO_3 additions to H_2SO_4 (Fig. 11). However, in HNO_3 + HCl mixtures, pitting is the mechanism of corrosion, rather than uniform corrosion, which occurs in H_2SO_4 + HNO_3 mixtures. In addition, small changes in HCl concentration can result in enormous changes in corrosion rates (Fig. 12).

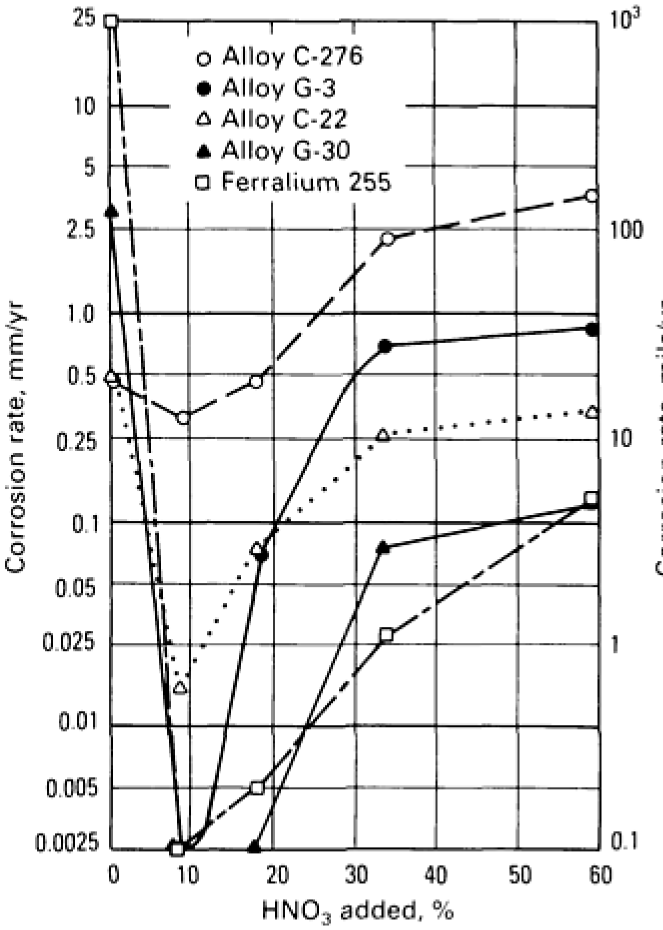

Fig. 11 Effect of HNO_3 on the corrosion of various alloys and Ferralium 255 in a 4% HCl solution at 80 °C (175 °F). Source: Ref 25

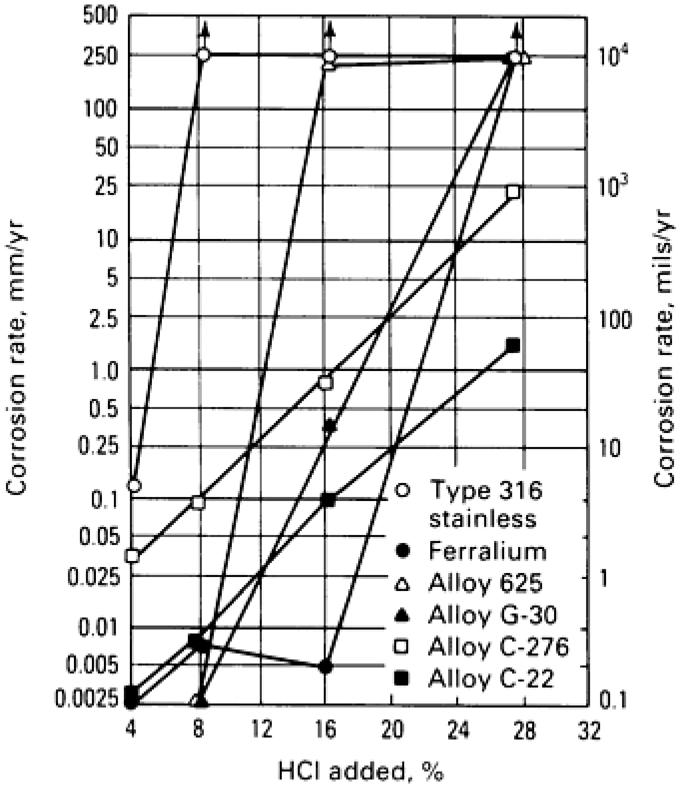

Fig. 12 Effect of HCl additions on the corrosion rates of various alloys in 9% HNO_3 at 52 °C (125 °F)

Nitric + Hydrofluoric Acid Mixtures. The addition of HNO_3 to HF reduces the corrosion rate initially, but beyond 10% HNO_3, the corrosion rate increases. Increasing the HF concentration results in an increasing corrosion rate (Fig. 13). However, unlike the case of HCl addition, the higher-chromium alloys generally showed lower rates, irrespective of molybdenum level. Intergranular corrosion was also observed in many of these alloys. In all of the above cases, increasing temperature caused increased corrosion rates.

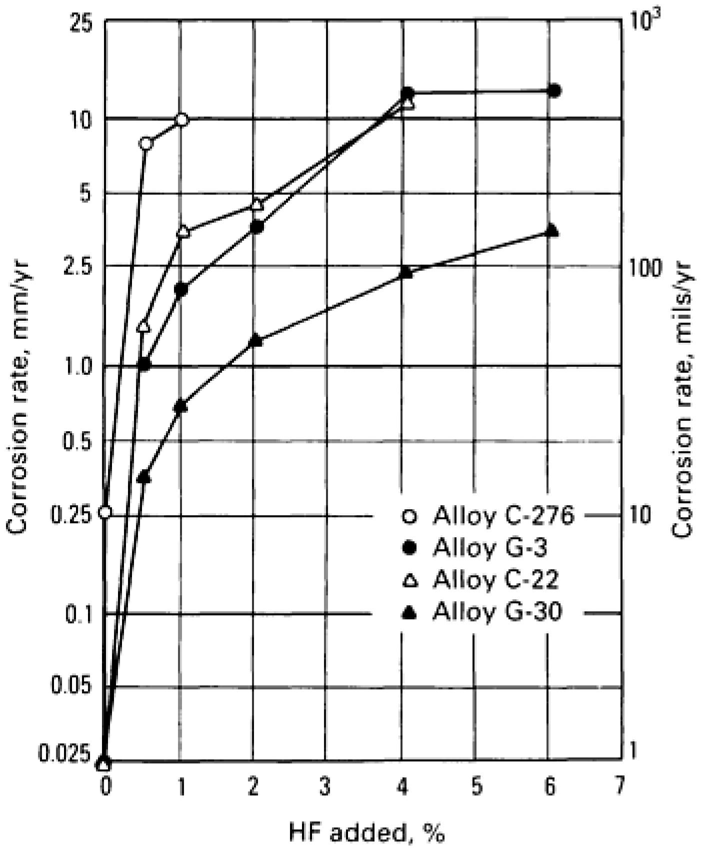

Fig. 13 Effect of HF additions on the corrosion of various alloys in 20% HNO_3 solutions at 80 °C (175 °F)

Corrosion Resistance of Nickel-Base Alloys in Alkalies

Nickel 200 and 201 are used extensively in caustic production and processes involving all concentrations and temperatures of sodium hydroxide (NaOH) and potassium hydroxide (KOH). This resistance prevails even when these alkalies are molten. The lower-carbon Nickel 201 is used at temperatures above 315 °C (600 °F) to avoid graphite precipitation. Isocorrosion curves for Nickel 200 and 201 are shown in Fig. 14. Nickel 200 is used extensively in caustic evaporator service where dilute caustic is concentrated up to 50%. In this service contaminants such as chlorates, hypochlorites and chlorides can cause increased corrosion rates, especially under velocity conditions (Ref 43, 44, 45, 46). Though nickel is resistant to most alkalies, it is not resistant to ammonium hydroxide (NH_4OH) solutions.

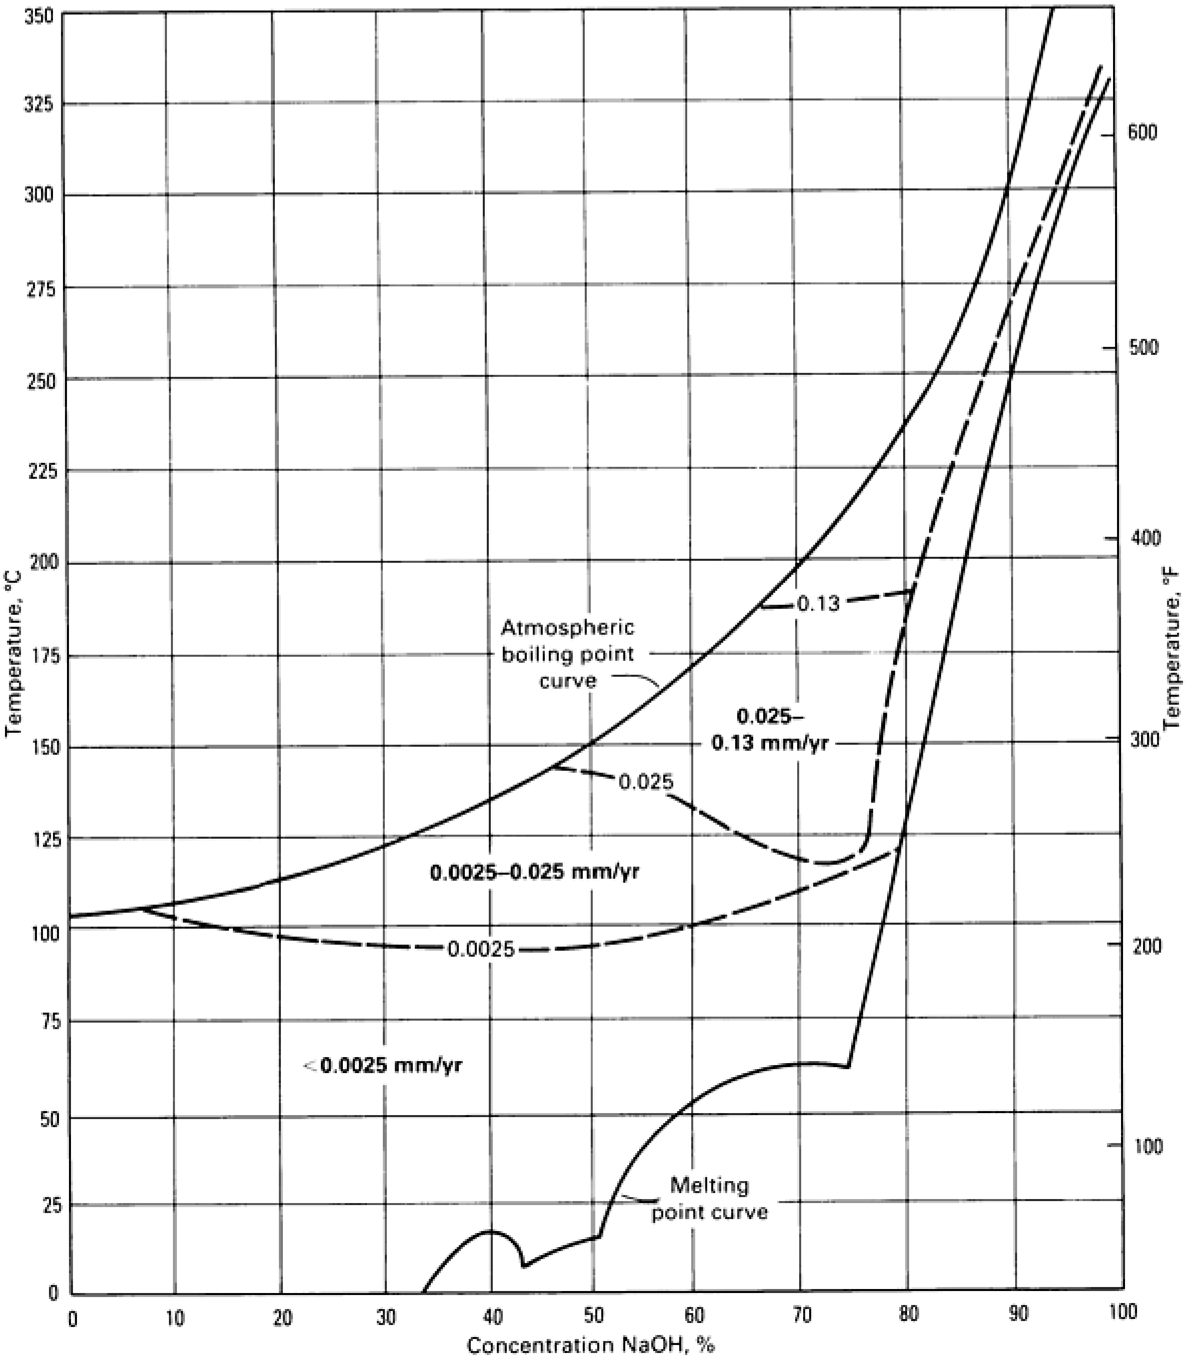

Fig. 14 Isocorrosion diagram for Nickel 200 and Nickel 201 in NaOH. Source: Ref 42

The resistance of nickel alloys to general corrosion and SCC increases with increasing nickel content. In some caustic applications where higher strength or resistance to other corrodents is required, alloys 400, 600, C-276, and others are used. These alloys are highly resistant to general corrosion and SCC, but can be attacked at high caustic concentrations and temperatures.

Alloys 600 and 800 have been used extensively in nuclear steam generator service at about 300 °C (570 °F). In this service resistance to caustic, which can be formed and concentrated at tube sheets, is of concern (Ref 47). The higher-chromium alloy 690 is more resistant to SCC under some conditions.

Environmental Embrittlement of Nickel-Base Alloys

Juri Kolts, Conoco Inc.

Nickel-base alloys are frequently used because of their improved resistance to environmental embrittlement over steels and stainless steels. However, nickel-base alloys can exhibit environmental embrittlement under the combined action of tensile stresses (either residual or applied) and specific environmental conditions. In the most severe cases, cracking or failure may result after an incubation period in which no apparent damage has occured. These incubation periods may be of the order of minutes, days, months, or years.

The embrittlement of nickel-base alloys by the combined action of tensile stress and a suitable environment is thought to occur by two phenomena: hydrogen embrittlement and SCC. No inference is made as to the mechanisms of embrittlementor to what extent hydrogen is involved in SCC. Phenomenologically, hydrogen embrittlement is distinguished from SCC in this section by the influence of two parameters (environmental temperature and anodic/cathodic polarization) on the susceptibility of alloys to embrittlement. Increasing the temperature from ambient generally results in increasing susceptibility to SCC and decreasing susceptibility to hydrogen embrittlement. Cathodic polarization often results in increasing hydrogen embrittlement and decreasing SCC susceptibility.

Hydrogen embrittlement and SCC have only recently been recognized as important phenomena in nickel-base alloys. However, because these alloys are often used specifically to solve problems of hydrogen embrittlement and SCC, these topics are of great importance.

Stress-Corrosion Cracking

The nickel-base alloys are generally used to combat SCC where austenitic stainless steels have failed because of SCC. However, two events have recently occurred that require increased knowledge of the SCC resistance of nickel-base alloys. First, a large number of alloys have been developed and included in the market; this has resulted in an almost continuous change in performance (alloy content) between stainless steels and the numerous nickel-base alloys. Second, the nickel-base alloys have been historically considered to be immune to SCC in all but a few environments, but the increased requirements for current processes have extended the use of materials to temperatures at which the SCC of nickel-base alloys must be considered.

Stress corrosion cracking of nickel-base alloys has been found to occur in three types of environments: high-temperature halogen ion solutions, high-temperature waters, and high-temperature alkaline environments. In addition, SCC has been detected in liquid metals, near-ambient-temperature polythionic acid solutions, and environments containing acids and hydrogen sulfide (H_2S).

High-Temperature Halogen Ion Solutions

Although the nickel-base alloys are specifically used for resistance to SCC in high-temperature Cl^- solutions, virtually every nickel-base alloy is susceptible to SCC in chloride solutions if the proper conditions exist. Table 16 lists the alloy-environment combinations in which SCC has been detected. Unlike the common stainless steels, which show SCC at low temperatures, low chloride contents (ppm ranges), and near-neutral solutions, the conditions that promote SCC in nickel-base alloys are much more severe. Stress-corrosion cracking is promoted by the following parameters in aqueous halide systems:

- Elevated temperatures, especially above 205 °C (400 °F)
- High Cl^- contents in the percent range
- Acidity, usually in the range pH <4
- Aeration or presence of other oxidizing species
- Presence of H_2S
- High stress and/or high-strength materials

Although Table 16 lists the alloy-environment combinations that exhibit SCC, this does not suggest that only these alloys exhibit SCC in the respective solutions. Other nickel-base alloys that are less resistant than the reported alloys may not have been tested in a particular investigation.

Table 16 SCC of nickel-base alloys in halogen ion containing environments

Alloy	Environment	Ref
800, 825, 718	Boiling (155 °C, or 310 °F) 42% $MgCl_2$,	48

B-2	HCl + H_2S, 175 °C (350 °F)	58

Because of the range of alloy compositions available, large differences in performance have been shown among the various nickel-base alloys. In the nickel-chromium-molybdenum-iron alloy systems, increasing the molybdenum and

nickel contents (correspondingly decreased iron contents) appears to improve performance. Some evidence suggests that precipitation-hardenable alloys, such as X-750 and IN-718, have lower SCC resistance than nonprecipitation-hardenable alloys at comparable strength levels with otherwise similar compositions. Many of the test results have been developed under severe conditions. Stress-corrosion cracking may not necessarily occur in field applications with environments similar to those in Table 16, because all of the above parameters, along with tensile stress, must be present for SCC to occur.

Factors that may reduce susceptibility to SCC include:

- Lower stress level
- Presence of naturally occurring or intentionally added inhibitors
- Changes in alloy potential by galvanic coupling
- Lower material strength
- Time at temperature
- Surface treatments
- Concentration of environmental species
- Increasing pH

Fracture modes cannot be used to distinguish the mode of cracking unambiguously; however, there are general guidelines. Cracks in high-temperature chloride solutions are generally branching and transgranular. The precipitation-hardened nickel-base alloys, however, may frequently show either transgranular or intergranular cracking. The cracking in alloys B and B-2 tends to be intergranular in halogen ion solutions, although transgranular cracking can also occur. Stress-corrosion cracking in nickel-base alloys often occurs with the presence of a large number of secondary cracks. Of course, cracking occurs in the presence of tensile, rather than compressive, stresses. Excessive uniform corrosion or pitting need not be associated with SCC.

The application of nickel-base alloys in the oil and gas industry has made halogen ion SCC an area of special interest. Much research has been generated in developing materials selection criteria for production fluids with temperatures up to 230 °C (450 °F). Hydrogen sulfide has been found to play a significant role in decreasing resistance to SCC in oil and gas applications. However, because most produced fluids are fully deaerated, the main oxidant that must be considered is elemental sulfur. Pressure, temperature, and pH are important environmental parameters. Although there is little agreement regarding specific alloy selection criteria, the SCC resistance of nickel-base alloys has become a major basis for alloy selection for deep, hot sour gas wells.

High-Temperature Waters

Because of the commercial importance of nuclear energy, the intergranular SCC of alloy 600 in high-temperature pressurized water has been extensively investigated. Alloys 600, 800, and 690 are used in steam generator tubing in pressurized water reactors (Ref 59). Stress-corrosion cracking has occurred in this environment and is generally intergranular. Although much of the literature deals with SCC of alloy 600, this is not the only alloy that exhibits SCC in high-temperature waters. Table 17 shows this phenomenon to extend to stainless steels and other nickel-base alloys. Although alloy 600 is susceptible to cracking in steam generators, it is much more resistant than type 304 stainless steel (Ref 48).

Table 17 SCC of nickel-base alloys in high-temperature waters

Alloy	Environment	Ref
B-2/B	Deionized H_2O + O_2, 205 °C (400 °F)	56
X-750	Pressurized and boiling water reactors (150-175 °C, or 300-350 °F)	60
600	Pressurized water reactors	60, 61
901	Steam turbines	62
800	Pressurized water reactors	63
718	Light water reactors	64
Type 304 stainless steel	Pressurized water reactors	65

Heat treatments that affect grain-boundary structure and composition can be important in determining susceptibility to SCC. Control of such elements as phosphorus, carbon, nitrogen, and niobium can play a significant role in controlling crack behavior (Ref 60, 66). Many investigations have been conducted on the effect of various heat treatments of alloy 600 (Ref 67, 68), usually in the range of 595 to 705 °C (1100 to 1300 °F), on the susceptibility to SCC in waters. Aging in a temperature range that causes semicontinuous precipitation of carbides at grain boundaries and partitioning of solute elements at these boundaries is beneficial. The heat treatments are selected to reduce significant chromium depletion in the grain-boundary region.

Alloy selection and control of metallurgy have not been the only methods of controlling SCC in high-temperature waters. Operating procedures, water equality, design, and control of manufacturing have also been important. Control of steam purity is of primary importance with limits set not only on total purity level but also on the concentrations of individual impurities. Generally, all-volatile water treatments are specified.

Reduction in both residual stresses and operating stresses is the third major method of controlling SCC of nickel-base alloys in nuclear applications. Design considerations include minimizing carryover and reducing temperatures of superheated hot spots that permit concentration by evaporation of wet regions.

Caustic Environments

Many investigators believe that SCC in oxygenated water and high-temperature caustic SCC are related. Consequently, a number of alloy evaluations have been made of alloys 600, 800, and 690 in caustic environments at temperatures near 315 °C (600 °F). Stress-corrosion cracking in caustic solutions is highly dependent on applied potential, with a number of potential regions present where SCC can occur (Ref 69).

In austenitic stainless steels, the caustic cracking is often transgranular and not easily distinguished from chloride SCC. Alloys 600 and 800 generally exhibit intergranular SCC in high-temperature caustic environments, although alloy 800 can exhibit transgranular cracking.

Table 18 outlines some of the alloy environment combinations that have caused SCC in alkaline environments. All major classes of nickel-base alloys exhibit SCC in alkaline environments. Of the alloys considered for nuclear applications, alloy 690 appears to possess better resistance to caustic SCC than alloys 600 or 800.

Table 18 Alloy-alkaline environment combinations found to cause SCC of nickel-base alloys

Alloy	Environment	Ref
6B, B, C-276, MP35N	NaOH, 175 °C (350 °F)	70
600, 800, 690	NaOH, 325 °C (620 °F)	71
722	50% NaOH, 315 °C (600 °F)	72
600	LiOH, 335 °C (635 °F)	53
600	10% NaOH, 285 °C (550 °F)	60
800	10% NaOH, 285 °C (550 °F)	69
400	10% NaOH, 300 °C (570 °F)	73

Other Environments

Stress-corrosion cracking of nickel-base alloys can occur in polythionic acids at or near ambient temperatures (Table 19). Polythionic acids are often produced by partial oxidation of wet H_2S when exposed to air. Intergranular cracking generally occurs only in highly sensitized alloys after extended exposure to sensitizing temperature ranges. Usually alloys that are not stabilized and contain high carbon (for example, alloys 600 and 800) are the most readily susceptible to this form of SCC.

Table 19 SCC in other alloy-environment combinations

Alloy	Environment	Ref
200	Room-temperature-mercury	74
400, 405, K500, 625, 718, X-750, 200, 600	Room-temperature-mercury	75
200, 600	Room-temperature polythionic acids	56
600 or 800, sensitized	Room-temperature polythionic acids	53, 59, 76

Stress-corrosion cracking has been found in near-ambient-temperature HCl environments containing H_2S. The cracking is transgranular and does not occur without H_2S. Corrosion inhibitors can mitigate this form of SCC.

Hydrogen Embrittlement

Hydrogen embrittlement of nickel-base alloys is exemplified by three forms: brittle (usually intergranular) delayed fracture, a loss in reduction of area while often retaining a microvoid coalescent fracture, or a reduction in properties such as fatigue strength. Although cleavage-type cracks have been reported in nickel-base alloys, they are not the predominant mode of fracture. Table 20 lists alloys and environments in which hydrogen embrittlement is known to occur.

Table 20 Nickel-base alloys exhibiting hydrogen embrittlement

Alloy	Environment	Ref
600	Cathodic charge/tensile test	77
C-276, C-4, MP35N, 625, 718		78, 79
Pure nickel	Cathodic charge H_2SO_4	80
K500	Sour oil and gas environment	81
X750	5% NaCl + 5% CH_3COOH + H_2S	82
718, A286, 625	Hydrogen gas (35 MPa, or 5000 psi) charged at room temperature	83
Pure nickel, 600	Hydrogen gas charged at 723 K, tested at room temperature	84
K500	Cathodic charge, seawater	85

Delayed Failure. The most severe form of embrittlement by hydrogen generally as a delayed failure or a reduction of K_{ISCC} to values at which sustained crack growth can occur. Under these circumstances, fracture can occur after an alloy has been placed in service under stress. With few exceptions, fully annealed nickel-base alloys are essentially immune to hydrogen-induced delayed failure. Only when the strength level of the alloys is increased by cold working or by heat treatment is the incidence of hydrogen embrittlement significant. Also, only the low-iron-containing alloys (generally less than 10% Fe) are significantly affected.

The susceptibility of precipitation-hardenable alloys, such as alloys X-750, alloy K-500, and alloy IN-718, has been reported from laboratory tests and from field exposures. The susceptibility to embrittlement decreases with decreasing strength level and correspondingly with increasing aging temperatures. However, at similar strength levels, increased aging temperatures appear to be beneficial (Ref 86). Some of the solid-solution alloys, such as alloy C-276 and alloy 625, are susceptible to hydrogen embrittlement under conditions of hydrogen charging when cold worked to high strength levels. Aging at temperatures (540 °C, or 1000 °F) at which ordering and/or grain-boundary segregation can occur greatly increases this susceptibility to hydrogen embrittlement (Ref 87, 88, 89). Alloy B-2 is susceptible to hydrogen embrittlement in H_2S-containing environments even in the annealed condition.

Some nickel alloys do not show significant susceptibility to hydrogen embrittlement. These alloys include alloys 825, G, and G-3, and alloy 20Cb3, as well as austenitic nickel-base alloys with correspondingly high iron contents.

Reductions in Ductility or Tensile Strength. Reductions in ductility have been observed during simultaneous deformation of nickel-base alloys and charging in gaseous hydrogen-containing atmospheres. Although these conditions generally do not pose a risk of failure, they have been used as a method of comparing the relative hydrogen embrittlement susceptibilities of alloys.

Annealed nickel has been shown to be susceptible to intergranular hydrogen embrittlement. This phenomenon appears to be related to the sulfur content/segregation in nickel.

Large reductions in the ductility of nickel-base alloys have been observed at a strain rates near 10^{-4} to $10^{-6}s^{-1}$. Although the fracture mode may remain microvoid coalescence, reductions in the dimple size ratio occur in air (Ref 90). In some alloys, intergranular fractures may occur. The embrittlement during slow strain rate testing is often associated with the dislocation transport of hydrogen (Ref 91).

Increasing the temperature above room temperature often results in decreasing susceptibility to hydrogen embrittlement (Ref 52). Reducing the temperature much below ambient may also reduce susceptibility (Ref 80, 83).

The nickel-base alloys often exhibit such high corrosion resistance that the corrosion currents do not generate sufficient hydrogen to cause embrittlement, even in the most susceptible alloy conditions. However, the application of external cathodic currents, as in cathodic protection, or the generation of hydrogen on susceptible nickel-base alloys by coupling to active metals that do corrode in an environment may charge hydrogen into the nickel-base alloys, thus causing embrittlement in susceptible alloys. Alternatively, hydrogen can be charged into alloys at elevated temperatures at which corrosion rates may be high (Ref 92). Subsequent slow strain rate testing can then exhibit ductility losses.

Fabrication and Weldability of Nickel Alloys

Samuel Dwight Kiser, Inco Alloys International, Inc.

Nickel-base alloys can be fabricated with most conventional welding processes, such as gas tungsten arc, gas metal arc, and shielded metal arc welding using coated electrodes. As the nickel content of an alloy increases, several general trends can be observed:

- Toleration for contamination decreases
- Puddle viscosity during welding increases
- Coefficient of expansion decreases as iron is replaced by nickel
- Penetration during welding decreases

Because of these differences between high-nickel materials and iron-base alloys, alternate techniques must sometimes be used for nickel-base alloys to produce acceptable weldments. For example, greater care in precleaning and cleanliness during welding are required to prevent the occurrence of contamination-induced cracking. The increased puddle viscosity (lack of fluidity) can result in poor wetting or in lack-of-fusion defects along bead edges. Also, if no weave is used, rollover or a very poor wetting profile is sometimes encountered. Because penetration is naturally low with high-alloy materials, the angle formed between the base alloy and the weld bead edge should be greater than 100° to facilitate good tie ins with subsequent beads. Figure 15 shows acceptable and unacceptable wetting profiles fornickel alloy weldments.

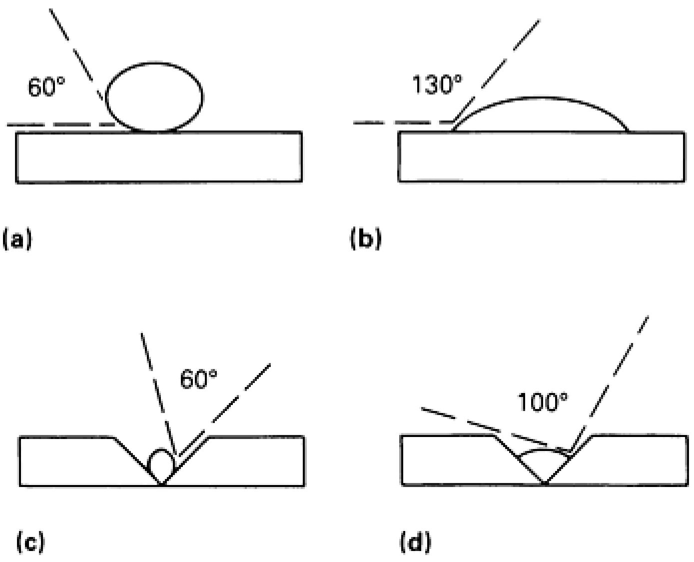

Fig. 15 Acceptable (b and d) and unacceptable (a and c) wetting profiles for nickel alloy weldments. (a) and (b) Overlay welds. (c) and (d) Butt welds

In Fig. 15(a) and 15(c), the highly convex weld with poor wetting can be caused by too slow a travel speed, too low a voltage, lack of weave, or the wrong polarity. Oxidized or dirty base metal can also inhibit wetting. It is very difficult to fuse these profiles into subsequent beads. Entrapped slag or lack-of-fusion defects often result from attempts to tie into these profiles.

Figures 15(b) and 15(d) illustrate good wetting profiles that easily accommodate subsequent beads. These profiles are produced by a proper balance of travel speed, parameters, weave, and base plate preparation. Also, greater viscosity usually requires increased included angles for butt joints (75 ± 5° is recommended for nickel-base alloys).

With regard to the subject of bead contour, it should be noted that each bead produced should be slightly convex. Highly stressed flat or concave weldments are prone to centerline cracking. Particular care should also be devoted to producing slightly convex stops. Convex welds can be produced by reducing voltage or by reducing travel speed; convex stops are made by back filling the crater area.

The relatively low coefficient of expansion of nickel-base alloys, as compared to that of stainless steels, gives nickel-base austenitic alloys better resistance to cracking during welding than the fully austenitic stainless steels. Although both fully austenitic alloy families (stainless and nickel alloys) have low tolerances to contamination, the lower coefficient of expansion of nickel-base alloys allows the joining of nickel to take place under lower shrinkage stresses and thus results in a decreased tendency toward shrinkage cracks.

The tendency for reduced penetration in high-nickel alloys has been discussed briefly. It can be rendered harmless by using increased root gaps, decreased lands, and greater included angles.

Welding Corrosion-Resistant Composites

To reduce material costs in corrosion applications, a relatively thin layer of corrosion-resistant material is sometimes applied over a less resistant, less expensive structural material. Welding is employed in such fabrications, and special considerations are necessary to achieve adequate corrosion resistance in the weldments.

Weld overlay cladding is commonly applied to steel, and the typical items that are overlaid include tubesheets and flanges. Common problems encountered in overlaying are excessive iron dilution and irregular penetration patterns. Excessive iron dilution usually does not result in corrosion problems, because multilayer overlays are most often specified. However, most overlay procedures are qualified by bend tests, and excessive iron dilution can cause failure of such tests. Irregular penetration patterns also result in bend test difficulties.

Excessive iron dilution and irregular penetration patterns can both be improved by maintaining approximately 50% bead overlap. Excessive iron dilution can be reduced by selecting smaller-diameter electrodes, by implementing lower heat input procedures, and by dissipating much of the arc energy on each previous bead.

Welded Metal Linings and Cladding. In the installation of applied linings and the fabrication of bonded clad plate, the primary concern is to produce weldments of equal or greater corrosion resistance than that of the lining or cladding material. The added limitation of only one or two layers of weldment sometimes prohibits the normal choice of consumable. For example, if it is known that certain weldments that contain some iron dilution must be exposed to the same corrosion media as the lining or cladding, then overalloyed filler metals are often selected.

Overalloyed consumables should be selected so that after dilution the weldment is still of slightly higher alloy content than the lining or cladding. For example, many alloys containing 4 to 6% Mo and clad materials have been welded with welding alloy 112 or alloy 625 filler metals, which contain 9% Mo. The consumable contains about 60% Ni, which accepts iron dilution well, and when the 9% Mo is diluted with moderate amounts of iron, there remains enough molybdenum to impart greater pitting and crevice corrosion resistance in the weld than in the cladding or lining.

Corrosion of Welds and Heat-Affected Zones

As was briefly addressed in the discussion "Welding Corrosion-Resistant Composites" in this article, the corrosion resistance of weldments is often very important in the fabrication of nickel alloys and their linings and clad plates. For general corrosion resistance, the selection of a welding consumable is straightforward; the companion wires and electrodes designed for use with the particular base alloy are usually used. If the fabrication is destined for service in which intergranular attack may occur, low-carbon or stabilized alloys and welding consumables are usually selected. In

this way, the danger of grain-boundary precipitation of carbides and intermetallic phases (sensitization) is minimized. The phenomenon of sensitization, along with the resulting intergranular corrosion, is most prevalent in certain stainless steels (see the articles "Corrosion of Stainless Steels" and "Corrosion of Weldments" in this Volume), but nickel-base alloys are subject to similar mechanisms.

Intergranular attack may be counteracted by three methods. The first method involves the selection of alloy and welding consumables that contain extra-low carbon such that carbide precipitation is minimized because of insufficient carbon.

The second method involves the selection of stabilized alloys and welding consumables, which contain such carbide-stabilizing elements as titanium and niobium. Such alloys are rendered insensitive to intergranular attack by the formation of harmless titanium and niobium carbides, rather than chromium carbides. Appropriate annealing treatments are also used to promote the formation of these harmless carbides and to allow the rediffusion of chromium to depleted areas when slight chromium carbide precipitation may have occurred.

Third, if the fabrication is small enough and simple enough, a postweld heat treatment may be performed after all welding has been completed. This heat treatment will redissolve any precipitated carbides. The fabrication is then rapidly cooled (quenched) from the treatment to prevent reprecipitation of carbides.

In applications in which pitting or crevice corrosion attack is expected, alloys must be selected with great care. Furthermore, welding consumables and procedure must be chosen with even greater care.

The localized nature of pitting and crevice corrosion dictates that materials that have been developed and fabricated to resist these types of attack must have reasonably continuous surfaces, must be fabricated without the introduction of crevices and laps, and must have reasonable chemical homogeneity on a microscopic scale. These requirements are not difficult to achieve in wrought alloy forms (hot-rolled plate, rod and bar, and so on). The initial requirements of chemical composition can be met with weldments, but homogeneity within an as-deposited weld cannot be achieved. A weld is a casting, and dendrite formation and growth occur first from the highest melting point constituents as the weld puddle solidifies. As dendrite growth continues, lower melting point materials are typically relegated to the interdendritic spaces, which causes chemical segregation within the weld.

It is commonly known that molybdenum imparts pitting resistance to chromium-containing alloys of iron and nickel. It is not as widely known that molybdenum also serves as an effective melting range depressant. Therefore, the dendrites (those areas that solidify first) characteristically contain lower levels of molybdenum than interdendritic areas (the last to solidify). This means that base metals must be selected to have adequate corrosion resistance in the service environment and that overalloyed filler metals, as described earlier, must be used to ensure that weld metal dendrites have a molybdenum content at least equal to that of the base metal.

Major Applications and Corrosion Performance of Nickel Alloys

J.R. Crum, Inco Alloys International, Inc.

Nickel-base alloys are used for corrosion resistance or for combined corrosion resistance and high-temperature strength in a wide range of commercial applications. These various applications may demand resistance to aqueous corrosion mechanisms, such as general corrosion, localized attack, and SCC, or resistance to elevated-temperature oxidation, sulfidation, and carburization. Many nickel-base alloys have been developed to resist these and other forms of attack. The alloys often find application in areas outside the specific industry or process for which they were designed. A list of the nickel-base alloys discussed in this section and their nominal chemical compositions is given in Table 1. Alloys containing 30% or more nickel are considered.

Chemical-Processing Applications

Caustic Soda. The chemical-processing industry involves a great variety of corrosive environments. Thus, a variety of nickel alloys are used in this industry. A major use for Nickel 200 is in the production of NaOH. Nickel 200 exhibits outstanding corrosion resistance to NaOH at concentrations up to anhydrous at boiling or molten temperatures. Caustic soda (NaOH) is normally produced at 11 to 15% concentration and further concentrated by evaporation to 50% or higher. As NaOH concentration and temperature increase during the evaporation process or during other chemical-processing conditions, the corrosivity increases dramatically. Similarly, increasing the nickel content of nickel-base alloys produces

increasing resistance to general corrosion and SCC in caustic. Thus, a number of nickel-base alloys can be used for handling NaOH, depending on solution concentration and temperature.

At temperatures above 315 °C (600 °F), Nickel 200 is replaced by Nickel 201 because of its low carbon content. In the handling of brines in NaOH production as well as the commercial production of salt, alloy 400 has performed well in a variety of components, such as heat exchangers, vacuum pans, heater tubes, rotary dryers, and transfer piping. In acidic salt environments, however, high-molybdenum nickel alloys, such as 825, 625, G-3, G-30, C-22, and C-276, are used.

Mineral Acids. The production of mineral acids requires the use of nickel alloys. In the production and handling of H_2SO_4, alloys 825 and 400 and alloy 20-type materials are used. When the acid becomes contaminated with halides, high-molybdenum alloys are used, such as alloys G, 625, C-22, C-4, C-276, and ALLCORR. These alloys are also specified where H_2SO_4 is used in the production of other chemicals, such as H_3PO_4, HF, titanium dioxide (TiO_2), ammonium sulfate [$(NH_4)_2SO_4$], and in the refining of copper and nickel ores. Hydrochloric acid is best handled by alloy B-2, especially at elevated temperatures. Some alloys suitable for handling various concentrations of H_3PO_4 are 825, G-3, G-30, and 625.

The extreme reactivity of HF excludes many materials from equipment for making HF and from equipment for processes that employ HF as a catalyst or reagent. Alloy 400 is used in valves in HF alkylation, storage tanks, and retorters. Where HF and H_2SO_4 are used, alloy 825, 625, G-3, and C-276 are used.

Nickel alloys are extensively used in the production of HNO_3. Alloy 617 is used for its high-temperature strength and corrosion resistance in the catalyst-support grids in high-pressure plants. In older plants, alloys 600 and 601 are used because of lower pressure. Alloy 800 is used in the heat-exchanger train. Where reboiling conditions exist, alloy 690 has given exceptional performance.

There are many more areas in the chemical-processing industry in which nickel alloys are used than can be covered in this brief summary (see the article "Corrosion in the Chemical Processing Industry" in this Volume). A few other important applications are used of alloy 600 or Nickel 200 in chlorination processes, such as the Kroll process for production of zirconium and titanium. The production of organic acids and compounds (acetic and formic acids, phenol, fertilizers, urea, pesticides, and plastic) are other examples. All use the alloys discussed above in various chemical-handling equipment, such as pumps, piping, valves, bellows, evaporators, heat exchangers, scrubbers, linings, and tanks.

Water and Seawater Applications

Nickel and nickel-base alloy generally have very good resistance to corrosion in distilled water and freshwater. Typical corrosion rates for Nickel 200 (commercially pure nickel) in a distilled water storage tank at ambient temperature and domestic hot water service are <0.0025 mm/yr (<0.1 mil/yr) and <0.005 mm/yr (<0.2 mil/yr), respectively. Nickel-copper alloys such as 400 and R-405 also have very low corrosion rates and are used in freshwater systems for valve seats and other fittings. Because of the cost of nickel alloys, less expensive stainless steels or other materials are usually specified for pure or freshwater applications unless increased resistance to SCC or pitting is required. Alloys 600 and 690, for example, are used for increased SCC resistance in high-purity water nuclear steam generators.

In steam-hot water systems, such as condensers, appreciable corrosion of Nickel 200 and alloy 400 may occur if noncondensables (CO_2 and air) in the steam exist in certain proportions. Deaeration of the feedwater or venting of the noncondensable gases will prevent this attack. Alloy 600 is resistant to all mixtures of steam, air, and CO_2 and is particularly useful in contact with steam at high temperatures.

Nickel 200 and alloy 400 and nickel-base alloys containing chromium and iron are very resistant to flowing seawater, but in stagnant or very low velocity seawater, pitting or crevice corrosion can occur, especially under fouling organisms or other deposits. In moderate- and high-velocity seawater or brackish water, alloy 400 is frequently used for pump and valve trim and transfer piping. It has excellent resistance to cavitation erosion and exhibits corrosion rates less than 0.025 mm/year (1 mil/yr). Alloy 400 sheathing also provides economical seawater splash zone protection to steel offshore oil and gas platforms, pilings, and other structures. Although pitting can occur in alloy 400 under stagnant conditions, such pitting tends to slow down after fairly rapid initial attack and rarely exceeds 1.3 mm (50 mils) in depth. Age-hardened alloy K-500, with corrosion resistance similar to that of alloy 400, is frequently used for high-strength fasteners and pump and propeller shafting in freshwater and seawater applications.

Other nickel-base alloys containing chromium and molybdenum offer increased resistance to localized corrosion in stagnant seawater. Corrosion resistance of some nickel-base alloys and type 316 stainless steel in ambient temperature seawater is compared in Table 21. In hot seawater applications, such as heat exchangers, highly alloyed materials such as alloys 625 or C-276 may be required. In addition, alloys 625, 400, and K-500 are frequently specified for U.S. Naval wetted components in contact with seawater. Specific high tensile strength requirements are met with alloy 718.

Table 21 Resistance of various alloys to stagnant seawater

3-year exposure tests

Alloy	Maximum pit depth	
	mm	**mils**
625	nil	nil
825	0.025	0.98
K-500	0.864	34
400	1.067	42

Atmospheric Applications

Nickel and nickel-base alloys have very good resistance to atmospheric corrosion. Corrosion rates are typically less than 0.0025 mm/yr (0.1 mil/yr), with varying degrees of surface discoloration depending on the alloy (Table 22). Nickel 200 will become dull and acquire a thin adherent corrosion film, which is usually a sulfate. A greater tarnish will result in industrial sulfur-containing atmospheres than in rural or marine atmospheres.

Table 22 Atmospheric corrosion and pitting of nickel-base alloys

Results of a 20-year exposure 24.4 m (80 ft) from the ocean Kure Beach, NC

Alloy	Average weight loss, mg/dm^2	Average corrosion rate[(a)]	
		mm/yr	**mils/yr**
Nickel 200	468.6	<0.0025	<0.1
Alloy 800	27.9	<0.0025	<0.1
Alloy 600	19.7	<0.0025	<0.1
Alloy 400	644.7	<0.0025	<0.1

(a) No pitting recorded for Nickel 200 and alloy 600. The average of the four deepest pit depths for the other three alloys was less than 0.025 mm (0.001 in.).

Corrosion of alloy 400 is negligible in all types of atmospheres, although a thin gray-green patina will develop. In sulfurous atmospheres, a brown patina may be produced. Because of its low corrosion rate and pleasing patina, alloy 400 has been used for architectural service, such as roofs, gutters, and flashings, and for outdoor sculpture.

Nickel alloys containing chromium and iron, such as alloys 600 and 800, also have very good atmospheric corrosion resistance, but may develop a slight tarnish after prolonged exposure, especially in industrial atmospheres. Nickel-chromium-molybdenum materials such as alloys 825, 625, G, C-276, and C-22 develop very thin and protective passive oxide films that prevent even significant tarnishing. A mirror finish can be maintained after extended exposure to the atmosphere.

Although alloy 400 has been used for atmospheric service in the past, atmospheric exposures requiring nickel alloys are now relatively infrequent. Less costly low-alloy stainless steels or plated materials are normally used.

Applications in Pulp and Paper Mills

Nickel alloys are used in pulp and paper mills generally where conditions are the most corrosive. Alloys 600 and 800 have been utilized for over 25 years for digester liquor heater tubing because their high nickel content provides excellent resistance to chloride SCC. In the disposal of organic wastes in unevaporated black liquor, alloy 600 has been used for the reactor vessel, transfer lines, and piping.

A major problem in this industry has been the cracking of steel digesters in the weld area. A practical solution to the problem is to weld overlay the weld area with alloy 600 or 625 filler metals. Other methods are the use of alloy 600 or 625 sheet liners to cover repaired weld areas or the use of alloy clad steel plate in the initial digester fabrication.

One of the oldest applications of nickel alloys in the pulp and paper industry is alloy K-500 doctor blades. Alloy K-500 provides high corrosion resistance with the abrasive and wear resistance needed for good service even in wet creping operations.

The bleaching circuit and pollution control areas are the most demanding corrosive environments in the pulp and paper mill process. Alloys needed in this area must be resistant to oxidizing conditions of high-temperature low-pH liquors containing chlorine, chlorine dioxide, oxygen, hypochlorate, peroxides, and chlorides. Only the high-molybdenum alloys 625, C-276, and C-22 have the required corrosion resistance to resist these aggressive liquors. In equipment used to clean off-gas from the recovery boiler, alloys 825, 625, G, and C-276 have been used, depending on the severity of the conditions. Typical conditions found are acid mists, low-pH liquors containing chlorides and organics, and sometimes high temperatures. Alloy G scrubbers have given over 10 years of good service at one pulp and paper mill. Other plants have used alloys 625 and C-276 for internal components of scrubbers, fans, ducting, and so on. Detailed information on corrosion in pulp and paper mills is available in the article "Corrosion in the Pulp and Paper Industry" in this Volume.

Flue Gas Desulfurization Applications

Nickel alloys were first used in flue gas desulfurization (FGD) systems in wet-induced draft fans in a particulate scrubber system in 1972. Alloy 625 replaced type 316 stainless steel because of the inadequate mechanical properties of type 316. Construction of FGD equipment increased greatly after the Clean Air Act Amendments were enacted in 1977. Nickel alloys saw limited use during the early years because of their high initial cost. Today, there are over 125 FGD units operating in the United States, all having some nickel alloy applications.

During the period of rapid growth in the utilization of FGD equipment, the industry experienced severe corrosion problems at nearly every operating FGD system. Catastrophic failures were reported for coatings and linings on carbon steel, nonmetallics, stainless steel, and occasionally of nickel alloys. The corrosion problems were due to hot acids (nitric, sulfurous, sulfuric, hydrochloric, and hydrofluoric), chlorides, fluorides, and crevice conditions.

A wide variety of nickel alloys are available for use in FGD applications. Alloys 825 and G are significantly more corrosion resistant in sulfurous and sulfuric acids than austenitic stainless steels. With increasing molybdenum levels,

alloys 625, ALLCORR, G, and C-276 are used to combat pitting and crevice corrosion. These nickel alloys have been successfully used in FGD components, such as quenchers, absorber towers, dampers, stack gas reheaters, wet ID fans and fan housings, outlet ducting, and stack liners. Some innovative FGD applications include the use of alloy 625 in a unique heat recovery system, all-alloy scrubber towers constructed with alloy 625, the application of thin-gage nickel alloy clad steel in new construction, and nickel alloy sheet liners to repair existing FGD components. Severe corrosion problems in FGD systems can be prevented and long life achieved economically by the proper application of nickel alloys in FGD systems. Additional information is available in the selected references at the end of this article.

Sour Gas Applications

Sour gas is defined by National Association of Corrosion Engineers (NACE) Materials Recommendation MR-01-75 as gas being handled at an absolute pressure in excess of 0.45 MPa (65 psi) with a partial pressure of H_2S greater than 345 Pa (0.05 psi). This combination can cause sulfide stress cracking. Sulfide stress cracking can be controlled by using resistant alloys, by controlling the environment, or by isolating the component from the sour environment. The sulfide stress cracking problem is complicated because the environment normally also contains brackish water and CO_2 and is found at 65 at 245 °C (150 to 475 °F), depending on the depth and location of the well.

The best nickel alloys to use in these environments are those containing a minimum of 42% Ni (to resist chlorides), high chromium, and at least 3% Mo, Alloys 825, 925, 2550, 28, G-3, and C-276 are good examples. These are normally furnished for production tubing with minimum yield strengths of 758 or 862 MPa (110 or 125 ksi). Yield strengths up to 1030 MPa (150 ksi) minimum have been used. These strengths are obtained through cold work.

Similar strengths are required for tools and components. These can be much larger in cross section and therefore cannot be cold worked to derive strength. In these cases, precipitation-hardenable alloys are used. The same basic guidelines for composition--high nickel, high chromium, and at least 3% Mo--hold true for these components. The best alloy for use in each environment is usually determined by corrosion testing in that environment. The NACE specification MR-01-75 includes a list of alloys that have passed their initial corrosion screening tests. A list is also provided of the maximum hardness that an alloy can have and still resist sulfide stress cracking. More information on corrosion in the oil patch is available in the article "Corrosion in Petroleum Production Operations" in this Volume.

Applications in Fused Salts

Most applications for nickel alloys in fused salts occur in the heat treating of metals with salt baths. Common heat-treating applications and temperature ranges are:

- *Cyaniding:* 760 to 870 °C (1400 to 1600 °F)
- *Austempering:* 205 to 595 °C (400 to 1100 °F)
- *Martempering:* 205 to 370 °C (400 to 700 °F)
- *Tempering:* 165 to 760 °C (325 to 1400 °F)
- *Heat Treating of tool steels, stainless steels, aluminum, and copper alloys:* 205 to 1095 °C (400 to 2000 °F)

At temperatures in the range of 205 to 815 °C (400 to 1500 °F), cyanides, nitrates, and nitrites are employed. As the temperature requirements increase beyond 705 °C (1300 °F), various chloride mixtures of sodium, potassium, and barium are utilized. It is the higher-temperature chloride mixtures that high-nickel alloys find significant applications. Increasing the temperatures and basic oxide contents normally increase corrosion rates.

Alloy 600 has proved to be one of the most resistant alloys to high-temperature chloride salt attack. Alloys 601, 617, 690, RA330, 800, and 825 also provide useful resistance.

Heating and Heat-Treating Applications

Cast and wrought nickel-iron-chromium and nickel-chromium alloys are commonly used for heating and heat treating. To be useful in these applications, an alloy must possess a high degree of environmental resistance, thermal fatigue resistance, high-temperature strength and stability, and, in most uses, good workability and weldability.

In heating and heat treating, the alloys of construction may encounter oxidation, sulfidation, carburization, nitridation, carbonitridation, and molten salt corrosion. Alloy selection will depend, in part, on which of these high-temperature corrosion environments are encountered in given service. Resistance to high-temperature oxidation is generally an essential criteria for alloy selection because most heating elements, furnace muffles, retorts, and radiant tubes are exposed to air on at least one side.

Those alloys that develop tight adherent oxide films, such as alloys 601, 617, and 214, generally provide the best long service life, particularly under cyclic temperature conditions. In intermediate-temperature environments that are alternately oxidizing and carburizing, the nickel-iron-chromium alloys are used. In carburizing and carbonitriding applications, nickel-iron-chromium and nickel-chromium alloys have all proved their resistance over the years in many types of service. Alloy 600 has shown exceptional resistance to both carburization and nitridation. The higher iron versions of the nickel-iron-chromium alloys offer the best sulfidation resistance.

The nickel-iron-chromium and the nickel-chromium alloys, such as RA330, 800, 601, 617, and X, have good overall high-temperature strength and microstructural phase stability. These alloys can be readily fabricated with sound welds by using weld metals specifically developed for them. These alloys can also be repair welded by a variety of joining processes.

These alloys have been used for years to manufacture heating elements, recuperators, retorts, radiant tubes, belts, baskets, and other furnace hardware. Heating and heat-treating operations include annealing, quenching and tempering, carburizing, carbonitriding, nitriding, powder metallurgy sintering, brazing, and enameling. More information on materials for and corrosion of heating and heat treating equipment is available in the article "Corrosion of Metal Processing Equipment" in this Volume.

Petrochemical and Refining Applications

The petrochemical and refining industries are defined as those involved in the production of basic organic chemicals and fuels from petroleum-base feedstocks. Examples include fuels and lubricants, ethylene and ethylene derivatives, steam hydrocarbon reforming, NH_3, methanol, and the many organic chemicals. In general, most petrochemical and refining applications are endothermic, requiring temperatures from 425 to 1000 °C (800 to 1830 °F) and higher. Typical environmental conditions include oxidizing, carburizing, nitriding, sulfidizing, and halogen gases (chlorine, hydrogen chloride, fluorine, and so on). Materials used in these applications must exhibit corrosion resistance, metallurgical stability, and strength in these high-temperature environments.

Alloys 800H and 800HT are the standard materials for intermediate temperatures (620 to 925 °C, or 1150 to 1700 °F). These alloys combine corrosion resistance with strength and metallurgical stability (Fig. 16). Major applications include hydrogen reformer manifolds and pigtail piping, ethylene dichloride furnace tubing, transfer piping, and high-temperature pressure vessels.

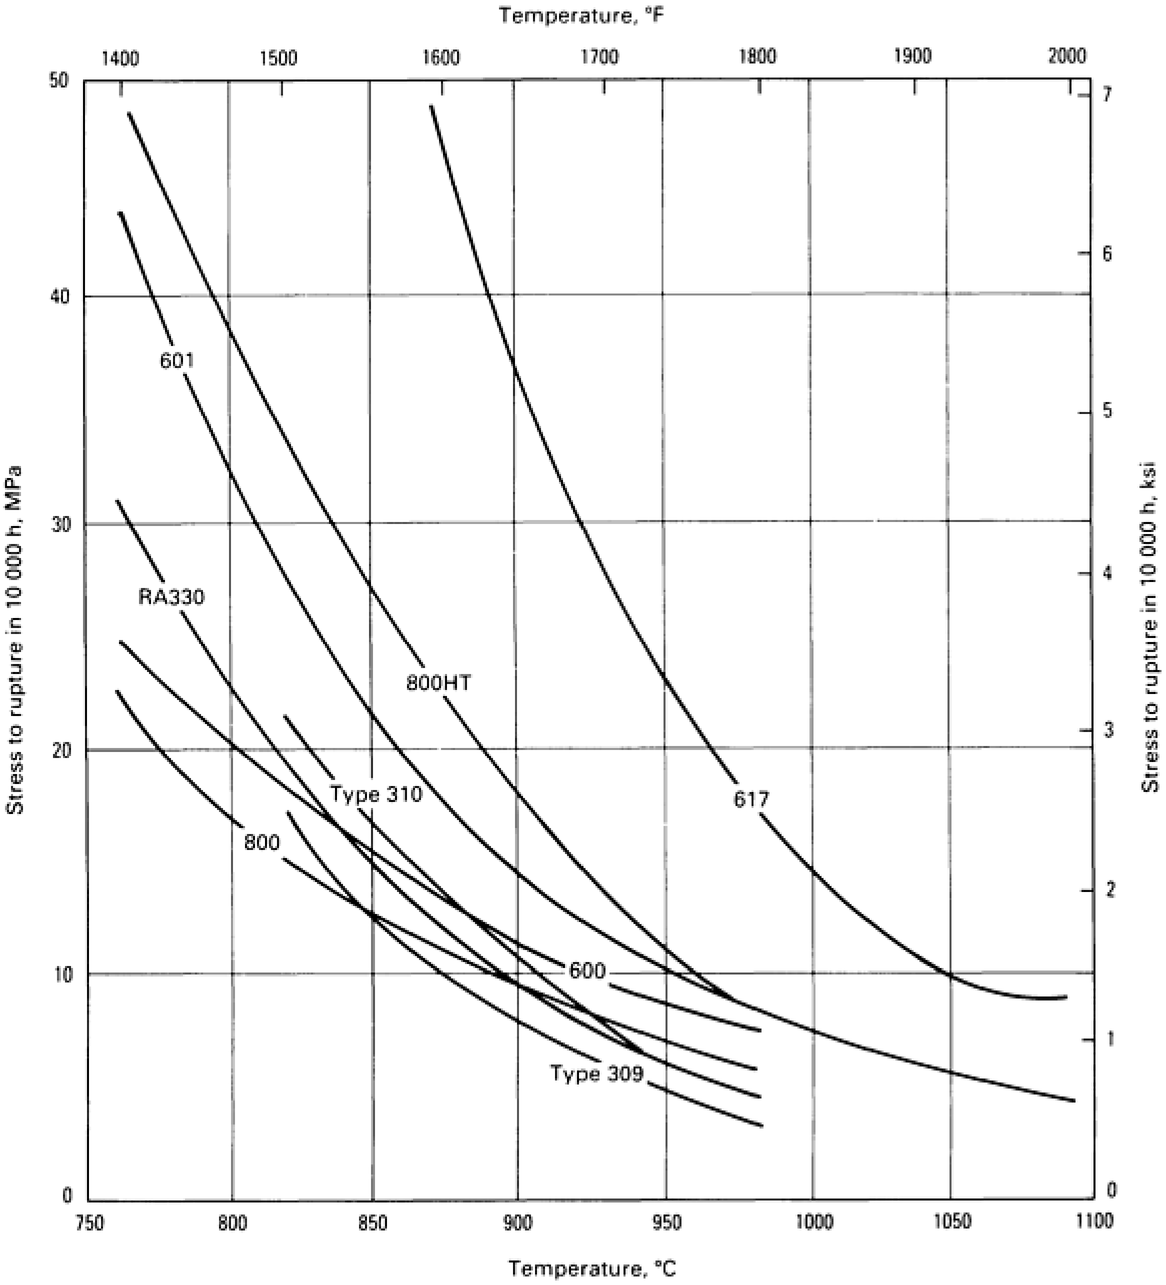

Fig. 16 High-temperature stress rupture data for various nickel-base and stainless alloys. Test duration was up to 10,000 h. Data are from manufacturers' published data.

As the environments become more aggressive and high-temperature strength requirements more demanding, alloys 600, 601, 617, 625, and X are utilized. High-temperature halogenations require alloys 600 and 625, while high-temperature oxygen requires alloy 601. Aggressive carburizing and nitriding environments utilize alloys 600 and 617. Expansion joints for high-temperature applications require alloys with good fatigue resistance such as alloys 617 or 625. More information on corrosion of petroleum refining equipment is available in the article "Corrosion in Petroleum Refining and Petrochemical Operations" in this Volume.

Nuclear Fuel Cycle Applications

Nickel 200 and 201 can be found in gaseous diffusion enrichment equipment because of their excellent corrosion resistance to HF-UF_x. For similar corrosion resistance reasons, Nickel 200 and 201 and alloys 400 and 600 are used in nuclear fuel reprocessing fluorination and hydrofluorination reactors.

The nickel-chromium-iron alloys are very popular materials for critical applications in pressurized and boiling water reactors because of their excellent corrosion resistance in steam and water environments and because of their resistance to chloride SCC. The age-hardenable alloy X-750 is used as a spring material for fuel pellet hold down springs, fuel element divider plates, and reactor scram springs, and for bolting. Another age-hardenable alloy, alloy 718, because of its high strength and spring characteristics, is also used for fuel assembly divider plates. It also has demonstrated excellent wear resistance in sodium fast breeder reactor environments. The single most significant application of nickel-base alloys in the nuclear industry has been the use of alloy 600 for steam generator tubing in pressurized water reactors. An alternate material for this application is alloy 690. Because of its high chromium content, alloy 690 has provided acceptable corrosion resistance to molten glass in nuclear fuel waste vitrification furnaces.

Alloy 825, because of its resistance to H_2SO_4 corrosion, and alloys 625 and C-276, because of their corrosion resistance to chloride- contaminated H_2SO_4, have been shown to be excellent materials of construction for radioactive waste disposal evaporators. Detailed information on corrosion in these types of applications is available in the article "Corrosion in the Nuclear Power Industry" in this Volume.

Corrosion of Cobalt-Base Alloys

Chairman: Aziz I. Asphahani, Haynes International, Inc.

Introduction

Paul Crook, Haynes International, Inc.

MANY OF THE COMMERCIAL cobalt alloys that are current in use stem from the work of Elwood Haynes at the turn of the century. He discovered the high strength and stainless nature of the binary cobalt-chromium alloy, and he later identified tungsten and molybdenum as powerful strengthening agents within the cobalt-chromium system. When the discovered these alloys, Haynes suggested that they might be used for cutting tools, cutlery, and surgical instruments. He named them the Stellite alloys because of their permanent, starlike luster (the Latin for star is *stella*).

Because of their high strength over a wide temperature range and their resistance to many environments, cobalt-chromium alloys have found two major uses within industry. First, they are used to resist wear, particularly in hostile environments, and second, they are used as structural materials at high temperatures. Typically, the alloys used to resist wear contain higher carbon levels (0.25 to 2.5%) for carbide formation, and they are normally cast or applied to critical surfaces by welding (a process known as hardfacing). Alloys used for structural purposes at high temperatures are normally low in carbon, contain appreciable quantities of nickel, and are available as wrought products. The carbides in the wear-resistant alloys enhance abrasion resistance but reduce ductility.

Physical Metallurgy

Table 1 gives the compositions of commercial cobalt-base alloys. As can be deduced from Table 1, the chief difference among the individual Satellite hardfacing alloys is carbon content and thus carbide volume fraction in the material.

Table 1 Compositions of a variety of commercial cobalt-base alloys

Compositions of cobalt-base alloys for orthopedic implants are given in Table 12.

(a) Maximum

Chromium has a dual function in the Satellite alloys. It is both the predominant carbide former (that is, most of the carbides are chromium rich) and the most important alloying element in the matrix, where it provides added strength (as a solute) and resistance to corrosion and oxidation. The most common carbide in the Satellite alloys is a chromium-rich M_7C_3 type, although chromium-rich $M_{23}C_6$ carbides are abundant in low-carbon alloys such as Satellite alloy 21.

Tungsten and molybdenum in the Satellite alloys serve to provide additional strength to the matrix. They do so by virtue of their large atomic size (that is, they impede dislocation flow when present as solute atoms). When present in large quantities (for example, in Satellite alloy 1), they participate in the formation of carbides during alloy solidification and promote the precipitation of M_6C. They also improve general corrosion resistance of the alloys. Although these alloying elements are critical to the performance of the Satellite alloys in service, the main reason for the commercial success of the Satellite alloys is the cobalt.

Cobalt imparts to its alloys an unstable, face-centered cubic crystal (fcc) structure with a very low stacking fault energy. The instability arises from the fact that elemental cobalt, if cooled extremely slowly, transforms from an fcc to hexagonal close-packed (hcp) crystal structure at 417 °C (782.6 °F). In most cobalt alloys, the transformation temperature is somewhat higher.

Because of the sluggish nature of the transformation, the fcc structure in cobalt and its alloys is usually retained to room temperature, and hcp formation is triggered only by mechanical stress or time at elevated temperature. The unstable fcc structure, as well as its associated low stacking fault energy, are believed to result in:

- High yield strengths

- High work-hardening rates (due to the interaction between stacking faults)
- Limited fatigue damage under cyclic stresses (due to the lack of cell walls within plastically deformed material)
- The ability to absorb stresses (through transformation of the structure to hcp)

The first three of these attributes are believed to be important in preventing metallic damage during sliding wear. The last two are believed to be responsible for the outstanding resistance to cavitation and erosion-corrosion of the cobalt alloys.

The size and shape of the carbide particles within the Satellite alloys are strongly influenced by cooling rate and subtle chemistry changes. This is illustrated in Fig. 1 and 2, which show typical overlay microstructures as applied by different welding processes. Such changes markedly affect abrasion resistance, because there is a distinct relationship among the size of abrading species, the size of the structural hard particles, and the abrasive wear rate.

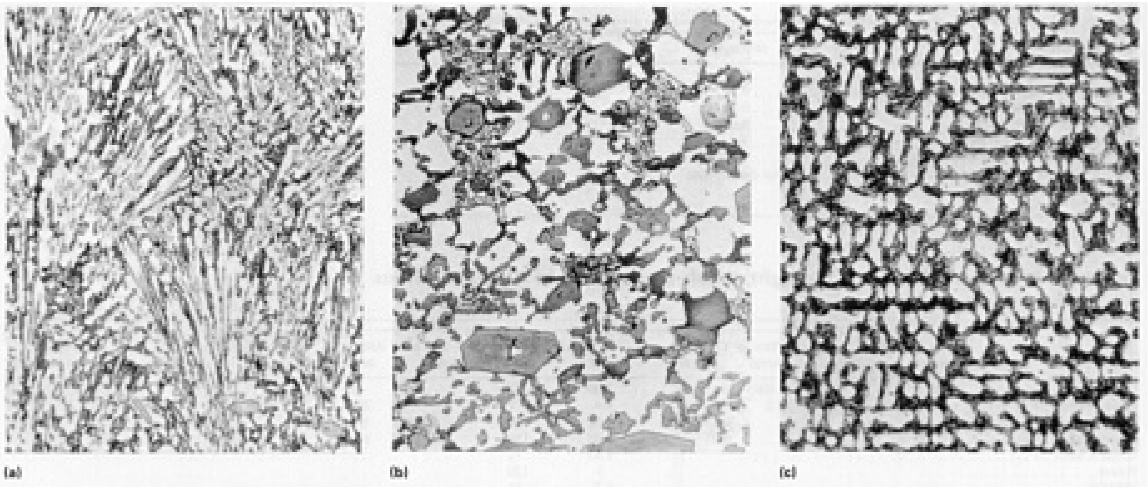

Fig. 1 Typical overlay microstructures of Stellite 1 alloy applied by different weld processes. (a) Three-layer gas tungsten arc. (b) Three-layer oxyacetylene. (c) Three-layer shielded metal arc. See also Fig. 2. All 500×

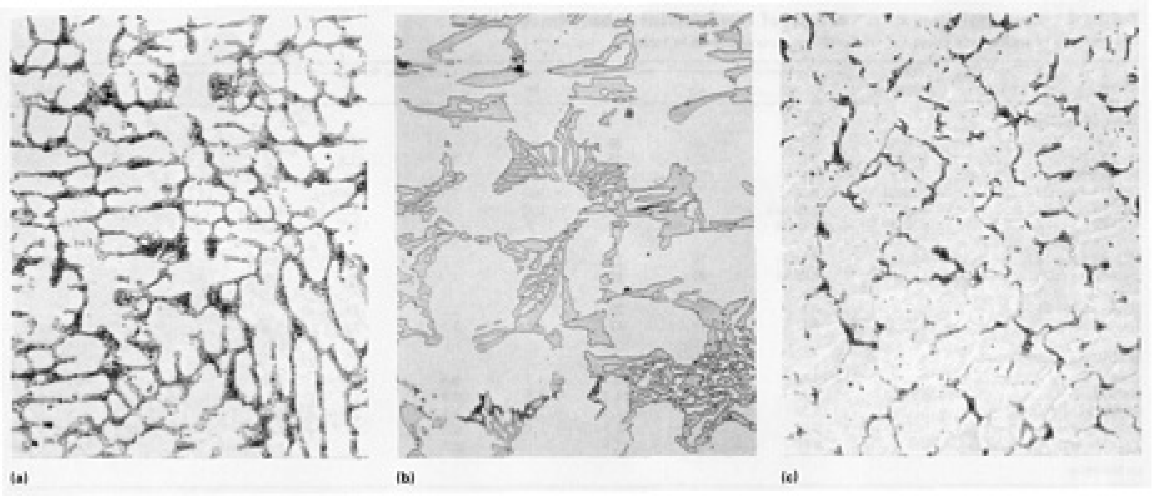

Fig. 2 Typical overlay microstructures of Stellite 6 alloy applied by different weld processes. (a) Three-layer gas tungsten arc. (b) Three-layer oxyacetylene. (c) Three-layer shielded metal arc. See also Fig. 1. All 500×

The success of the structural cobalt alloys can be attributed to both their inherent strength (over a wide temperature range) and their resistance to the environment. Their strength stems largely from the unusual microstructural properties of cobalt

and from the strengthening solutes, such as chromium and tungsten. Their corrosion properties will be discussed in subsequent sections of this article.

The structural alloys generally contain significant quantities of nickel. This serves to stabilize the fcc structure with a view toward improved ductility during service. With sufficient nickel, the structural cobalt alloys tend to exhibit twinning during deformation.

Although the structural cobalt alloys are low in carbon as compared to most of the wear-resistant alloys, they nevertheless depend on carbide precipitation for additional strength. The most abundant carbide in the structural cobalt alloys is chromium-rich $M_{23}C_6$, although M_6 and MC carbides are common, depending on the type and level of other alloying additions, such as tungsten and tantalum. Table 1 lists the compositions of several structural cobalt alloys.

Behavior of Cobalt-Base Alloys in Corrosive Environments

Narasi Sridhar, Haynes International, Inc.

A variety of cobalt-containing alloys, ranging in cobalt content from 19 to 60% will be discussed in this section (see Table 1). Because the corrosion properties of these alloys have thus far not been examined systematically with respect to such variables as alloying elements, the aim in this discussion is to describe the corrosion resistance of commercially available cobalt-base alloys in various environments. Stress-corrosion interactions will not be considered. This section will also exclude hardfacing alloys, which are discussed in the section "Fabrication and Weldability of Cobalt-Base Alloys" in this article.

General Corrosion

The corrosion behavior of pure cobalt has not been documented as extensively as that of nickel. The behavior of cobalt is similar to that of nickel, although cobalt possesses lower overall corrosion resistance (Ref 1). For example, the passive behavior of cobalt in 1 *N* sulfuric acid (H_2SO_4) has been shown to be similar to that of nickel, but the critical current density necessary to achieve passivity is 14 times higher for the former (Ref 2). Several investigations have been carried out on binary cobalt-chromium alloys. In cobalt-base alloys, it has been found that as little as 10% Cr is sufficient to reduce the anodic current density necessary for passivation from 500 to 1 mA/cm^2 (3225 to 6.5 mA/in.^{2}) (Ref 2). For nickel, about 14% Cr is needed to reduce the passivating anodic current density to the same level. The corrosion rates of a variety of cobalt-chromium alloys in several oxidizing and reducing media are shown in Table 2. In another study, researchers measured the open-circuit potentials in a dilute salt solution (Ringers solution) of a number of cast binary cobalt-chromium alloys having 10 to 40% Cr (Ref 4). They found that the behavior of the alloy was controlled not only by chromium content but also by microstructural changes produced by the addition of chromium to cobalt. Addition of up to 25% Cr made the alloys more noble. However, above 25% Cr, precipitation of chromium-rich σ phase made the alloys more active because of local chromium depletion around the σ-phase precipitates. Unfortunately, they did not measure corrosion rates of these alloys.

Table 2 Corrosion of cobalt- and nickel-base alloys in aqueous solutions

Alloy	Solution and temperature	Corrosion rate		Ref
		mm/yr	**mils/yr**	
Cobalt	1 *N* HNO_3, 25 °C (75 °F)	223	8900	2
Nickel	1 *N* HNO_3, 25 °C (75 °F)	19	770	2
Ni-20Cr	11% HNO_3, hot	nil		3
Co-20Cr	11% HNO_3, boiling	nil		3
Co-20Cr	11% H_2SO_4, boiling	110	4400	3

Another study examined the effect of alloying elements in cobalt-base alloys in H_2SO_4 and phosphoric acid (H_3PO_4) (Ref 5). These alloys contained 2% C for abrasive wear resistance. The data are given in Table 3. It can be seen that addition of nickel and copper lowered the corrosion rates significantly. Addition of molybdenum or nickel plus molybdenum did not have a great effect, possibly because of intermetallic precipitation. These researchers also conducted tests in an H_3PO_4 solution under abrasive conditions and found molybdenum, nickel, and copper to be highly beneficial (Ref 5).

Table 3 Effect of alloying additions on the corrosion of cobalt-base alloys in acid media

Data obtained in 192-h tests at 25 °C (75 °F)

Alloy composition	Weight loss, mg/cm^2	
	10% H_2SO_4	**28% P_2O_5 + 13% H_2SO_4 + 2% HF**
Co-2.1C-31Cr-12W	0.03	0.09
Co-2.1C-32Cr-12.5W-19.5Ni	0.02	0.03
Co-2.2C-32Cr-18.8Ni-14W	0.04	0.06
Co-2.3C-32Cr-14W-9.4Mo	0.06	0.06
Co-2.1C-32Cr-17.6Ni-13W	nil	nil
Co-2.2C-31Cr-18Ni-15W-9Mo-4Cu	1.8	1.0

Source: Ref 5

The corrosion resistance of a number of commercial cobalt-base alloys in H_2SO_4 and hydrochloric acid (HCl) is given in Tables 4 and 5. It should be noted that all of these alloys, regardless of their chromium and molybdenum contents, exhibit similar corrosion resistance in dilute H_2SO_4 (Table 4). Thus, the high-chromium Haynes alloys 6B and 21 show approximately the same corrosion rates as the lower-chromium Haynes alloys 188 and 556. Similar behavior has been observed in the nickel-iron-chromium-molybdenum alloys (Ref 6). In H_2SO_4 and HCl, the nickel and cobalt contents govern the behavior of the alloy as long as minimum amounts of chromium and molybdenum or tungsten are present. The corrosion resistance of wrought cobalt-base alloys in HCl solutions is given in Table 5. Again, as with the nickel-iron-chromium-molybdenum alloys, the corrosion resistance of cobalt-base alloys is not good except in very dilute HCl.

Table 4 Corrosion of various wrought cobalt-base alloys in H_2SO_4 solutions

Tests were conducted in four 24-h periods.

Alloy	Corrosion rate

Because many of the commercial alloys contain appreciable amounts of chromium, their corrosion resistance of dilute nitric acid (HNO_3) is quite good (Table 6). However, in concentrated HNO_3, Haynes alloy 6B exhibited high corrosion rates, while Haynes alloys 188 and 25, which have lower chromium, showed lower corrosion rates. This could have been a consequence of the high carbon content of alloy 6B. High carbon and chromium are present intentionally in this alloy to provide chromium carbides for abrasion resistance. However, concentrated HNO_3 is known to attack high-chromium phases such as σ phase and chromium-rich carbides.

(b) Five 24-h test periods.

The corrosion resistance of some cobalt-base alloys in a variety of reducing and oxidizing environments is given in Table 7. In highly oxidizing chromic acid (H_2CrO_4), the chromium-containing alloys, whether cobalt- or nickel-base, do not show good resistance, because the passive chromium oxide film is unstable in this acid. However, high amounts of tungsten seem to decrease the corrosion rates of Haynes alloys 188 and 25. In H_3PO_4, the corrosion rates of the cobalt-base alloys are very high. Although there are no compositionally equivalent nickel-base alloys, the corrosion rates of many of the commercial nickel-chromium-molybdenum-iron alloys in H_3PO_4 are lower (Ref 7). In acetic acid, the corrosion rates of all of the alloys are quite low. Nickel is widely used in caustic service. The nickel-chromium-molybdenum alloys offer lower corrosion resistance than nickel. In comparison, the cobalt-base alloys do not offer very high resistance to corrosion in caustic environments. Indeed, the data in Table 7 seem to indicate that the corrosion rates of the three cobalt-base alloys tested in caustic decreased with increasing nickel content (alloy 6B < 25 < 188).

Addition of oxidizing agents to H_2SO_4 results in lower corrosion rates for the cobalt-chromium-molybdenum-tungsten alloys, just as in the case of the nickel-base alloys. This is shown in Table 8 for the 50% H_2SO_4 + 2.5% ferric sulfate ($Fe_2(SO_4)_3$) mixture recommended by the American Society For Testing and Materials (ASTM) as an intergranular corrosion test solution.

Table 8 Corrosion of cobalt-base alloys in a boiling oxidizing mixture of 50% $H_2SO_4$and 2.5% $Fe_2(SO_4)_3$

Localized Corrosion

The resistance to localized corrosion (pitting and crevice corrosion) of the cobalt-base alloys is generally determined by the chromium, molybdenum, and tungsten contents. Generally, localized corrosion resistance is measured by immersion tests in oxidizing chloride solutions or by electrochemical tests in chloride solutions. Crevice corrosion resistance is usually measured by attaching blocks to the sample in order to create a crevice between the sample and the block. The test methods are outlined in Ref 7, 8, 9, 10.

An example of the localized corrosion resistance of several cobalt-base alloys in an oxidizing chloride-containing test solution is given in Table 9. This is an extremely acidic chloride solution containing ferric and cupric salts to increase the oxidizing potential of the solution. As the results indicate, there is a wide variation in alloy performance. Havar alloy and Haynes alloy 556 start to corrode at a rapid rate at about 70 °C (160 °F). Alloys MP35N, 188, and 21 begin to corrode rapidly near the boiling point of the solution. Alloy 25 exhibits the highest resistance of these cobalt-base alloys. Alloy 6B is not listed in Table 9, because it exhibits a high corrosion rate even in less severe solutions, such as 10% ferric chloride ($FeCl_3$). The corrosion rates of the alloys tested are given in Table 9. In the 20 to 22% Cr alloys, the alloys containing the lowest molybdenum and tungsten (alloys Havar and 556) show the highest corrosion rates. The alloy with the intermediate molybdenum level (alloy MP35N) shows lower corrosion rates, while the alloys with high tungsten (alloy 25) and high chromium plus molybdenum (alloy 21) show even lower rates. The exception to this case is alloy 188, which shows higher corrosion rates than alloy 25 in spite of similarity in composition. Unfortunately, no data are available at intermediate temperatures, so a more accurate comparison of alloys cannot be made.

Table 9 Results of pitting corrosion tests in an aqueous mixture of 11.5% H_2SO_4 + 1.2% HCl + 1% $CuCl_2$ + 1% $FeCl_3$ at various temperatures

Test duration: 24 h

Alloy	Corrosion rate, mm/yr (mils/yr)		
	Room	**70 °C (160 °F)**	**Boiling**
Havar	nil	15 (600)	5.6 (2200)
MP35N	nil	nil-0.015 (0.6)	0.076-50 (3-2000)
Haynes alloy 21	nil	nil	0.76 (30)
Haynes alloy 188	nil-0.01 (0.4)	0.005-0.2 (0.2-8)	2.5-24.1 (100-950)
Haynes alloy 25	0.0076-0.025 (0.3-1.0)	nil-0.01 (0.4)	nil-0.05 (2)

Results of corrosion tests conducted in a milder localized test environment of $FeCl_3$ are given in Table 10. Again, the trend is similar to that shown in Table 9 in that Haynes alloys 188 and 25 are superior in pitting resistance to Haynes alloy 556. In summary, it is believed that the effects of alloying elements (chromium, molybdenum, and tungsten) on pitting resistance are qualitatively similar in cobalt-base alloys to those observed in nickel-base alloys. Their effects in cobalt-base alloys cannot be predicted precisely, however, because of the lack of extensive data.

Environmental Embrittlement of Cobalt-Base Alloys

Juri Kolts, Conoco Inc.

Cobalt-base alloys are primarily used in high-temperature applications. In such uses, hydrogen embrittlement and stress-corrosion cracking (SCC) are generally not thought to be important. However, in applications in which cobalt-base alloys are used for aqueous corrosion service, both of these modes of fracture may become important.

Hydrogen Embrittlement

Cobalt-base alloys can be used to combat hydrogen embrittlement where steels have failed by this mechanism. The literature on the hydrogen embrittlement of cobalt-base alloys is not very extensive. Most of the experimental work has been performed on Haynes alloys 188 and 25 and on alloy MP35N. The performance of these alloys is in many ways similar to that of many nickel-base alloys (Ref 11, 12).

Effects of Strength Level. The cobalt-base alloys can be processed to achieve much higher yield/tensile strengths than most of the nickel-base alloys. Susceptibility to hydrogen embrittlement is closely related to yield strength; therefore, the potential for hydrogen embrittlement in cobalt-base alloys may be higher than in nickel-base alloys, not because of a higher inherent susceptibility to embrittlement, but because of the higher strength levels achievable in cobalt-base alloys.

Annealed cobalt-base alloys do not show significant susceptibility to hydrogen embrittlement, even in the most severe hydrogen-charging conditions. When cold worked to levels exceeding 1380 MPa (200 ksi) yield strength, the cobalt-base alloys may not exhibit embrittlement (Ref 13). Two factors--impressed hydrogen charging and low-temperature aging (as is the case for nickel-base alloys)--are often required to produce hydrogen embrittlement.

External Hydrogen Charging. Because of the high corrosion resistance of many cobalt-base alloys, the alloys may not corrode at a sufficient rate even in acid systems to charge hydrogen into the alloys. Hydrogen charging will often be achieved through the cathodic protection systems used to protect other components in a system or through the galvanic coupling of cobalt-base alloys to more actively corroding metals. Hydrogen entry may be enhanced by the presence of hydrogen recombination poisons, such as sulfides, cyanides, or other substances commonly found to be effective hydrogen recombination poisons on steels. Under such conditions, cobalt-base alloys with yield strengths over 1380 MPa (200 ksi), and especially greater than 1724 MPa (250 ksi), can exhibit hydrogen embrittlement. The time to failure (usually by an intergranular mode) is strongly dependent on the charging current (Ref 14).

Effect of Thermal Treatments. The aging of cobalt alloys has two opposite effects on hydrogen embrittlement, depending on the temperature range. At temperatures ranging from 205 to about 650 °C (400 to 1200 °F), aging is highly detrimental to hydrogen embrittlement resistance (Ref 15, 16). Aging above about 760 °C (1400 °F) is highly beneficial (Ref 17). The most susceptible microstructures are produced by a combination of cold work and aging near 540 to 650 °C (1000 to 1200 °F). Aging at temperatures above 790 °C (1450 °F) produces microstructures that are extremely resistant to embrittlement.

Long-term aging treatments that take place for periods of years at temperatures as low as 205 °C (400 °F) may have a noticeable detrimental effect (Ref 18, 19). Very high strength levels and hydrogen charging are both required to produce this effect.

Effect of Other Factors. Anisotropy in mechanical properties may play an important role in hydrogen embrittlement (Ref 16). Crack path sensitivity is greater in directions transverse to the direction of mechanical working. Other factors, such as stress level, environmental temperature, and environment corrosivity, have effects similar to those seen in steels and nickel-base alloys (see the articles "Environmentally Induced Cracking," "Corrosion of Alloy Steels," and "Corrosion of Nickel-Base Alloys" in this Volume).

Stress-Corrosion Cracking

Only a limited number of environments have been reported to cause SCC of cobalt-base alloys. These include two general classes of environments: acid chlorides and strong alkalies. Both of these environments produce SCC only at temperatures exceeding about 150 to 175 °C (300 to 350 °F) (Ref 20), although useful lives can be expected even above 205 °C (400 °F) (Ref 21). The fracture mode in sodium hydroxide (NaOH) was intergranular on Stellite alloy 6B (Ref 22). In acid chlorides containing hydrogen sulfide (H_2S), the SCC of Haynes alloy 188 was intergranular; cracking of alloy MP35N was reported to be transgranular (Ref 20).

Minor surface SCC has been reported for MP35N in hypersaline geothermal brine at 200 to 230 °C (390 to 445 °F) (Ref 23). In some conditions, cobalt-base alloys have been shown to be susceptible to SCC in boiling magnesium chloride

($MgCl_2$) at 155 °C (310 °F) (Ref 24), although other alloys are resistant at this temperature (Ref 25). No data have been obtained for $MgCl_2$ solutions at higher temperatures.

The SCC behavior discussed above is similar to that found for nickel-base alloys where much more data are available. In view of these similarities, the article "Corrosion of Nickel-Base Alloys" in this Volume may provide further insight into the possible environments in which precautions must be taken or additional data developed for cobalt-base alloy applications.

Fabrication and Weldability of Cobalt-Base Alloys

S.J. Matthews, Haynes International, Inc.

The weldability of wrought cobalt-base alloys, especially those with greater than 10% Ni, is very similar to the weldability of nickel-base alloys (see the article "Corrosion of Nickel-Base Alloys" in this Volume). Conventional fusion-welding processes can be used, although oxyacetylene welding is not recommended for low-carbon cobalt-base alloys. Gas tungsten arc welding generally produces the most satisfactory results.

Sound welds are readily obtained with good joining practices. Joint preparations and cleaning before welding are the most important joining practices. For low-carbon cobalt-base alloys (<0.15% C), preheat is not required, and weld interpass temperatures should be below 95 °C (200 °F).

Cobalt alloys are highly susceptible to weld cracking at high temperatures when they are contaminated with copper. Molten copper will initiate liquid-metal embrittlement in the heat-affected zone (Ref 26). For example, a minute amount of copper that is inadvertently transferred onto the surface of a sheet from a backing bar can cause severe cracking if the copper melts during welding. This may be prevented by plating the copper backing with nickel or chromium to prevent accidental copper transfer. Copper or brass wire brushes can also contaminate the metal and should not be used for cleaning.

Hardfacing and Wear

A sizeable amount of cobalt alloy used for corrosion environments is in the form of hardfacing deposits, for which the primary need is wear protection as well as corrosion resistance. Hardfacing is a term that describes the application of a material to the surface of a component by welding for the main purpose of reducing wear. The article "Hardfacing, Weld Cladding, and Dissimilar Metal Joining" in Volume 6 of *ASM Handbook,* formerly 9th Edition *Metals Handbook,*contains detailed information on hardfacing materials and processes. Wear can be defined as the loss of material by abrasion, sliding wear, or erosion (solid particle/liquid droplet/cavitation).

Abrasion accounts for the largest share of industrial wear problems. It occurs when hard particles are forced against and move along a solid surface. The basic mechanisms of abrasion include cutting, plowing, and chipping. The predominant mechanism will depend on the size, shape, and hardness of the abrasive relative to the hardness of the wearing surface. Cobalt hardfacing alloys designed to resist abrasion generally contain large amounts of chromium carbide. Their abrasion resistance depends on the volume fraction, size, and morphology of the carbide structure. As a general rule, the higher the abrasion resistance of a cobalt-base hardfacing alloy, the lower its corrosion resistance.

Sliding wear (also called metal-to-metal wear) occurs when two contacting metal surfaces slide under load. At a low contact load, it is common to encounter a mild, oxidative wear mode (controlled by surface films and generating oxide wear debris). A more severe wear that generates metallic wear debris is encountered at higher contact loads, that is, galling. Unlike abrasion, hard phases play only a secondary role in controlling the galling resistance of an alloy. The factors that contribute to the sliding wear resistance of an alloy are largely determined by matrix composition and deformation characteristics. Cobalt-base hardfacing alloys have an industry accepted reputation for outstanding resistance to sliding wear and galling.

Erosion is another form of surface degradation. It differs from the previous modes of wear in that the energy required to cause damage originates from momentum transfer rather than large-scale traction forces. Solid-particle erosion results from the impingement of gas-borne hard particles onto a solid surface. Liquid droplet erosion occurs when high-speed liquid drops strike a solid surface. Cavitation erosion occurs when gas bubbles (formed by high fluid flow rates or rapid pressure drops) in a liquid collapse on a solid surface, striking it with minute liquid jets.

Like abrasion, solid-particle erosion mechanisms include cutting and plowing. The mechanisms of liquid droplet erosion and cavitation erosion are primarily fatigue and fracture. Because some mechanisms of solid-particle erosion are similar to abrasion, cobalt alloys with high volume fractions of hard phases are also effective in resisting solid-particle erosion. However, alloys that can withstand large plastic strains without fracturing are also useful under some service conditions. The alloy characteristics that provide resistance to liquid droplet and cavitation erosion are more difficult to define, although the ability to accommodate strain through slip or transformation, combined with good fatigue resistance, appears to be important. It is generally recognized that cobalt-base wear alloys, specifically in wrought form, have excellent liquid droplet and cavitation erosion resistance.

Hardfacing Welding Processes

With regard to the subject of hardfacing, it should be noted that the operation involves the deposition of an overlay, usually by welding or allied process (that is, thermal spray). A wide variety of welding and thermal spray processes are available. Table 11 lists the commonly used processes, along with their advantages and disadvantages. Part size and shape, accessibility considerations, base material composition, dilution requirements, area to be surfaced, and the number of parts to be hardfaced usually influence process selection. Cobalt-base alloys are available in a wide variety of different product forms for depositing hardfacing overlays (bare cast rod, coated electrodes, tubular wires, solid wires, and powder).

Table 11 Advantages and disadvantages of commonly used hardfacing processes and consumables

Process	Consumables[(a)]	Advantage	Disadvantage
Gas tungsten arc	CR	High-quality deposits	Relatively slow process
Shielded metal arc (coated electrode)	CR, TW	Portability (field repair)	Slag removal and low deposit efficiency
Open arc	TW	High deposition rate	Spatter and rough deposits
Submerged arc	TW	High deposition rate and efficiency	High base metal dilution
Gas metal arc	TW	Good quality and good deposition rate	Relatively high dilution
Oxyacetylene	CR, TW, P	Low dilution	Slow process
Plasma arc	CR, TW, P	Very smooth high-quality deposits	Some overspray (powder loss) with plasma-transferred arc process
Flame spray	P	Very smooth deposit (after fusing)	Maximum thickness of 3.2 mm ($\frac{1}{8}$ in.)
Plasma spray	P	No dilution, no distortion	Only thin coatings, not 100% dense
Jet Kote II surfacing system	P	High-quality, dense coatings	Higher gas consumption than flame spray
Laser	P	High volume production	Very expensive equipment

capability

(a) CR, cast rod; TW, tube wire; P, powder

Most welding processes are readily adaptable to hardfacing if proper techniques are implemented to prevent stress cracking and to minimize base metal dilution. Stress cracking generally occurs as a result of thermally induced stresses. The occurrence of thermally induced stress can be minimized by the liberal use of preheat, high interpass temperature, and very slow cooling. The hardfacing of transformation-hardenable steels, such as type 410 stainless steel, can compound the stress operating on the hardfacing deposit during cooling and can require special precautions to minimize cracking. Specifically, preheat and interpass temperatures should be maintained above the M_s temperature (temperature at which austenite begins to transform to martensite) of the steel. Depending on the size and mass of the part, a postweld heat treatment immediately after hardfacing may also be required to minimize cracking.

Three welding processes that have been extensively used for hardfacing with cobalt-base alloys are oxyacetylene, gas tungsten arc, and plasma-transferred arc.

The oxyacetylene process is characterized by the lowest achievable base metal dilution (<5%); unfortunately, the process is relatively slow and time consuming, depositing only about 1 kg/h (2.2 lb/h) of hardfacing deposit. Furthermore, the low-carbon cobalt-chromium-molybdenum alloys such as Stellite alloy 21 intrinsically do not have good oxyacetylene weldability. Stellite alloy 6 can deposited by oxyacetylene. However, proper melting practice and chemistry control are required during the manufacture of the cast rod in order to produce consumables that do not generate porosity during oxyacetylene deposition.

Gas Tungsten Arc Welding. Oxyacetylene methods have given way in many cases to the gas tungsten arc processes, especially when hardfacing austenitic stainless steels, which will sensitize if exposed to a carburizing oxyacetylene flame. Because gas tungsten arc is a more intense heat source, more base metal dilution (∼20%) can be expected. However, overall dilution can usually be minimized by using two or more layers of hardfacing deposit. Hot cracking can be a potential problem in gas tungsten are hardfacing. Hot cracking may be caused by high levels of deleterious elements, such as sulfur. Attempts to hardface a free-machining steel, such as type 303 or 303Se, may result in hot cracking because the presence of harmful elements will be introduced to the deposit through base metal dilution.

The plasma-transferred arc process is characterized by the ideal combination of relatively low base metal dilution (∼10%) and a relatively high deposition rate (up to 5 kg/h, or 11 lb/h). In the plasma-transferred arc process, powder is used as the consumable, rather than a cast welding rod.

The plasma-transferred arc process in a mechanized rather than a manual process. It can be described as follows. A tungsten electrode, recessed into a torch body, generates a transferred arc to the workpiece. Plasma gas (usually argon) is ionized within the torch and exits through a constricted orifice. At this location, the hardfacing filler material is introduced in powder form through powder injection ports assisted by an argon carrier gas. The powder particles melt completely and resolidify as a fusion welded overlay. The weldability of cobalt-base alloy-powders for plasma-transferred arch hardfacing is very good, and they will usually produce clean, smooth, sound deposits.

Hardfacing by Thermal Spray

Hardfacing techniques that use welding as the method of deposition should always attempt to minimize base metal dilution for the obvious reason that excessive base metal dilution will compromise the metallurgical effectiveness of the hardfacing alloy. The deposition of cobalt-base alloys by thermal spray methods offers the advantage of no base metal dilution because most spray processes to do not melt the substrate material. Cobalt hardfacing alloys in powder form can be deposited by the conventional flame spray process. The flame spray process is usually followed by a second fusing operation with an oxyacetylene torch. For this reason, cobalt-base alloys intended for spray and fuse deposition are modified with intentional additions of boron to lower the melting point and to allow for good fusing.

Cobalt-base alloy hardfacing powders that are not modified with boron can be deposited by other thermal spray processes, but in these cases, higher-energy processes are used, such as plasma spray, detonation gun, or Jet Kote. All three of these processes are designed to achieve an extremely high velocity gas stream into which the hardfacing alloy powders are introduced. Powder particles pick up heat and kinetic energy from the high-velocity stream and are driven against the substrate surface; this produces an extremely dense coating. Coating densities, however, never achieve full theoretical density, and some degree of porosity is intrinsic to this type of hardfacing.

For maximum effectiveness in corrosion environments, thermal spray coatings are generally sealed with a suitable sealer, such as epoxy. More information on thermal spray materials and processes is available in the articles "Thermal Spray Coatings" in this Volume, "Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering" in *Powder Metal Technologies and Applications,* Volume 7, and "Thermal Spray Coatings" in *Surface Engineering,* Volume 5 of *ASM Handbook.*

Applications*

Phillip J. Andersen, Zimmer; Paul Crook, Haynes International, Inc.

Cobalt-base alloys are used in applications that require good corrosion and wear resistance. These alloys generally possess good high-temperature strength and therefore are used in such applications as jet engine turbines and gas turbine generators. The good wear resistance, fatigue strength, and biocompatibility of cobalt-base alloys have prompted their use as orthopedic implants. Cobalt-base alloys are also used in the nuclear power and chemical-processing industries. These latter three applications will be discussed in more detail in this article.

Note cited in this section

* The section on orthopedic implants was written by Phillip J. Andersen; the sections on nuclear and chemical-processing applications were written by Paul Crook.

Orthopedic Implants

Cobalt-base alloys are widely used for the fabrication of various devices that are surgically implanted in the body. These devices must be highly reliable. The failure of certain implants (for example, heart valves) can be fatal, and the failure of other implants can necessitate further surgery. The longevity of implants is therefore a critical requirement. The lifetime of a device is influenced by a variety of factors, including patient variables (weight, activity level, compliance with physician instructions), surgical technique, and device variables (design, materials, manufacturing practice).

Implant materials must meet exacting requirements if the device is to perform its function successfully for extended periods of time. These requirements include biocompatibility, mechanical strength, corrosion and wear resistance, and approval by various regulatory agencies. Only a few materials meet these requirements at this time. The vast majority of metallic implants are made from type 316L stainless steel (covered by ASTM F 138), cobalt-chromium-molybdenum alloys (ASTM F 75, F 799), MP35N (cobalt-nickel-chromium-molybdenum alloy) (ASTM F 562), unalloyed titanium, and Ti-6Al-4V (ASTM F 67 and F 136). More information on materials for orthopedic implants and corrosion in biomedical applications is available in the article "Corrosion of Metallic Implants and Prosthetic Devices" in this Volume.

The use of cobalt-base alloys as orthopedic implants dates back at least as far as 1924, when Stellite alloy was implanted in dogs by A.R. Zierold (Ref 27). C.S. Venable and W.G. Stuck implanted cobalt-chromium bone screws in animals in 1937 and observed positive results (Ref 28). Similar experimental results were observed in subsequent experiments. Dr. Smith-Petersen implanted "moulds" made from the cobalt-base alloy Vitallium in humans in 1938. These moulds were basically as shell that was placed over the femoral head to reduce pain and to increase mobility (Ref 29). Investment cast cobalt-base alloys were subsequently used for endoprostheses in 1950 (Ref 30). An endoprosthesis consists of a large ball that replaces the femoral head attached to a shaft that extends down into the intermedullary canal of the femur. Endoprostheses remain in wide use today.

More recently, total hip replacement has become common. In this surgery, a plastic socket is placed into the acetabulum, while a metallic hip stem consisting of a shaft and ball is placed in the femur. The shaft is often held in place by a poly

(methyl methacrylate) (PMMA) cement that acts like a grout between the bone and the stem. This ball and socket arrangement replaces a diseased joint to provide mobility and pain relief. These types of devices are shown in Fig. 3.

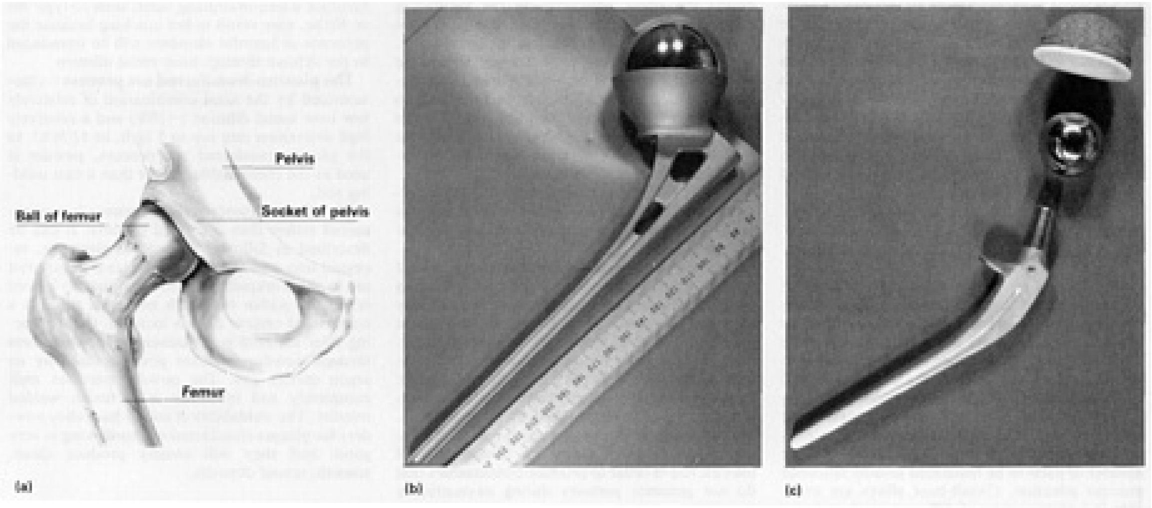

Fig. 3 The natural hip joint (a) and two types of artificial joints (b and c). The cast cobalt-chromium-molybdenum endoprosthesis (b) has a large diameter head that articulates in the acetabulum (the natural socket of the pelvis). The total hip replacement (c) replaces both the femoral head and the socket of the pelvis. The prosthesis shown in (c) uses a modular cobalt-chromium-molybdenum head that fits on a forged cobalt-chromium-molybdenum stem; the socket component is ultrahigh molecular weight polyethylene with a metal backing.

Cobalt-base alloys are also widely used in total knee replacements and, to a lesser extent, as implants that fix bone fractures, that is, bone screws, staples, and plates. The support structures for heart valves are also often fabricated from cobalt-base alloys. A variety of dental implants have also been produced from cobalt alloys (see the article "Tarnish and Corrosion of Dental Alloys" in this Volume).

Alloys Used

Most of the cobalt-base alloys currently in use as implants meet the requirements of ASTM F 75, F 799, or F 562. Standards F 75 and F 799 describe requirements for cobalt-chromium-molybdenum alloys, while F 562 describes requirements for a cobalt-chromium-nickel-molybdenum alloy. The compositions of these alloys are listed in Table 12.

Table 12 Compositions of cobalt-base alloys for orthopedic implants

Alloy type	Alloy designation/ applicable ASTM standard	Composition, %[a]											
		C	**Co**	**Cr**	**Fe**	**Mn**	**Mo**	**N**	**Ni**	**P**	**S**	**Si**	**Ti**
Cobalt-chromium-molybdenum	F 75	0.35	bal	27-	0.75	1.0	5-7	. . .	1.0	. . .	. . .	1.0	. . .

				30									
Cobalt-chromium-molybdenum, thermomechanically processed	F 799	0.35	bal	26-30	1.5	1.0	5-7	0.25	1.0	. . .	. . .	1.0	. . .
Cobalt-nickel-chromium-molybdenum	F 562	0.025	bal	19-21	1.0	0.15	9-10.5	. . .	33-37	0.015	0.01	0.15	1.0

(a) Maximum unless range is given

The cobalt-chromium-molybdenum alloy is available with either carbide strengthening or nitrogen solid-solution strengthening. Investment cast cobalt-chromium-molybdenum alloys are carbide strengthened; a typical investment cast microstructure is shown in Fig. 4. The grains in this microstructure are quite coarse, and the carbides are large. Higher-strength fine-grain cobalt-chromium-molybdenum devices have been made by forcing of nitrogen-strengthened bar stock or by not isostatic pressing (HIP) of carbide-strengthened powders (Ref 31, 32). Microstructures of these materials are shown in Fig. 5.

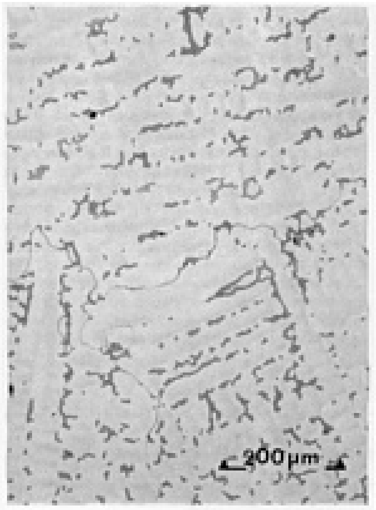

Fig. 4 Microstructure of investment cast cobalt-chromium-molybdenum alloy. Note the relatively coarse carbides and the large grain size (ASTM macrograin size 7.5). Compare with Fig. 5

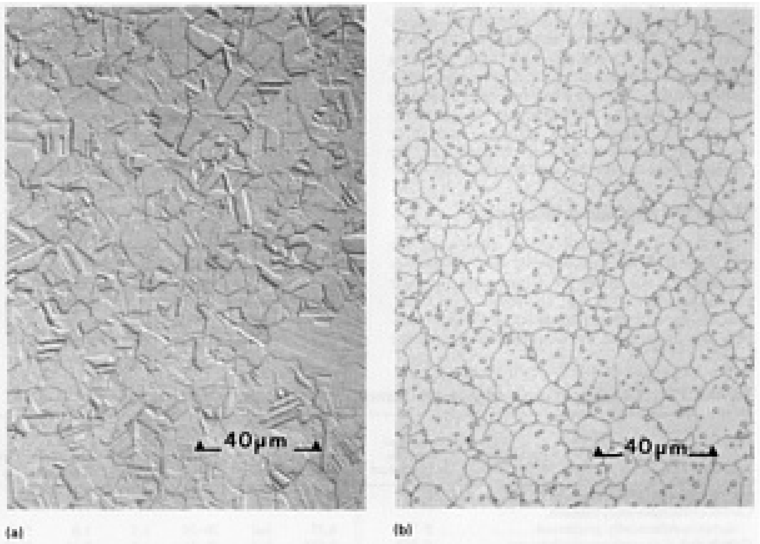

Fig. 5 Microstructures of high-strength fine-grain cobalt-chromium-molybdenum alloy. (a) Forged. (b) HIP powder. Note the decrease in grain size from Fig. 4.

The cobalt-nickel-chromium-molybdenum alloy MP35N has also been successfully used as an implant. This alloy can be strengthened by work hardening and by a precipitation reaction. The alloy was widely used in the mid-1970s to early 1980s, but is popularity in the United States has declined recently. This appears to be at least partially due to concerns about nickel release from the alloys, which can cause metal sensitivity reactions in some patients.

Manufacturing Techniques

The earliest cobalt-base implants were made by classical investment-casting techniques. This technology is well suited to a variety of medical device applications. Unfortunately, the fatigue failure of a small percentage of cast cobalt-chromium-molybdenum total hip implants has been observed.

Fatigue failure typically occurs after the PMMA cement layer around the implant degrades, leaving only the tip of the stem fixed. Under these conditions, there is a long moment arm acting on a relatively small implant cross section. This is shown schematically in Fig. 6. A loose implant is generally cause for reoperation prior to mechanical failure, but occasionally, the fatigue limit is exceeded and the device fails.

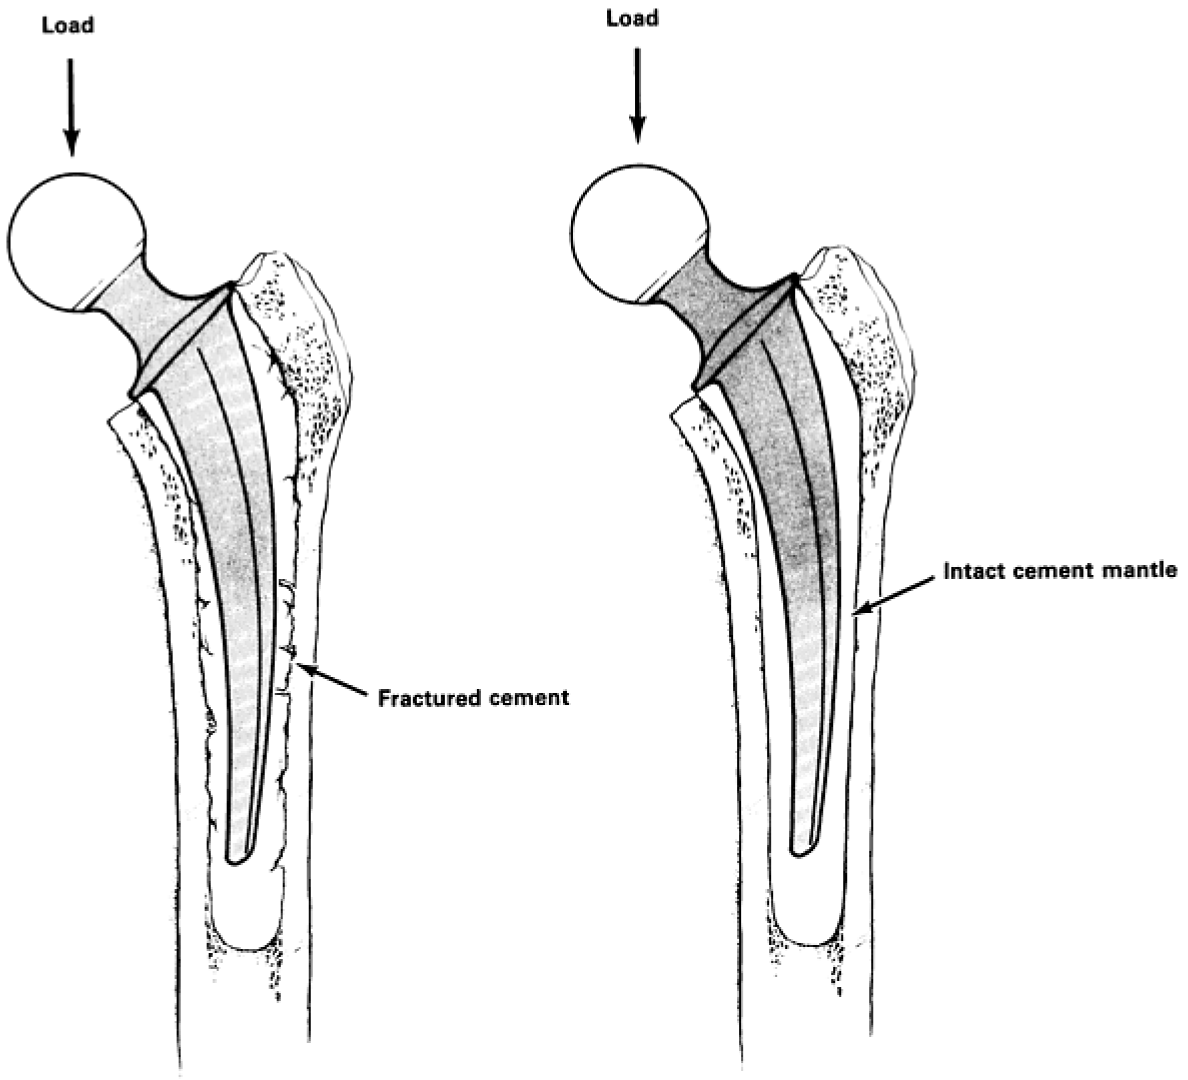

Fig. 6 Fracture of the cement mantle around a femoral hip stem results in increased stresses in the distal region of the stem. Loads applied to hips with fractured cement (a) act over a longer lever arm; and on a small cross section. This can lead to fatigue failure of the distal portion of the stem. The load applied to a hip with intact cement (b) acts over a short lever arm and is distributed over a large area.

Several approaches are available for improving the mechanical properties of cobalt-chromium-molybdenum alloys in order to provide a greater margin of safety. Finer grain size materials that are free of residual casting porosity and inclusions have dramatically improved high-cycle fatigue strength compared to the as-cast alloy. These structures can be achieved by closed die forging or by powder metallurgy techniques such as HIP. The fatigue limit of these alloys is two to three times higher than that of cast cobalt-chromium-molybdenum. Closed die forgings are currently the most common approach to producing total hip implants with high fatigue strength. These techniques have been applied since the mid-1970s. Only one failure has been reported out of the thousands of hip stems fabricated by these methods (Ref 33).

The most recent development in total hip implants is the application of porous coatings to certain regions of the implant. The porous coating can be used either to enhance fixation with the PMMA cement or to provide sites that bone or fibrous tissue can grow into. In the latter case, cement is not used; this eliminates the potential breakdown of cement over long periods of time. In cobalt-base devices, relatively large spherical powders (250 to 1000 μm in diameter) are sintered onto the implant to create a porous layer. Porous-coated implants are typically investment cast; forged implants are not used, because the sintering cycles cause grain growth and a dramatic reduction in fatigue strength. Figure 7 shows an SEM micrograph and a cross-sectional view of a porous-coated cobalt-chromium-molybdenum component.

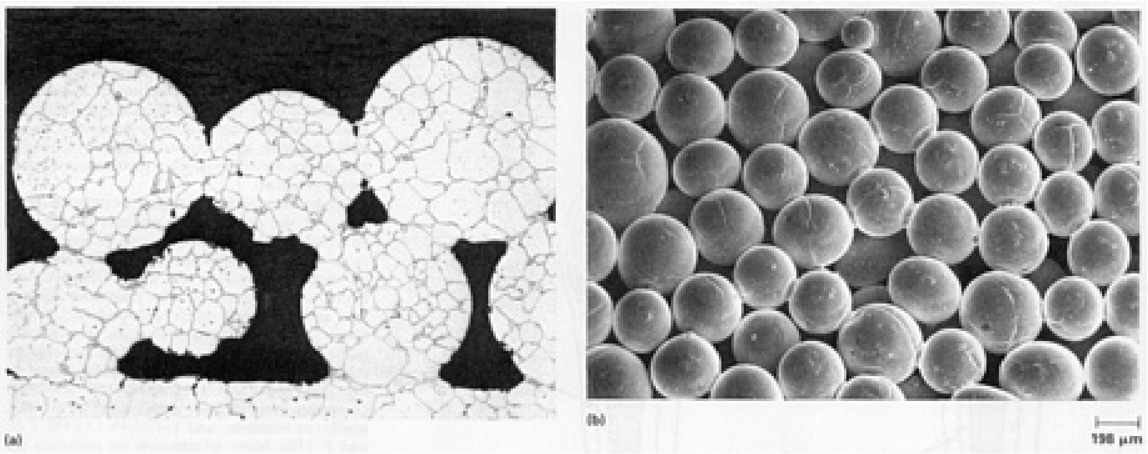

Fig. 7 Micrographs of a porous-coated cobalt-chromium-molybdenum implant material. (a) Cross section of coating; voids within the coating and the substrate are caused by incipient melting of carbides during the sintering process. (b) SEM micrograph of the porous layer. Note the interparticle necking.

Properties of Cobalt Alloy Implants

The properties of interest for orthopedic implant materials include biocompatibility, corrosion resistance, water resistance, and such mechanical properties as strength, ductility, and high-cycle fatigue behavior.

Biocompatibility is a measure of the interaction between the living host and the implanted material. All implants cause some response because the body recognizes them as foreign objects. The good biocompatibility of cobalt-chromium-molybdenum components was a major factor in the early interest in this material. Cobalt-chromium-molybdenum is well tolerated by the body. Typically, a thin, fibrous layer is formed when these alloys are implanted in direct apposition to bone; more severe reactions to these materials are extremely rare.

There is some controversy regarding the biocompatibility of porous-coated cobalt-base implants (Ref 34, 35). This concern is due to the greater surface area of the porous layer and the fact that the porous-coated implant can be in direct contact with bone. However, in traditional cemented implants, most of the device is isolated from bone by the cement layer. Thus, porous-coated implants can result in potentially higher release of metal ions (especially chromium and nickel) into the surrounding tissues.

Corrosion resistance is a key aspect of the biocompatibility of a material. The corrosion resistance of all implanted metals depends on the formation of passive films. In the cobalt-base alloys, a Cr_2O_3film is formed. More information on the formation of passive films in implant materials is available in the article "Corrosion of Metallic Implants and Prosthetic Devices" in this Volume.

Wear behavior is important because artificial joints are subject to millions of cycles during their lifetimes. Total knee and hip components have a highly polished metal surface that articulates on an ultrahigh molecular weight polyethylene bearing surface. Retrieved cobalt-chromium-molybdenum implants generally show very low amounts of wear.

The mechanical properties of cobalt-base alloys depend on processing history. The tensile properties required by ASTM specifications for cast and wrought cobalt-base implant alloys are shown in Table 13. Fatigue properties are extremely important in such applications as total hip replacements. High-cycle fatigue endurance limits measured by several investigators using various test methods are shown in Table 14. The wrought products have fatigue strengths that are two or three times higher than those of cast or porous-coated cobalt-chromium-molybdenum.

Table 13 Specified minimum mechanical properties of cobalt-base alloys used for orthopedic implants

Alloy designation	Tensile strength		Yield strength, 0.2% offset		Elongation, %	Reduction of area, %
	MPa	**ksi**	**MPa**	**ksi**		
F 75	655	95	450	65	8	8
F 799	1172	170	827	120	12	12
F 562						
Solution annealed[(a)]	793-1000	115-145	241-448	35-65	50	65

(a) Annealed 1 to 2 h at 1050 ± 15 °C (1925 ± 25 °F), air cooled, and water quenched.

(b) Cold worked 53%, aged 4 h at 540 to 650 ± 15 °C (1000 to 1200 ± 25 °F), and air cooled

Table 14 Reported fatigue strengths of cobalt-base alloys

Alloy	Test technique	10^7 cycle endurance limit		Ref
		MPa	**ksi**	
Cast F 75	Rotating beam	267	38.7	36
		310	45	31
Forged F 799	Rotating beam	793-966	115-140	31

Forged F 562	Rotating beam	515	75	37
Cold-worked and aged F 562	Tension-tension	862	125	38

Nuclear Power Applications

Despite the maintenance hazards imposed by irradiated cobalt (which, under neutron bombardment, is transformed to a radioactive isotope with a long half-life), wear alloys of the cobalt-chromium type have been extensively used to protect the sealing surfaces of steam control and safety valves within the nuclear industry. Their use in these valves arises from their outstanding resistance to galling, steam erosion, and, to a lesser extent, oxidation/corrosion. Stellite alloy 21 and 6 are the most popular for valve facing. Application techniques include tungsten inert gas (with cast rod) and plasma-transferred are welding (with powder).

The wrought version of Stellite alloy 6 has been used for control shaft guide bushings in sodium-cooled reactors. Resistance to galling and the corrosive effects of liquid sodium (at operating temperatures up to 900 °C, or 1650 °F) were the factors involved in the selection of this alloy.

Away from the reactor core, the cobalt-chromium high-temperature alloy Haynes alloy 25 has been used in the form of tubing to construct nitrogen gas heaters part of a closed-loop gas turbine system. In this case, the cobalt alloy was selected for its high-temperature strength and resistance to nitriding at elevated temperatures. More information on materials and corrosion in nuclear power plants is available in the article "Corrosion in the Nuclear Power Industry" in this Volume.

Chemical-Processing Industry

Within the chemical-(and food) processing industry, cobalt alloys play a vital role in protecting critical components from the combined effects of wear and corrosion. In particular, they are extensively used to protect control valve sealing faces and pump seals and bearings. Normally, they are applied as weld overlay coatings, but they are also used in the form of small castings, wrought products, and small powder metallurgy parts. Example of applications and environments in which the cobalt alloys have been successfully used in the chemical-processing industry are given in Table 15. Detailed information on materials used and corrosion in chemical-processing applications is available in the article "Corrosion in the Chemical Processing Industry" in this Volume.

Table 15 Some applications for cobalt-base alloys in the chemical and food processing industries

Application	Environment	Alloy	Form	Wear Mode
Mixer for glass production (linings and bearings)	Dry ingredients (Sand, soda ash, feldspar, borax, barium)	Haynes alloy 6B	Wrought plates and half sleeves	Abrasion
Hot asphalt agitator bearings	Hot asphalt at 480 °C (900 °F)	Haynes alloy 6B	Wrought half sleeves	Abrasion/erosion
Catalytic reactor valves (butadiene production)	Butane at 650 °C (1200 °F)	Stellite alloy 6	Weld overlay	Galling
Scraper blades on rotary filters for TiO_2 production	Muds containing dilute H_2SO_4	Haynes Alloy 6B	Wrought plate	Abrasion
Pug mill paddles and extrusion screws in catalyst manufacture	Kaolin clay and H_2SO_4	Stellite alloy 1	Weld overlay	Abrasion
Screw conveyor bearings in household cleaner production	Silica	Haynes alloy 6B	Wrought half sleeves	Abrasion
Cutters for synthetic fibers	Polyesters	Haynes alloy 6B	Wrought plate	. . .

Meat grinder blades	Meat	Stellite alloy 19PM	P/M	. . .
Extrusion cooker screw flights	Cereal doughs at up to 205 °C (400 °F)	Stellite alloy 12	Weld overlay	Abrasion
Screws for oil extraction	Vegetable oils, seeds	Stellite alloy 12	Weld overlay	Abrasion
Homogenizer valves	Various liquids	Stellite alloy 6	Weld overlay	Cavitation, erosion

Corrosion of Titanium and Titanium Alloys

Ronald W. Schutz, TIMET Corporation; David E. Thomas, RMI Company

Introduction

TITANIUM ALLOYS were originally developed in the early 1950s for aerospace applications, in which their high strength-to-density ratios were especially attractive. Although titanium alloys are still vital to the aerospace industry for these properties, recognition of the excellent resistance of titanium to many highly corrosive environments, particularly oxidizing and chloride-containing process streams, has led to widespread nonaerospace (industrial) applications. Because of decreasing cost and the increasing availability of titanium alloy products, many titanium alloys have become standard engineering materials for a host of common industrial applications (Ref 1). In fact, a growing trend involves the use of high-strength aerospace-founded titanium alloys for industrial service in which the combination of strength to density and corrosion resistance properties is critical and desirable.

The objectives of this article are severalfold and include:

- Describing and characterizing the relevant modes of corrosion observed on titanium alloys
- Providing a comprehensive overview of the available corrosion data base on titanium alloys
- Providing basic explanations, relevant summaries, and guiding comments relative to the data base, where applicable
- Offering practical strategies for expanding the useful corrosion resistance of titanium in corrosive environments

References are provided as sources of additional information.

The designations and nominal compositions of commercial titanium alloys addressed in this article are listed in Table 1. The first eight alloys listed are titanium alloys that are commonly used in industrial applications in which corrosion resistance is often of primary concern. It is for this reason that most of the corrosion data presented in this article applies to this group of alloys. With the exception of the Ti-6Al-4V alloy, these alloys consist of single α-phase (hexagonal close-packed crystal structure) or near-α alloys containing relatively small amounts of βphase (body-centered cubic crystal structure) in an αmatrix.

Table 1 Designations and nominal compositions of titanium alloys

Common alloy designation	UNS designation	Nominal composition, %	ASTM grade	Alloy type
Grade 1	R50250	Unalloyed titanium	1	α
Grade 2	R50400	Unalloyed titanium	2	α
Grade 3	R50550	Unalloyed titanium	3	α
Grade 4	R50700	Unalloyed titanium	4	α

Ti-Pd	R52400/ R52250	Ti-0.15Pd	7/11	α
Grade 12	R53400	Ti-0.3Mo-0.8Ni	12	Near-α
Ti-3-2.5	. . .	Ti-3Al-2.5V	9	Near-α
Ti-6-4	R56400	Ti-6Al-4V	5	α-β
Ti-6-2-1-.8	. . .	Ti-6Al-2Nb-1Ta-0.8Mo	. . .	Near-α
Ti-5Ta	. . .	Ti-5TA	. . .	Near-α
Ti-5-2.5	. . .	Ti-5Al-2.5Sn	. . .	α
Ti-8-1-1	. . .	Ti-8Al-1V-1Mo	. . .	Near-α
Ti-6-2-4-2	. . .	Ti-6Al-2Sn-4Zr-2Mo	. . .	Near-α
Ti-4-3-1	. . .	Ti-4Al-3Mo-1V	. . .	α-β
Ti-550	. . .	Ti-4Al-2Sn-4Mo-0.5Si	. . .	α-β
Ti-6-6-2	. . .	Ti-6Al-6V-2Sn-0.6Fe-0.6Cu	. . .	α-β
Corona 5	. . .	Ti-4.5Al-1.5Cr-5Mo	. . .	α-β
Ti-6-2-4-6	R56260	Ti-6Al-2Sn-4Zr-6Mo	. . .	α-β
Ti-10-2-3	. . .	Ti-10V-2Fe-3Al	. . .	Near-β
Transage 129	. . .	Ti-2Al-11.5V-2Sn-10Zr	. . .	Near-β
Transage 207	. . .	Ti-2.5Al-2Sn-9Zr-8Mo	. . .	Near-β
Ti-15-3-3-3	. . .	Ti-15V-3Sn-3Cr-3Al	. . .	β
Ti-3-8-6-4-4	R58640	Ti-3Al-8V-6Cr-4Zr-4Mo	. . .	β

Ti-13-11-3	. . .	Ti-3Al-13V-11Cr	. . .	β
Ti-8-8-2-3	. . .	Ti-8V-8Mo-3Al-2Fe	. . .	β
Ti-15-5	. . .	Ti-15Mo-5Zr	. . .	β

The rest of the titanium alloys were developed for aerospace purposes, in which significantly increased strengths are achieved by solid-solution alloying and stabilization of two-phase structures. These alloys, which contain varying amounts of stabilized β phase, are generally heat treatable (aged) to high strength levels. Titanium alloy metallurgy (Ref 2) and the mechanical and physical properties of titanium alloys have been extensively reviewed in the literature (Ref 3, 4, 5, 6, and 7).

Mechanism of Corrosion Resistance

The excellent corrosion resistance of titanium alloys results from the formation of very stable, continuous, highly adherent, and protective oxide films on metal surfaces. Because titanium metal itself is highly reactive and has an extremely high affinity for oxygen, these beneficial surface oxide films form spontaneously and instantly when fresh metal surfaces are exposed to air and/or moisture. In fact, a damaged oxide film can generally reheal itself instantaneously if at least traces (that is, parts per million) of oxygen or water (moisture) are present in the environment. However, anhydrous conditions in the absence of a source of oxygen may result in titanium corrosion, because the protective film may not be regenerated if damaged.

The nature, composition, and thickness of the protective surface oxides that form on titanium alloys depend on environmental conditions. In most aqueous environments, the oxide is typically TiO_2, but may consist of mixtures of other titanium oxides, including TiO_2, Ti_2O_3, and TiO (Ref 8). High-temperature oxidation tends to promote the formation of the chemically resistant, highly crystalline form of TiO_2 known as rutile, whereas lower temperatures often generate the more amorphous form of TiO_2 anatase, or a mixture of rutile and anatase (Ref 8). Although these naturally formed films are typically less than 10 nm thick (Ref 9) and are invisible to the eye, the TiO_2 oxide is highly chemically resistant and is attacked by very few substances, including hot, concentrated HCl, H_2SO_4, NaOH, and (most notably) HF. This thin surface oxide is also a highly effective barrier to hydrogen, as discussed in a later section in this article.

Furthermore, the TiO_2 film, being an *n*-type semiconductor, possesses electronic conductivity. As a cathode, titanium permits electrochemical reduction of ions in an aqueous electrolyte. On the other hand, very high resistance to anodic current flow through the passive oxide film can be expected in most aqueous solutions. Because the passivity of titanium stems from the formation of a stable oxide film, an understanding of the corrosion behavior of titanium is obtained by recognizing the conditions under which this oxide is thermodynamically stable. The Pourbaix (potential-pH) diagram for the titanium-water system at 25 °C (75 °F) is shown in Fig. 1 and depicts the wide regime over which the passive TiO_2 film is predicted to be stable, based on thermodynamic (free energy) considerations. Oxide stability over the full pH scale is indicated over a wide range of highly oxidizing to mildly reducing potentials, whereas oxide film breakdown and the resultant corrosion of titanium occur under reducing acidic conditions. Under strongly reducing (cathodic) conditions, titanium hydride formation is predicted.

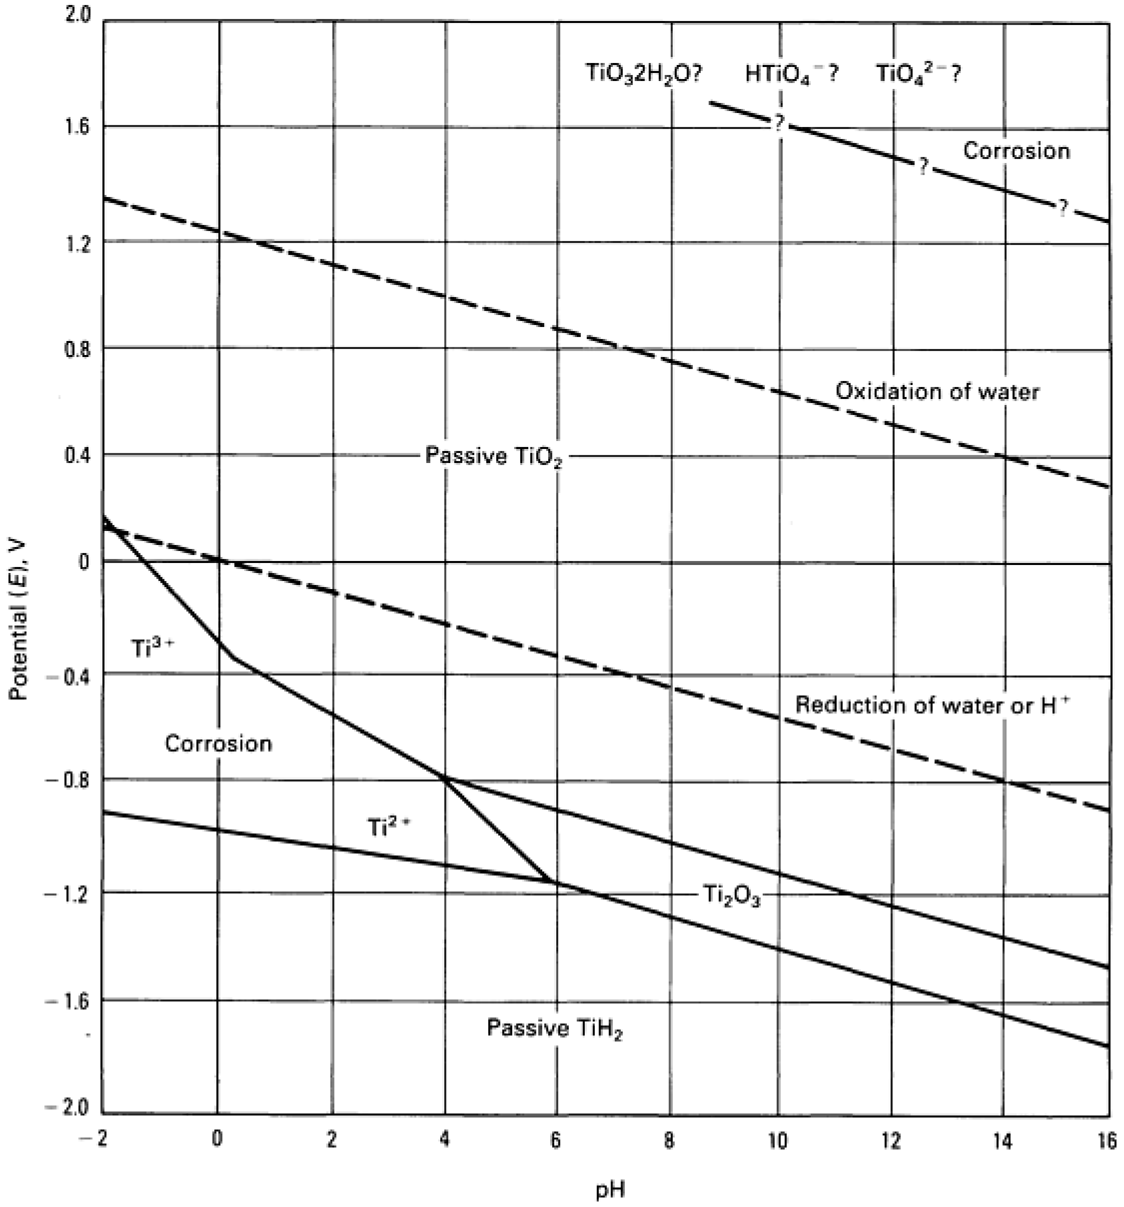

Fig. 1 Pourbaix (potential-pH) diagram for the titanium-water system at 25 °C (77 °F). Source: Ref 10

Thus, successful use of titanium alloys can be expected in mildly reducing to highly oxidizing environments in which protective TiO_2 and Ti_2O_3 films form spontaneously and remain stable. On the other hand, uninhibited, strongly reducing acidic environments may attack titanium, particularly as temperature increases. However, shifting the alloy potential in the noble (positive) direction by various means can induce stable oxide film formation, often overcoming the corrosion resistance limitations of titanium alloys in normally aggressive reducing media.

Enhancing Corrosion Resistance

The methods of expanding the corrosion resistance of titanium into reducing environments include:

- Increasing the surface oxide film thickness by anodizing or thermal oxidation
- Anodically polarizing the alloy (anodic protection) by impressed anodic current or galvanic coupling with a more noble metal in order to maintain the surface oxide film
- Applying precious metal (or certain metal oxides) surface coatings

- Alloying titanium with certain elements
- Adding oxidizing species (inhibitors) to the reducing environment to permit oxide film stabilization

Of these five methods, the last two have been very practical, effective, and most widely used in actual service.

Alloying titanium with precious metals (such as palladium), nickel, and/or molybdenum or coating with certain precious metals (or their oxides) facilitates cathodic depolarization by providing sites of low hydrogen overvoltage on alloy surfaces and by shifting alloy potential in the noble (positive) direction. For example, this is the basis for the significantly improved crevice corrosion resistance of titanium grades 7 and 12 in reducing acids and hot brines as compared to that of unalloyed titanium.

Various dissolved reducible (oxidizing) species in normally reducing media also serve to depolarize cathodic reactions on titanium alloy surfaces; this passivates the alloy by shifting the alloy potential in the noble direction. Many of these species, which include a host of multivalent transition metal ions, are very potent inhibitors and may be effective at concentrations of 100 ppm or less (see the section "Inhibition of Reducing Acid Corrosion" in this article). These inhibiting species often occur as natural process stream constituents or contaminants and need not be intentionally added to achieve complete titanium alloy passivation. More information on the five methods listed above are provided in the section "Expanding and Enhancing the Corrosion Resistance of Titanium" in this article.

Alloy Composition Effects. The nature of the oxide film on titanium alloys basically remains unaltered in the presence of minor alloying constituents; thus, small additions (<2 to 3%) of most commercially used alloying elements or trace alloy impurities generally have little effect on the basic corrosion resistance of titanium in normally passive environments. For example, despite small differences in interstitial element (carbon, oxygen, and nitrogen) and iron content, all unalloyed grades of titanium posses the same useful range of resistance in environments in which corrosion rates are normally very low (Ref 11, 12). However, under active conditions in which titanium exhibits significant general corrosion, certain alloying elements may accelerate corrosion. Increasing the alloy iron and sulfur content, for example, increases corrosion rates when corrosion rates exceed 0.13 mm/yr (5 mils/yr) (Ref 11, 12). Thus, minor variations in alloy chemistry may be of concern only under conditions in which the passivity of titanium is borderline or when the metal is fully active. On the other hand, minor nickel and palladium additions are highly effective in expanding the corrosion resistance of titanium alloys under reducing conditions.

The influence or certain major alloying elements on the general and crevice corrosion behavior of various commercial titanium alloys has been determined in reducing aqueous acid media (Ref 13). Results indicate that vanadium and, especially, molybdenum additions ($\geq$4% Mo) improve corrosion resistance but that increasing the aluminum content appears to be detrimental. The influence of alloying elements on the resistance of titanium alloys to pitting and stress-corrosion cracking (SCC) is addressed in subsequent sections of this article.

Weldments (Ref 12) and castings (Ref 14, 15) of the first eight titanium alloys listed in Table 1 generally exhibit corrosion resistance similar to that of their unwelded, wrought counterparts. These titanium alloys contain so little alloys content and second phase that metallurgical instability and thermal response are not significant. Therefore, titanium weldments and associated heat-affected zones generally do not experience corrosion limitations in welded components when normal passive conditions prevail for the base metal. However, under marginal or active conditions (for corrosion rates $\geq$0.10 mm/yr, or 4 mils/yr), weldments may experience accelerated corrosion attack relative to the base metal, depending on alloy composition (Ref 12). The increasing impurity (iron, sulfur, oxygen) content associated with the coarse, transformed-β microstructure of weldments appears to be a factor. Few published data are available concerning the corrosion resistance of other α-β and β titanium alloy weldments and castings.

Forms of Corrosion and Related Test Methods

Titanium alloys, like other metals, are subject to corrosion in certain environments. The primary forms of corrosion that have been observed on these alloys include general corrosion, crevice corrosion, anodic pitting, hydrogen damage, and SCC. In any contemplated application of titanium, its susceptibility to degradation by any of these forms of corrosion should be considered. In order to understand the advantages and limitations of titanium alloys, each of these forms of corrosion will be explained. Although they are not common limitations to titanium alloy performance, galvanic corrosion, corrosion fatigue, and erosion-corrosion are included in the interest of completeness. More information on the mechanisms of all these forms of attack is available in the Section "Forms of Corrosion" in this Volume.

General Corrosion

General corrosion is characterized by a relatively uniform attack over the exposed surface of the metal. At times, general corrosion in aqueous media may take the form of mottled, severely roughened metal surfaces that resemble localized attack. This often results from variations in the corrosion rates of localized surface patches due to localized masking of metal surfaces by process scales, corrosion products, or gas bubbles; such localized masking can prevent true uniform surface attack. When titanium is in the fully passive condition, corrosion rates are typically much lower than 0.04 mm/yr (1.5 mils/yr)--well below the 0.13-mm/yr (5-mils/yr) maximum corrosion rate commonly accepted by designers. This very small, acceptable corrosion is attributable to the finite oxidation (typically TiO_2 film growth) of titanium alloy surfaces. As a result, titanium is most often designed with a zero corrosion allowance in normal passive environments. In many environments in which titanium is fully resistant, slight surface oxide growth may occur; this oxide growth manifests itself as colored surfaces and very slight weight gain by test coupons.

General corrosion becomes a concern in reducing acid environments, particularly as acid concentration and temperature increase. In strong and/or hot reducing acids (in the absence of inhibitors), the oxide film of titanium can deteriorate and dissolve, and the unprotected metal is oxidized to the soluble trivalent ion ($Ti \rightarrow Ti^{3+} + 3e^-$). This ion has a characteristic violet color in acid solutions. If dissolved oxygen or other oxidizing species are present in hot acid, the Ti^{3+} ion is readily oxidized to the less soluble (pale yellow) Ti^{4+} ion, which may subsequently hydrolyze to form insoluble TiO_2 precipitates (scales). Titanium ion hydrolysis often produces highly colored metal surfaces, involving thin titanium oxide films that may inhibit subsequent corrosion. Gray-matte or dull silver surface finishes can also be observed in reducing acid exposures involving severe corrosion attack. These are titanium hydride surface films, which are typically of the order of 0.05 mm (2 mils) thick.

General Corrosion Testing. General corrosion rates for titanium alloys can be determined from weight loss data, dimensional changes, and electrochemical methods. Electrochemical anodic and cathodic polarization testing is often used to supplement weight loss testing. Polarization testing can identify whether the alloy is truly fully passive or possibly metastable; this is often not discernible from weight loss tests alone. The immersion test procedures described in ASTM G 1 and G 31 apply, provided several modifications are observed (Ref 16). These modifications focus on test sample surface preparation and posttest sample-cleaning procedures.

The type of surface finish tested should resemble the one expected in service. For titanium alloys, this will often be the pickled finish, although sandblasted or ground surfaces are also common. The initial degreasing of test samples should avoid chlorinated organic solvents (with higher-strength titanium alloys), anhydrous methanol, or hot alkaline cleaners, if possible. Acceptable cleaning solvents include methyl ethyl ketone (MEK), acetone, most alcohols, benzene, and most detergent solutions. The pickled finish can be prepared by pickling the metal in a 35 vol% HNO_3-5 vol% HF (balance water) solution at 20 to 55 °C (70 to 130 °F) for several minutes or more. Typically, 0.02 to 0.05 mm (0.8 to 2 mils) of surface is removed in this process, depending on surface requirements. More dilute solutions, such as 12 vol% HNO_3-1 vol% HF, can also be used if slower pickling rates are desired. In any case, a minimum 7/1 HNO_3/HF vol% ratio should be maintained to avoid excessive uptake of hydrogen in titanium alloys during pickling. After pickling, a quick rinse in deionized water leaves a shiny specimen that is ready for weighing after air drying. Blasted and abraded surfaces are prepared by procedures similar to those used for other metals.

After laboratory or *in situ* test exposure, titanium samples can be coated with tenacious, insoluble corrosion product (TiO_2) films or scales, which require removal before final weighing. Because titanium oxides are not soluble in common mineral acids, very light (<5-s exposure) sand-blasting has been found to be most effective. If scaling consists of silicaceous, carbonaceous, sulfate, or other typical process stream deposits, then acids or alkaline solutions that are properly inhibited with oxidizing species must be used; common amine inhibitors are not effective on titanium. Recommended cleaning solutions for these scales are discussed in detail in Ref 1. Serious consideration must be given to the presence of test medium contaminants that may significantly affect the corrosion rate of titanium. Metal ion contaminants or dissimilar-metal corrosion products can promote the passivity of titanium (see the section "Expanding and Enhancing the Corrosion Resistance of Titanium" in this article). The degree of aeration and other background chemistry variables in the test media that influence alloy passivity in service must be taken into account in order to avoid false test indicators.

Immersion testing will generate weight loss data, or corrosion current measurements can be obtained from electrochemical polarization tests (ASTM G 5). Corrosion rates in millimeters per year for titanium alloys can be calculated from weight loss data as follows:

$$\text{Corrosion rate} = \frac{(8.76 \times 10^4)(W)}{(d)(A)(t)} \quad \textbf{(Eq 1)}$$

where *d* is the titanium alloy density (in grams per cubic centimeter), *A* is the sample surface area (in square centimeters), *t* is the exposure time (in hours), and *W* is the weight change (in grams).

Corrosion rates (mm/yr) can be calculated from electrochemical measurements by using Eq 2:

$$\text{Corrosion rate} = \frac{(0.0033)(i_{corr})(\text{EW})}{d} \quad \textbf{(Eq 2)}$$

where i_{corr} is the measured corrosion current (in milliamps per square centimeter), *d* is alloy density (in grams per cubic centimeter), and EW is the equivalent weight for titanium. The equivalent weight for titanium is approximately 16 under reducing acid conditions and 12 under oxidizing conditions. The value of i_{corr} is typically determined from Tafel slope extrapolation or linear polarization methods (Ref 17, 18). More information on general corrosion testing is available in the article "Evaluation of Uniform Corrosion" in this Volume.

Crevice Corrosion

Titanium alloys may be subject to localized attack in tight crevices exposed to hot (>70 °C, or 160 °F) chloride, bromide, iodide, fluoride, or sulfate-containing solutions. Crevice can stem from adhering process stream deposits or scales, metal-to-metal joints (for example, poor weld joint design or tube-to-tubesheet joints), and gasket-to-metal flange and other seal joints.

The mechanism for crevice corrosion of titanium is similar to that for stainless steels, in which oxygen-depleted reducing acid conditions develop within tight crevices. The model for crevice corrosion is illustrated in Fig. 2. Dissolved oxygen or other oxidizing species in the bulk solution are depleted in the restricted volume of solution in the crevice. Finite surface oxidation in crevices consumes these species faster than diffusion from the bulk solution can replenish them (Ref 20). As a result, metal potentials in crevices become active (negative) relative to metal surfaces exposed to the bulk solution. This creates an electrochemical cell in which the crevices become anodic and corrode, and the surrounding metal surface is cathodic.

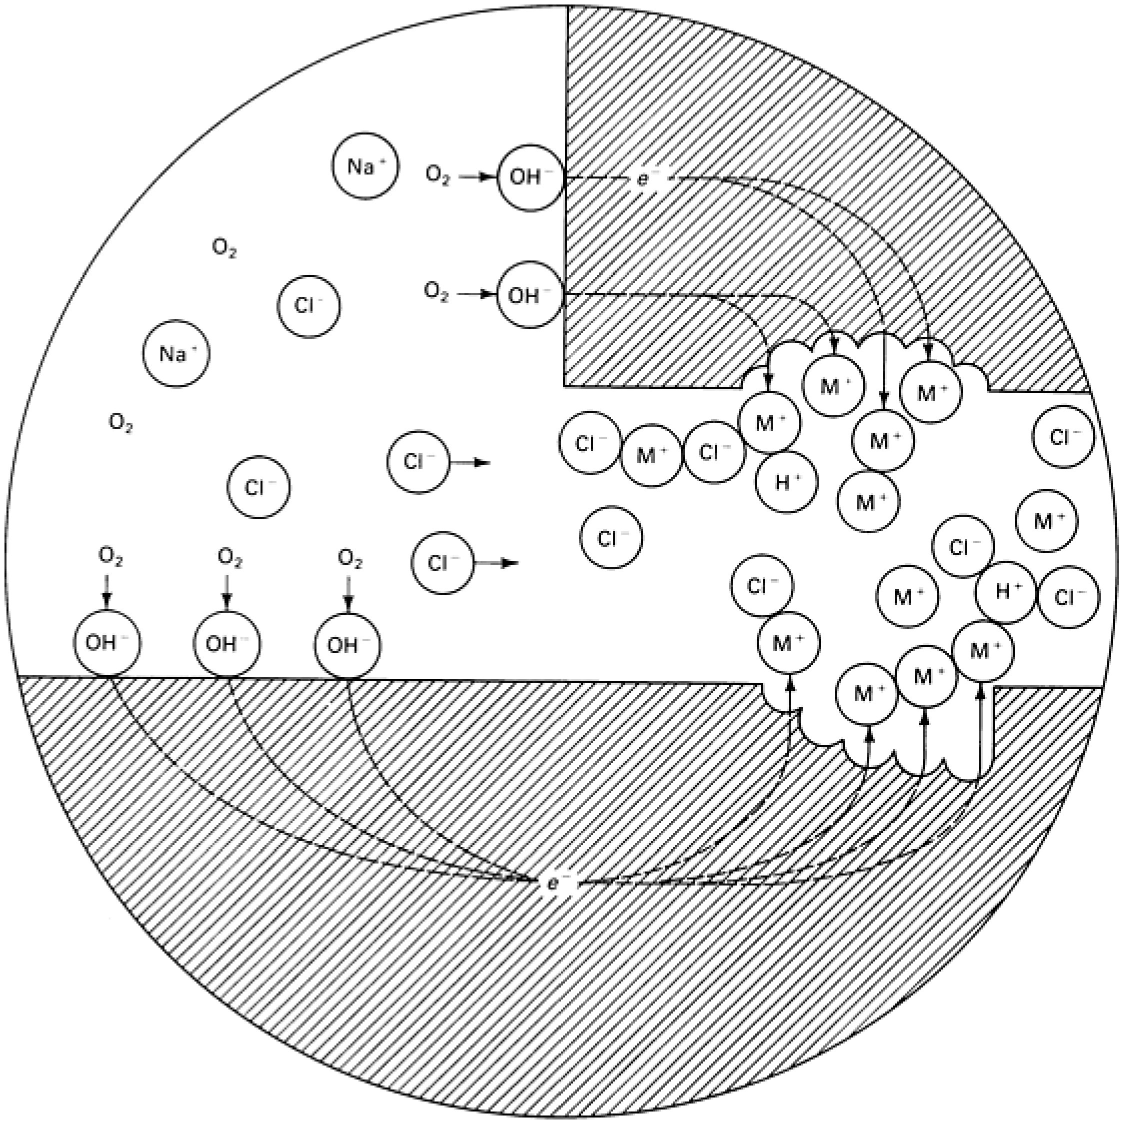

Fig. 2 Schematic showing the mechanism of crevice corrosion for titanium in aqueous chloride media. Source: Ref 19

Titanium chlorides formed within the crevice are unstable and tend to hydrolyze, forming hydrochloric acid (HCl) and titanium oxide/hydroxide corrosion products. Because of the small, restricted volumes of solution in these crevices, crevice pH levels as low as 1 or below can develop. These local reducing acidic conditions can result in severe and rapid localized active corrosion within crevices, depending on alloy resistance and temperature.

Although dissolved oxidizing species such as oxygen, chlorine, ferric ion (Fe^{3+}), and cupric ion (Cu^{2+}) tend to inhibit effectively the general corrosion of exposed titanium surfaces, most of these species tend to accelerate the onset and propagation of titanium alloy crevice corrosion. These species are excellent cathodic depolarizers and thus accelerate cathodic reduction kinetics, which often are rate controlling. These cationic oxidizing species will not diffuse into the active crevice to effect passivation. On the other hand, certain anionic oxidizing species, such as NO_3^-, ClO_3^-, OCl^-, CrO_3^{2-}, ClO_4^-, and MnO_4^-, can migrate into the crevice and inhibit crevice attack when present in halide solutions.

Crevice corrosion on titanium typically generates irregularly shaped pits (Fig. 3). Microstructural examination of hand-polished and etched sections of crevices often reveals a surrounding layer of precipitated titanium hydride in α alloys. These are a by-product of hydrogen reduction at cathodic sites surrounding the crevice.

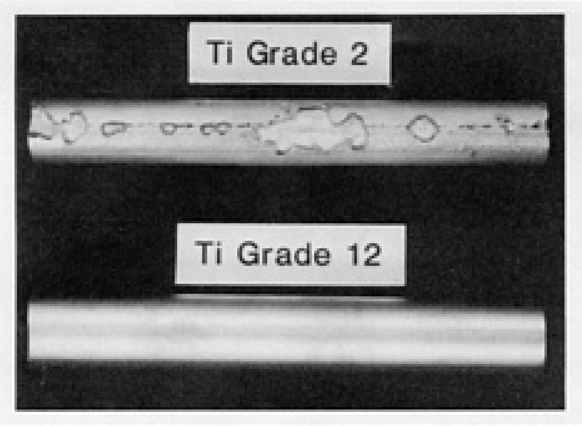

Fig. 3 Under-deposit (inside-diameter surface initiated) crevice corrosion of grade 2 titanium tubing in saturated NaCl brine. Grade 12 titanium is resistant in the same service.

Although frequently interpreted as a pitting phenomenon, smeared surface iron pitting of unalloyed titanium in hot brines appears to be a special case of crevice corrosion (Ref 21). It results when iron, carbon steel, or low-alloy steel is gouged, scratched, smeared, and embedded into a titanium surface, breaching the titanium oxide film. During hot (>80 °C, or 175 °F) brine exposure, the embedded iron can either corrode off the surface and permit repassivation or develop local acidic conditions if occluded by titanium metal smears or laps. Localized attack initiated by this mechanism creates a very characteristic circular pit morphology (Fig. 4) and can involve local hydrogen absorption. Pit initiation has not been observed with copper, nickel, or austenitic stainless steel alloys smeared into titanium surfaces. Titanium grades 7 and 12 appear to be much more resistant to this form of localized attack.

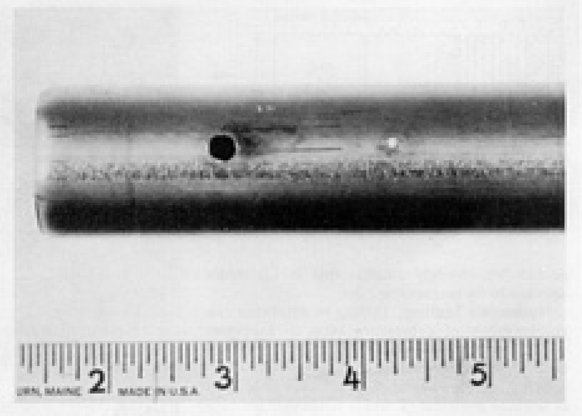

Fig. 4 Smeared surface iron pitting of unalloyed titanium tubing in hot brine service. Source: Ref 21

Several highly effective strategies are available for preventing titanium alloy crevice corrosion and smeared iron pitting, as discussed in a subsequent section of this article. In all cases, the basic remedy aims at maintaining creviced metal surfaces at sufficiently noble potentials where titanium alloy passivity is assured.

Crevice corrosion testing of titanium alloys generally aims at determining go/no-go performance information. The rate of crevice corrosion is of little practical interest, because crevice attack is generally insidious and very rapid. Thus, crevice corrosion cannot be tolerated in any form. Many crevice test assemblies have been used, including the multiple-crevice washer (Ref 22). Unfortunately, crevice corrosion initiation is not very reproducible, especially when pH and temperature conditions are marginal and few or no cathodic depolarizers are present.

Because the susceptibility of titanium to crevice corrosion increases dramatically as creviced surface area increases and crevice gap decreases, the larger sandwich-type crevice test assembly illustrated in Fig. 5 has proved to be most effective (Ref 16). This approach employs an assembly consisting of 25- × 25-mm (1- × 1-in.) minimum flat sheet or plate specimen, with thin gasket sheets (typically Teflon) interspersed to provide the desired number of metal-to-metal and metal-to-gasket crevices per assembly. This assembly is fastened together with a centerline titanium bolt and nut and tightened with a controlled torque (typically 2.8 N · m, or 2 ft · lb). Titanium assembly bolts are covered with an insulating Teflon sleeve to avoid galvanic interactions between coupons. Coupons must be flat and surfaces must be smooth to ensure tight, uniform crevice gaps. The preparation of crevice test coupons involves considerations similar to those described for general corrosion test coupons.

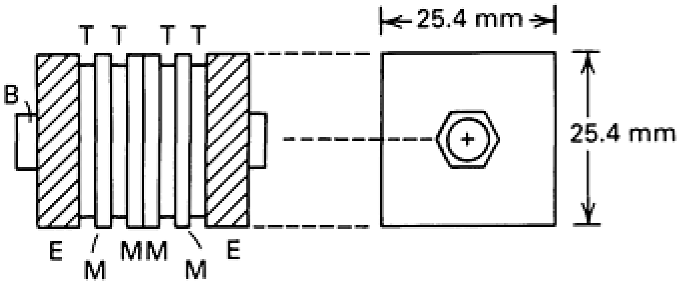

Fig. 5 Schematic of typical crevice corrosion test assembly used for titanium alloy sheet and plate samples. E, assembly and plates; M, alloy test coupons; T, Teflon sheet spacers; B, titanium bolt

Although crevice corrosion can actually initiate after several hours of exposure, test duration should be a minimum of 2 to 4 weeks in order to develop a sufficient degree of attack for detection and measurement purposes. Posttest evaluation of creviced coupons may require removal of titanium oxide/hydroxide corrosion products if crevice attack has occurred. Common mineral acids and reagents will not dissolve these tenacious deposits. A light (<5 to 8 s) sandblasting of the coupon will readily remove these scales and facilitate visual examination of pitted surfaces (ASTM G 46). Creviced coupon surfaces are often highly colored after exposure, but reveal no visible pits after sandblasting. This is indicative of the very slight growth of a protective surface titanium oxide film, which is considered quite normal and acceptable from a performance standpoint. Slight coupon weight gain is often measured in this situation. In addition to visual examination and weight change measurements, monitoring of creviced specimen potential (Ref 23) and current (Ref 24) has been used to a limited extent to identify the initiation of crevice corrosion. More information on testing of crevice corrosion specimens is available in the article "Evaluation of Crevice Corrosion" in this Volume.

Pitting

Pitting is defined as localized corrosion attack occurring on openly exposed metal surfaces in the absence of any apparent crevices. This pitting occurs when the potential of the metal exceeds the anodic breakdown potential of the metal oxide film in a given environment. When the anodic breakdown (pitting) potential of the metal is equal to or less than the corrosion potential under a given set of conditions, spontaneous pitting can be expected.

Because of its protective oxide film, titanium exhibits anodic pitting potentials, E_b, that are very high ($\gg$1 V); thus, pitting corrosion is generally not of concern for titanium alloys. For example, pitting potentials exceed +80 V versus the saturated calomel electrode (SCE) in sulfate and phosphate solutions and are typically in the +5- to +10-V range for chlorides. Although pitting is normally not a limiting factor in titanium performance, pitting potential values provide useful guidelines for titanium for anode applications in which impressed anodic potentials may be high.

The anodic pitting potential of titanium is dependent on alloy content, medium chemistry, temperature, potential scan rate, and, especially, surface condition. A more intrinsic alloy property is the repassivation (protection) potential, which is defined as the minimum potential at which pitting can be maintained (Ref 25). This pitting parameter is not sensitive to surface condition or measuring technique artifacts, and it represents a more conservative design guideline than the anodic breakdown potential. The repassivation potentials of titanium alloys are also very high relative to the alloy corrosion potentials, and this explains why titanium alloys are generally resistant to pitting attack. Anodic pitting and repassivation potential values for titanium alloys under various conditions are presented in the section "Anodic Pitting" in this article.

Pitting Potential Testing. The potentiostatic (constant potential) and potentiodynamic (potential scan) electrochemical techniques used on other metals to measure anodic pitting potential apply to titanium alloys as well (Ref 18). Guidelines are described in ASTM G 3 and G 5. Determination of anodic pitting potential requires slow scan rates (-0.5 m V/s) and consideration of the surface condition tested. For example, abraded or sandblasted sample finishes will exhibit significantly lower pitting potentials than as-pickled surfaces. Also, because of the relatively high pitting potential of titanium, a potentiostat with a potential scan range of at least -2 to +10 V (SCE) is generally required. Recommended auxiliary electrodes include high-density graphite, glassy carbon, or platinum.

Repassivation potentials are readily determined by using the galvanostatic method (Ref 25) or the constant potential-surface scratch test (Ref 18, 25). The galvanostatic method involves impressing an anodic current density of approximately 200 mA/cm^2 (1290 mA/in.^{2}) on the specimen for at least several minutes before measuring the repassivation potential of the sample. Reproducible, unambiguous repassivation potentials are more difficult to derive by using reverse scan potentiodynamic techniques.

Hydrogen Damage

Titanium alloys are widely used in hydrogen-containing environments and under conditions in which galvanic couples or cathodic charging (impressed current) causes hydrogen to be evolved on metal surfaces. Although excellent performance is revealed for these alloys in most cases, hydrogen embrittlement has been observed.

The surface oxide film of titanium is a highly effective barrier to hydrogen penetration. Traces of moisture or oxygen in hydrogen gas containing environments very effectively maintain this protective film, thus avoiding or limiting hydrogen uptake (Ref 26, 27, 28, and 29). On the other hand, anhydrous hydrogen gas atmospheres may lead to absorption, particularly as temperatures and pressures increase.

In α and α-β alloys, excessive hydrogen uptake can induce the precipitation of titanium hydride in the α phase. These acicular-appearing hydride platelets (Fig. 6) are brittle and have been well characterized in the literature (Ref 30, 31, and 32). Small amounts of hydride precipitates are not detrimental from an engineering standpoint in most cases, but cause severe reduction in alloy ductility and toughness when present in greater amounts. For example, hydride precipitates can be observed in grade 2 titanium microstructures at hydrogen concentrations above approximately 100 ppm, depending on the amount of β phase present, but these precipitates do not result in gross embrittlement of grade 2 titanium until levels in excess of 500 to 600 ppm are achieved.

Fig. 6 Photomicrograph of severely hydrided unalloyed titanium. Approximately 200×

Although uniaxial tensile properties may experience little effect from increasing hydrogen levels, biaxial or triaxial stress properties, such as bend ductility, cup (cold-drawing) formability, and impact toughness, in α and near-α alloys are very sensitive to hydrogen levels (Ref 31, 32, 33, 34, 35, and 36). In α and, especially, α-β alloys, hydrogen contents above critical levels can result in sustained-load cracking, which dramatically reduces useful maximum service loads in notched or cracked components under slow strain rate or constant tensile load situations (Ref 31, 32, 33, 34, 35, 36, and 37).

Beta titanium alloys have a very high solubility for hydrogen such that embrittlement is generally not associated with hydride precipitation (Ref 31, 36). Significant losses in ductility or formability may not occur below levels of several thousand parts per million of hydrogen (Ref 31). The tolerance to hydrogen decreases somewhat in the aged (high-strength) condition. This increased tolerance of the β alloys must be weighed against the significantly higher hydrogen uptake rates that result from the much larger hydrogen diffusion coefficient for β titanium (Ref 36, 38).

Factors that can lead to hydrogen uptake and possible embrittlement of α and near-α titanium alloys in aqueous media have been identified from field and laboratory experience. The three general conditions that must exist simultaneously for the hydrogen embrittlement of α alloys are (Ref 26, 29):

- A mechanism for generating nascent (atomic) hydrogen on a titanium surface. This may be from a galvanic couple, an impressed cathodic current, corrosion of titanium, or severe continuous abrasion of the titanium surface in an aqueous medium
- Metal temperature above approximately 80 °C (175 °F), where the diffusion rate of hydrogen into α titanium is significant (Ref 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, and 71)
- Solution pH less than 3 or greater than 12, or impressed potentials more negative than -0.70 V (SCE) (Ref 29, 41, 42, 43, and 44)

The key to preventing hydrogen embrittlement is simply to avoid one or more of these conditions.

Galvanic couples between titanium and certain active metals and excessive cathodic charging from impressed-current cathodic protection systems are the usual causes of excessive hydrogen absorption. In near-neutral electrolytes such as seawater, active metals such as zinc, magnesium, and aluminum can lead to hydrogen uptake and eventual embrittlement when coupled to titanium above 80 °C (175 °F) (Ref 29, 45). A similar problem occurs when titanium is in galvanic contact with carbon steels or active stainless steels in aqueous sulfide media above 80 °C (175 °F) (Ref 29). Like arsenic, antimony, and cyanide species, the sulfide acts as a hydrogen recombination poison (that is, prevents the recombination of atomic hydrogen) and enhances hydrogen uptake in this situation.

No hydrogen uptake and embrittlement problems occur when titanium is coupled to fully passive materials in a given environment. These compatible materials may include other titanium alloys, resistant stainless steels, copper alloys, and nickel-base alloys, depending on conditions.

Cathodic charging of hydrogen onto unalloyed titanium surfaces is not recommended when temperatures exceed 80 °C (175 °F). At metal temperatures below 80 °C (175 °F), thin surface hydride films may form on α titanium alloys (Fig. 7); these are usually not detrimental from the standpoint of corrosion or mechanical properties (Ref 46). However, very high cathodic current densities may lead to enhanced hydride film growth and eventual wall penetration and embrittlement even at room temperature. Practically speaking, impressed cathodic potentials should remain more noble than -1.0 V (SCE) in ambient-temperature seawater applications. Surface thermal oxides on titanium appear to inhibit hydrogen uptake effectively under moderate cathodic charging conditions, but can break down at high current densities (Ref 47).

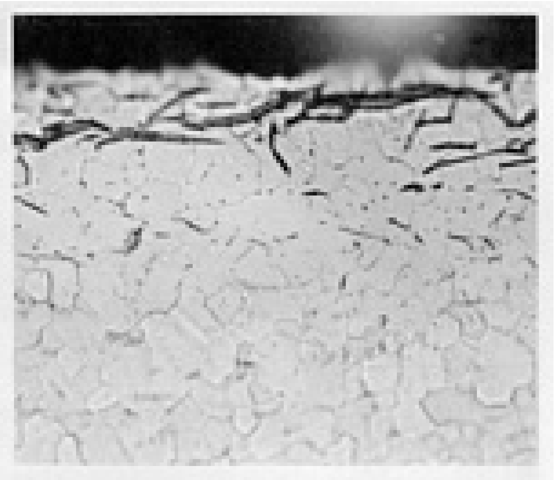

Fig. 7 Photomicrograph of unalloyed titanium sheet revealing a very thin, innocuous surface layer of titanium hydrides. Approximately 500×

High-temperature alkaline conditions may also result in excessive hydrogen uptake and embrittlement of titanium alloys. The nascent hydrogen generated on titanium surfaces from small but finite general corrosion in hot (>80 °C, or 175 °F), strongly alkaline (pH $\geq$12) media appears to be responsible.

Hydrogen Testing. Testing to determine the susceptibility of a titanium alloy to hydrogen uptake and embrittlement should simulate conditions expected in service. In hydrogen gas atmospheres, simple coupon exposures for as long as is deemed practical (1 week minimum) are recommended to ensure significant uptake, it if occurs. The gas atmosphere must duplicate exact gas chemistry, particularly with respect to water and oxygen content. Mere traces of moisture, for example, will effectively inhibit hydrogen absorption by titanium in dry hydrogen gas and possibly cause test interference.

Galvanic coupling tests or cathodic charging tests can also be conducted to evaluate susceptibility to hydrogen uptake. For a given environment, an active metal (iron, aluminum, etc.) sample is galvanically coupled to the titanium alloy sample such that a specific anode-to-cathode surface area is established. Impressed cathodic charging tests are performed in electrolytic cells containing a specific electrolyte. A power supply (potentiostat or galvanostat) impresses a constant potential or current on the cell such that the titanium is cathodic relative to an inert counterelectrode such as graphite or platinum. A reference electrode can also be used to control or to measure the polarization potential of the test cathode. A typical cathodic charging cell and procedures are presented in Ref 16.

The surface condition of the coupon is a critical variable in all hydrogen uptake tests. Studies have shown that abraded or sandblasted surfaces absorb hydrogen more readily than as-pickled surfaces. Thickening of the surface oxide film by anodizing or thermal oxidation further retards absorption. The actual surface finish anticipated in service should be evaluated.

After test exposure, sample evaluation may involve tensile, notched tensile, bend, ductility (for example, drawn cup), Charpy V-notch impact, and/or hydrogen analysis. Uniaxial, smooth-specimen tensile testing is generally of little value in diagnosing the subtle embrittling effects of hydrogen. Titanium alloys tend to exhibit susceptibility under biaxial or triaxial stress states; therefore, bend tests, cup tests, or notched tensile tests are generally more sensitive to hydrogen effects. Impact toughness testing will be particularly sensitive to hydrogen effects. Impact toughness testing can be an especially sensitive indicator of hydrogen effects in αalloys, whereas slow strain rate methods are very suitable for α-β alloys (Ref 31, 34, and 35). Because hydrogen content has relatively little effect on alloy hardness, hardness testing is generally not used.

Hydrogen analysis of coupons is performed by the hot vacuum extraction method. In the hot vacuum extraction apparatus, a small sample is heated to 1100 to 1400 °C (2010 to 2550 °F) for several minutes to reversibly release the absorbed hydrogen, followed by evolved gas measurements. More information on testing for hydrogen damage in metals is available in the article "Evaluation of Hydrogen Embrittlement" in this Volume.

Stress-Corrosion Cracking

Stress-corrosion cracking is a fracture, or cracking, phenomenon caused by the combined action of tensile stress, a susceptible alloy, and a corrosive environment. The metal normally shows no evidence of general corrosion attack, although slight localized attack in the form of pitting may be visible. Usually, only specific combinations of metallurgical and environmental conditions cause SCC. This is important because it is often possible to eliminate or reduce SCC sensitivity by modifying either the metallurgical characteristics of the metal or the makeup of the environment.

Another important characteristic of SCC is the requirement that tensile stress be present. These stresses may be provided by cold work, residual stresses from fabrication, or externally applied loads.

The key to understanding SCC of titanium alloys is the observation that no apparent corrosion, either uniform or localized, usually precedes the cracking process (Ref 48, 49). As a result, it can sometimes be difficult to initiate cracking in laboratory tests by using conventional test techniques.

It is also important to distinguish between the two classes of titanium alloys. The first class, which includes ASTM grades 1, 2, 7, 11, and 12, is immune to SCC except in a few specific environments. These specific environments include anhydrous methanol/halide solutions, nitrogen tetroxide (N_2O_4), red fuming HNO_3, and liquid or solid cadmium. The second class of titanium alloys, including the aerospace titanium alloys, has been found to be susceptible to several additional environments, most notably aqueous chloride solutions. However, this susceptibility is almost always associated with high stress concentrations typical of laboratory testing with loaded, precracked specimens, and generally is not observed with loaded smooth or notched specimens. In fact, the SCC susceptibility identified for these alloys is seldom observed in actual field applications.

Over the years, a variety of mechanisms or models have been proposed to explain SCC phenomena in titanium alloys (Ref 50, 51, 52, 53, and 54). In general, the mechanisms fall into two broad categories. The first category is the anodic electrochemical dissolution in highly localized areas that, aided by the applied tensile stress, propagates cracks into the metal. The second category involves the absorption of a species (often hydrogen) that embrittles the metal just ahead of the advancing crack, thereby promoting further crack growth.

The first mechanism, anodic-assisted cracking, generally begins when a corrosion pit is formed. In the presence of a tensile stress, the pit will produce a stress concentration that deepens the pit. If corrosion is not so rapid as to allow the advancing crack tip to blunt, the crack will continue to advance into the metal and eventually lead to failure. Once a crack initiates, the balance among the crack tip corrosion rate, the crack tip environment, and the crack tip stress state is critical to crack propagation.

The second mechanism, hydrogen-assisted cracking, is said to occur by absorption of hydrogen near the crack tip. Hydrogen absorption leads to embrittlement of the metal and promotes crack formation. The source of hydrogen is normally associated with anodic dissolution (that is, from the concurrent reduction reaction) at freshly exposed metal at the crack tip. As a result, anodic dissolution in the vicinity of the crack tip is normally required for this mechanism to operate. Obviously, this confuses the nature of the true mechanism, because the second mechanism relies to a certain extent upon at least a portion of the first mechanism to generate the embrittling species.

As might be expected, this situation has led to a great deal of discussion in the literature for many years. It is quite likely, given the tremendous diversity of cracking observations, that no single mechanism exists to explain SCC in titanium alloys. Stress-corrosion cracking mechanisms put forth for titanium alloys generally fall into the two categories discussed above. However, there is greater emphasis on the metallurgical aspects of SCC than is typical for other metal systems in the literature. It is sufficient to say that the makeup of the environment, the metallurgical characteristics of the metal, and the stress state of the system all influence the cracking mechanism. If one of these characteristics is altered, it should not be unexpected that a different mechanism may be necessary to explain the SCC phenomenon adequately.

Stress-Corrosion Testing. Because there is likely no universal, predictive mechanism for SCC, one must rely upon experience for successful application of metals in corrosive environments. Experience may come from actual service problems involving SCC or from laboratory tests designed to reveal susceptibility to SCC. It is often the case that service experience is not available, and laboratory tests are the sole basis for material selection.

In testing metals for SCC resistance, two principal variables must be considered: the environment to be employed and the specimen configuration to be selected. An environment must be selected that is representative of that expected in service.

More often than not, this choice is fixed by the intended application. Artificial environments selected to accelerate the test must be recognized as compromises and will not produce wholly reliable information, although they can be used for assessing the relative susceptibilities of various alloys.

Selection of specimen configuration is somewhat different from choosing the test environment in that the investigator is free to choose from a multitude of previously designed configurations. Unfortunately, these configurations do not always produce the same result, nor do they even evaluate the same properties.

Most specimen configurations used for SCC testing fall into three categories:

- *Category 1:* smooth, statically loaded specimens, such as U-bends, C-rings, bent beams, and dead-load tensile bars (ASTM G 30, G 35, G 36, G 38, G 47)
- *Category 2:* notched, and precracked specimens, such as cantilever beams, compact tension specimens, and double-cantilever beams (ASTM E 399)
- *Category 3:* smooth, dynamically loaded specimens, primarily the slow strain rate tensile specimens

Each of these categories is used to evaluate a different characteristic of the SCC process, so comparisons across specimen types can lead to incorrect conclusions.

Category 1 specimens are used to evaluate the susceptibility of a material to both initiation and propagation of SCC. Because the samples are smooth and subjected to a static load, they represent the most favorable conditions a material would experience in service. These samples are least effective when used in metal/environment combinations in which localized corrosion (for example, pitting) is unlikely, because SCC initiation may not occur for a long time. Thus, the test duration chosen is of paramount importance.

This configuration also provides limited quantitative information because the test gives simply all-or-nothing results. Once the specimen is stressed and exposed to an environment, it either cracks or it does not. If it does not crack, it is not assured that SCC cannot occur; the test duration may have been too short, or the stress too low, or the orientation incorrect. Data typically reported in addition to pass or fail usually consist of time to failure at a given stress level or something similar. Obviously, this information is of limited value to the person with the responsibility for selecting materials.

Category 2 specimens are quite different in that the initiation step is avoided by creating a crack in the material prior to the test. The specimen may be statically or dynamically loaded, depending on the information required, but is normally statically loaded. Because a crack is assumed to be present from the start, this configuration approaches worst-case conditions and is quite conservative. In addition, when precracked (fracture mechanics) specimens are used, quantitative information is produced that a designer can use to determine the most appropriate material for the application. For this reason, it is often the case that one notched, precracked specimen can provide far more information than dozens of smooth, statically loaded specimens.

With the category 2 specimen, it is often important that the fatigue precrack be initiated in the environment in which the SCC susceptibility test is to be performed. This is especially true for titanium, because the highly passive nature of the metal may repair the precracked area before the environment of interest can be introduced. Individual evaluations are required to determine whether precracking should be performed in the corrosive environment.

Category 3 specimens were developed from category 1 specimens in order to remove the uncertainty associated with SCC initiation. Because the smooth specimen is dynamically loaded to failure, the investigator is assured of two things. First, the specimen will always fail, although not always as the result of SCC. Second, at some point during the test, a crack will be mechanically produced that may serve as an initiation site for SCC. This specimen configuration also represents a worst-case situation because most materials are not intentionally subjected to mechanical fracture during their real-life exposure. The major difficulty with this configuration stems from the data produced; such data are far from quantitative. The quantitative data derived from these tests, such as the ratio of time to failure in air versus time to failure in the test environment, provide some comparative information, but are of limited value to the materials selector. Therefore, testing with category 3 specimens resolves some of the deficiencies of testing with the category 1 specimen, although it creates several new problems. Unfortunately, like category 1 specimens, the category 3 specimens are also pass/fail and produce essentially no quantifiable data.

Given the obvious advantages of category 2 specimens and the difficulty of initiating SCC on titanium category 1 specimens, it is not surprising that almost all of the laboratory testing of titanium alloys has been performed with category 2 specimens. In the following sections, metallurgical, environmental, and stress effects on the SCC susceptibility of titanium alloys be discussed. The data presented are primarily derived from fracture mechanics test procedures in corrosive environments and, as such, are quantitative in nature. In many cases, results are compared with those attained in noncorrosive environments (often air) to give the reader some appreciation for the degree to which exposure to the environment reduces fracture toughness.

Most fracture toughness data are presented in one of two general forms. The first form is designed to determine the threshold stress intensity required for SCC, K_{ISCC}, and it plots initial stress intensity factor, K_I, versus time to failure. The second form plots crack velocity versus applied stress intensity. The second form can also indicate K_{ISCC} if one exists.

Figure 8 shows several methods of presenting SCC data. Method a is typical of category 1 specimens, and methods b and c are typical of category 2 specimens. For category 3 specimens, data are usually presented in tabular form. Detailed information on SCC testing is available in the article "Evaluation of Stress-Corrosion Cracking" in this Volume.

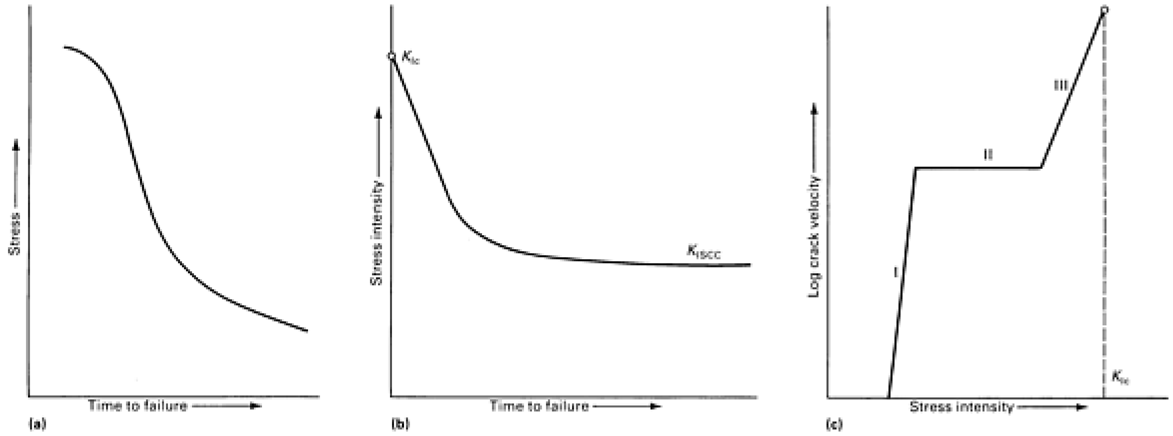

Fig. 8 Typical data representations for SCC using category 1 and category 2 specimens. (a) Stress versus time to failure for category 1 specimens. (b) and (c) Stress intensity versus time to failure and crack velocity versus stress intensity for category 2 specimens

Galvanic Corrosion

The coupling of titanium with dissimilar metals usually does not accelerate the corrosion of titanium. The exception is in strongly reducing environments in which titanium is severely corroding and not readily passivated. In this uncommon situation, accelerated corrosion may occur when titanium is coupled to more noble metals. In its normal passive condition, titanium is beneficially influenced by materials that exhibit more noble (positive) corrosion potentials. In this regard, graphite and various precious metals (such as platinum, palladium, ruthenium, iridium, and gold) provide anodic protection when coupled to titanium by further stabilizing the oxide film of titanium at more noble potentials.

As shown in Table 2, the corrosion potential of titanium under normally passive conditions is quite noble, but similar to stainless steel or nickel-base alloys in the passive condition. The small potential difference between these passive engineering alloys generally mean negligible galvanic interactions and good galvanic compatibility as long as passive conditions prevail for the alloys involved.

(a) No longer listed by the Copper Development Association; admiralty brasses are now inhibited with small additions of arsenic (CDA C44300), antimony (C44400), or phosphorus (C44500).

However, when titanium is coupled to a metal that is active in an environment, accelerated anodic attack of the active metal may result. The rate of accelerated attack depends on many factors, including the cathode-to-anode surface area ratio, concentration of dissolved cathodic depolarizers (for example, oxygen, or atomic hydrogen), temperature, solution flow velocity, and medium chemistry. Depending on environmental conditions, active metals may include carbon or low-alloy steels, aluminum, zinc, copper alloys, or stainless steels that are active (depassivated) or pitting. When galvanic corrosion is unacceptably high, consideration should be given to all-titanium component design, coupling to more compatible (passive) alloys, use of dielectric (insulating) joints, or cathodic protection of the active metal.

As discussed in the section "Hydrogen Damage," attention should be given to possible excessive hydrogen uptake by titanium when it is galvanically coupled to active metals. This is of concern in α titanium alloys when temperatures exceed 80 °C (175 °F) in conductive aqueous media, especially when hydrogen recombination poisons, such as sulfide ion (S^{2-}), arsenic, or cyanide ion (CN^-), are present.

Information on the evaluation of galvanic attack is available in the article "Evaluation of Galvanic Corrosion" in this Volume.

Erosion-Corrosion

Erosion-corrosion is defined as the acceleration in metal corrosion rate because of relative movement between a corrosive fluid and a metal surface. This form of attack is highly dependent on fluid velocity and is favored in areas where high local turbulence, impingement, or cavitation of the fluid occur on metal surfaces. Suspended solids in fluid can also result in abrasion, which can drastically accelerate metal removal.

In normal passive environments, the hard, tenacious TiO_2 surface film of titanium provides a superb barrier to erosion-corrosion. For this reason, titanium alloys can withstand flowing water or seawater velocities as high as 30 m/s (100 ft/s) with insignificant metal loss. The ability of the oxide film to repair itself when damaged and the intrinsic hardness of

titanium alloys both contribute to their excellent resistance to erosion-corrosion. Therefore, inlet turbulence in shell and tube heat exchangers, entrained gas bubble impingement, and pump cavitation effects are generally not of concern in titanium tubing, piping, and other components.

Titanium alloys exhibit relatively high resistance to fluids containing suspended solids. Critical velocities for excessive metal removal depend on the concentration, shape, size, and hardness of the suspended particles, in addition to fluid impingement angle (Ref 55), local turbulence, and titanium alloy properties. The typically low concentrations of silt entrained in seawater are generally of little consequence, but continuous exposure to high-velocity slurries of hard particles can lead to finite metal removal. The harder higher-strength titanium alloys, such as grade 4 or 5, may offer improved erosion resistance when marginal erosion of the softer unalloyed titanium grades is observed. When abrasive conditions are severe, application of hard surface coatings should be considered. In potential applications involving high-velocity slurries or suspended solids, it is advisable to conduct erosion tests whenever possible.

Corrosion Fatigue

Corrosion fatigue refers to the reduction in fatigue resistance of a metal due to the presence of a corrosive medium. Because of the protective oxide film of titanium, the smooth or notched fatigue strength of the more common titanium alloys (Table 1) and their weldments is not significantly affected by water, seawater, and many other aqueous chloride media (Ref 56, 57, 58, 59, 60). These alloys typically exhibit smooth fatigue run-out stress to tensile strength ratios in the range of 0.5 to 0.6, which remain unchanged in 3.5% sodium chloride (NaCl) solutions and in seawater (Ref 58, 61).

Corrosion in Specific Media

The corrosion rate data reviewed in the following sections were generated from both laboratory and field tests and, in some cases, from actual equipment service. Most of the data are derived from weight change measurements involving varying exposure periods. Samples of plate and sheet in the fully annealed condition were tested, most frequently in the as-pickled surface condition.

These corrosion rate values should be used as general indicators of corrosion resistance, but it must be recognized that corrosion rates can change with exposure time. For example, corrosion rates often decrease with exposure time in normal passive environments; this reflects the finite growth of the protective oxide film. In addition, these values do not always reveal whether the alloy is in a fully passive or stable condition. Therefore, supplemental electrochemical testing may be necessary when borderline passivity, such as in reducing environments, is suspected. Finally, it should be recognized that titanium alloy corrosion behavior is highly sensitive to small, even trace, concentrations of various oxidizing or complexing species in normally aggressive, reducing environments. Therefore, it is necessary to take all trace species or background contaminants in the anticipated service (degree of aeration, and so on) into account when deciding alloy suitability based on pure or simplified simulated medium chemistry. In cases in which the simulation of complex or variable media chemistry is difficult, *in situ* testing is recommended if possible. Supplemental corrosion data not presented in these sections can be found in the Appendices to this article.

General Corrosion in Specific Media

Water and Seawater. Titanium and its alloys are fully resistant to water, all natural waters, and steam to temperatures in excess of 315 °C (600 °F) (Ref 62). Slight weight gain is usually experienced in these benign environments, along with some surface discoloration at higher temperatures from finite passive film thickening. The immunity to attack of α alloys is observed regardless of oxygen level or in high-purity water, such as that normally used in nuclear reactor coolant systems (Ref 63, 64, 65, 66, and 67). The typical contaminants encountered in natural water streams, such as iron and manganese oxides, sulfides, sulfates, carbonates, and chlorides, do not compromise the passivity of titanium. In media containing chloride levels greater than 1000 ppm (for example, seawater) at temperatures about 75 °C (165 °F), consideration should be given to possible crevice corrosion when tight crevices exist in service (see the section "Crevice Corrosion" in this article).

Titanium alloys exhibit negligible corrosion rates in seawater to temperatures as high as 260 °C (500 °F). As shown in Table 3, extremely low corrosion rates of unalloyed titanium and Ti-6Al-4V after up to 3 years of exposure in ambient seawater are recorded. Pitting and crevice corrosion are totally absent in ambient seawater, even if marine deposits form and biofouling occurs. Titanium tubing exposed for 16 years to polluted and sulfide-containing seawater shows no evidence of corrosion (Ref 72). Similar reports of nil corrosion rate in ambient seawater have been reported for unalloyed titanium (Ref 73, 74) and titanium alloys, such as Ti-5Al-2Sn, Ti-13V-11Cr-3Al, Ti-6Al-2Nb-1Ta-0.8Mo, and titanium-palladium (Ref 74, 75, 76, and 77). Exposure of titanium to marine atmospheres (Ref 74, 78), splash or tide zone, and soils also does not cause corrosion (Ref 68, 69, 70, 71, and 79). As indicated in the section "Erosion-Corrosion" in this article, the excellent resistance of titanium to seawater is relatively unaffected by velocity.

Table 3 Corrosion of titanium in ambient seawater

Alloy	Ocean depth		Corrosion rate	
	m	ft	mm/yr	mils/yr
Unalloyed titanium	Shallow		8×10^{-7}	0.00003
Unalloyed titanium	720-2070	2360-6800	$<2.5 \times 10^{-4}$	<0.1

Ti-6Al-4V	1720	5640	8×10^{-6}	0.0003
Ti-6Al-4V	1720	5640	$<1 \times 10^{-3}$	<0.04

Source: Ref 67, 68, 69, 70, 71

Unalloyed titanium has provided more than 20 years of outstanding service in seawater for the chemical, oil refining, desalination, and power industries. As result of its immunity to ambient seawater corrosion, titanium is considered to be the technically correct material for many critical marine applications, including many naval and offshore components. More information on the applications of titanium in these industries is available in the articles "Corrosion in the Chemical Processing Industry," "Corrosion in Petroleum Refining and Petrochemical Operations," "Corrosion in the Nuclear Power Industry," and "Corrosion in Fossil Fuel Power Plants" in this Volume.

Oxidizing Media. Titanium alloys are generally highly resistant to oxidizing media and oxidizing acids over a wide range of concentrations and temperatures. Common chemicals in this category include chromic, nitric, perchloric, and hypochlorous acids and salts of these acids. Other oxidizing salts include thiosulfates, vanadates, permanganates, and molybdates. Corrosion rates at and below the boiling point of these aqueous salt solutions over the full range of concentration will typically be less than 0.03 mm/yr (1.2 mils/yr). Data for unalloyed titanium chromic acid solutions are given in Table 4.

Table 4 Corrosion of unalloyed titanium in chromic acid solutions

Concentration of CrO_3, %	Temperature		Corrosion rate	
	°C	**°F**	**mm/yr**	**mils/yr**

Nitric Acid. Unalloyed titanium has been extensively used for handling and producing nitric acid in applications in which stainless steels have experienced significant uniform or intergranular attack (Ref 67, 81, 82, and 83). Titanium offers excellent resistance over the full concentration range at subboiling temperatures. As temperatures exceed 80 °C (175 °F), however, the corrosion resistance becomes highly dependent on nitric acid purity.

In hot, very pure solutions or vapor condensates of nitric acid, significant uniform corrosion rates may occur, particularly as temperatures increase. The data plotted in Fig. 9 and 10 show that the mid-range HNO_3 concentrations (20 to 70 wt%) are most aggressive when full inhibition to attack is not achieved in pure refreshed solutions. In these situations, semiprotective oxide surface films form that do not fully retard continued oxidation of the metal surface.

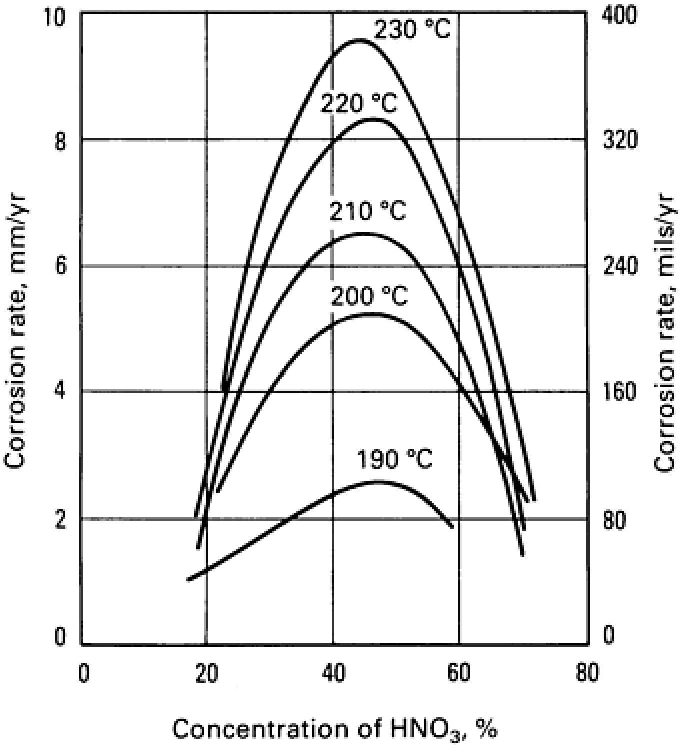

Fig. 9 Corrosion of unalloyed titanium in high-temperature HNO_3 solutions. Source: Ref 80, 86

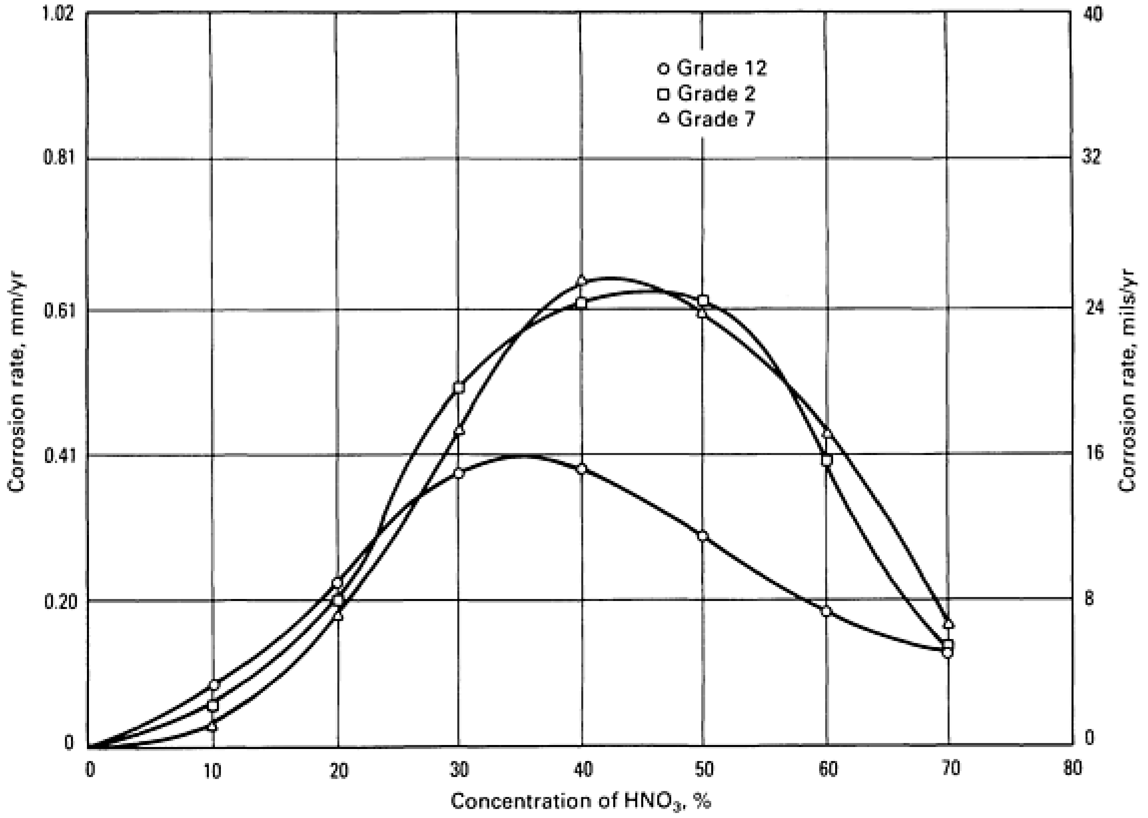

Fig. 10 Corrosion of titanium alloys in boiling, uninhibited HNO_3 solutions. Acid solutions were refreshed every

24 h.

As the impurity levels increase in hot HNO_3 solutions, the resistance of unalloyed titanium improves dramatically. In particular, relatively small amounts of certain dissolved metallic species, including Si^{4+}, Cr^{6+}, Fe^{3+}, Ti^{4+}, or various precious metal ions, can effectively inhibit the high-temperature corrosion of titanium in nitric acid (Ref 67, 82, 83, 84, 85, 86, 87, 88, and 89). This inhibitive effect is very potent, as shown in Fig. 11 and 12 for Cr^{6+} and Ti^{4+}, respectively, and in Table 5 for Ti^{4+}. Thus, titanium exhibits excellent resistance to recirculating nitric acid process streams, such as stripper reboiler loops (Table 6) in which steady-state levels of dissolved Ti^{4+} inhibitor are achieved. Hold tanks and stripper sumps are also good applications for similar reasons. Another good example of this inhibitive effect is the excellent performance of unalloyed titanium in evaporator reboilers and other components in the high-temperature metal-contaminated process streams used for U_3O_8 recovery (Ref 89, 90, 91, and 92).

Table 5 Effect of dissolved Ti^{4+} on the corrosion rate of unalloyed titanium in boiling HNO_3 solutions

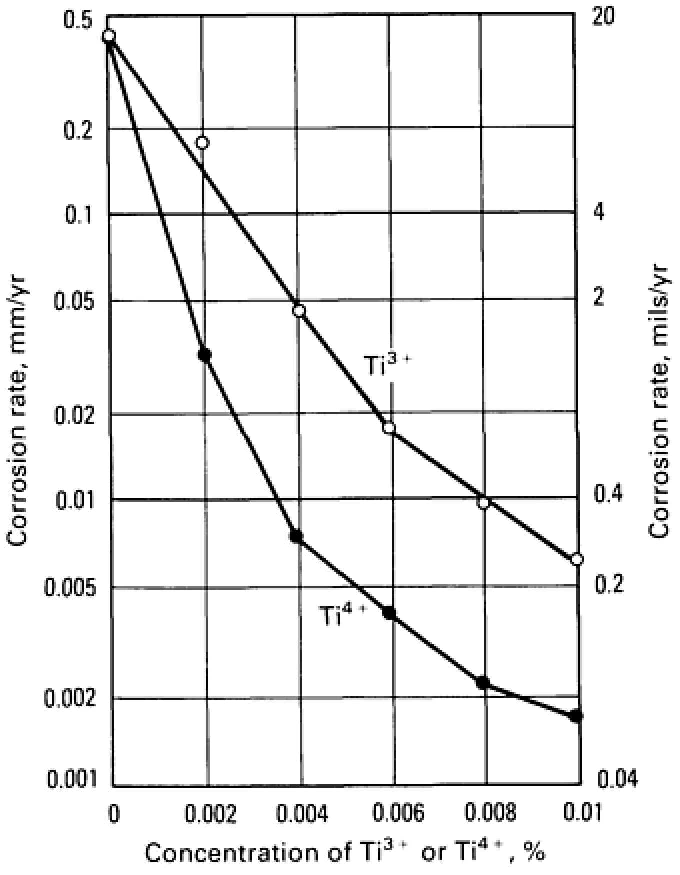

Fig. 12 Inhibitive effect of dissolved Ti^{2+} or Ti^{4+} ions on the corrosion of titanium after 65 h in boiling 6 *N* HNO_3 solutions. Source: Ref 88

The significant discrepancies and variations in titanium corrosion rates in hot HNO_3 media reported by investigators over the years appear to be the result of these inhibitive metal ion effects. Because titanium corrosion is inhibited by its own corrosion product (Ti^{4+}), the titanium surface area to acid volume ratio, the test duration, and the rate of solution replenishment will all be critical to the rate obtained. The container material and acid purity (chemistry) will also be influential. These factors are reviewed in more detail in Ref 93). Based on this information, it is clear that all design and operating factors must be taken into account when evaluating titanium for high-temperature concentrated HNO_3 service.

Limited corrosion testing of α-β and β titanium alloys in boiling HNO_3 indicates that increasing aluminum and β alloying elements tend to decrease corrosion resistance. The corrosion data for various titanium alloys listed in Table 7 show that α alloys are generally most resistant to hot HNO_3. Other studies have shown that high-purity (low iron, sulfur, and so on) unalloyed titanium does not experience the significant accelerated weldment attack in high-temperature HNO_3 exhibited at times by the less pure unalloyed grades and the near-α alloys.

Table 7 Corrosion of various titanium alloys in boiling HNO_3 solutions

Test duration: 196 h

Fuming Nitric Acid. Titanium alloys exhibit good resistance to white fuming nitric acid. However, dangerous and violent pyrophoric reactions may occur with titanium alloys exposed to red fuming nitric acid or to nitrogen tetroxide (see the section "Gases" in this article). The attack is intergranular and results in a surface residue of finely divided titanium particles that are highly reactive. The critical variables are the nitrogen dioxide (NO_2) and water contents of the acid (Fig. 13). Fuming nitric acid containing less than 1.4 to 2.0% water or more than 6% NO_2 may cause this rapid impact-sensitive reaction to occur (Ref 48, 94, 95, 96, 97, and 98). Both water and NO are effective inhibitors for this attack, but increasing oxygen and NO_2 are detrimental in this situation. Corrosion rate data in red fuming nitric acid for various alloys as a function of NO_2 and water content also can be found in Ref 8.

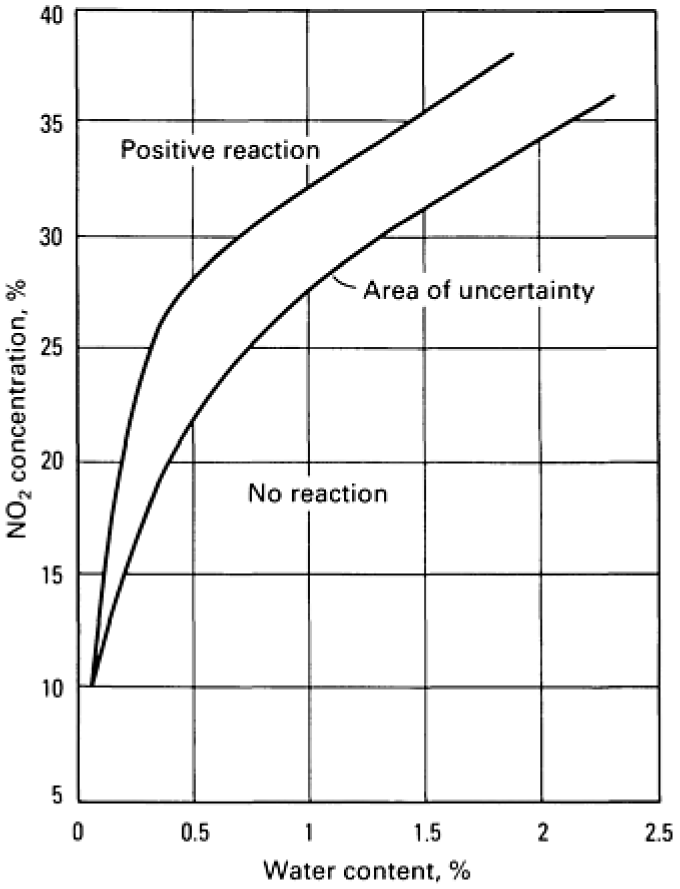

Fig. 13 Acid composition limits for avoiding rapid, pyrophoric reactions of titanium with red fuming HNO_3. Source: Ref 94

Other Oxidizing Media. Titanium alloys exhibit outstanding resistance to solutions of oxidizing chlorine compounds over the full range of concentrations and to relatively high temperatures. Various data for unalloyed titanium are presented in Table 8. Titanium is highly resistant to wet chlorine gas, although a minimum water content must be present, depending on temperature, to maintain full passivity. This is discussed in more detail in the section "Gases" in this article. Titanium is unique among the common engineering alloys in its immunity to general and pitting corrosion in oxidizing chloride environments. These comments also apply to bromine and iodine-containing media. Halide salts of oxidizing cationic species also enhance the passivity of titanium alloys such that negligible corrosion rates can be expected. Examples include $FeCl_3$, $CuCl_2$, and $NiCl_2$ solutions and their bromide counterparts.

Table 8 Corrosion of unalloyed titanium in solutions of oxidizing chlorine compounds

Reagent	Concentration, %	Temperature		Corrosion rate

(a) Welded sample.

Although peroxides are generally oxidizing, titanium alloys can experience general corrosion in aqueous peroxide solutions, depending on concentration, temperature, and pH. As shown in Table 9, corrosion rates are minimal in dilute near-neutral hydrogen peroxide solutions, but increase dramatically under alkaline conditions because of the formation of soluble titanium-peroxyl (complex) compounds (Ref 99, 100). However, corrosion is effectively inhibited by small additions of calcium, strontium, or barium ions (Ref 100). Sodium silicate and sodium hexametaphosphate additions have also been shown to reduce corrosion rates substantially (Ref 99). Significant attack may occur in highly concentrated (90%) H_2O_2 solutions.

(a) Acid solutions were prepared with HCl additions.

Reducing Acids. The corrosion resistance of titanium alloys in reducing acid media is very sensitive to acid concentration, temperature, background chemistry, and purity of the acid solution, in addition to titanium alloy composition. When the temperature and/or concentration of pure (uncontaminated) reducing acid solutions exceed certain values, the protective oxide film of titanium may break down, which would result in severe general corrosion. Included in this category are hydrochloric, sulfuric, hydrobromic, hydriodic, hydrofluoric, phosphoric, sulfamic, oxalic, and trichloroacetic acids.

Temperature-acid concentration guidelines for titanium grades 2, 7, and 12 in naturally aerated but pure (uninhibited) HCl, H_2SO_4, and H_3PO_4 solutions are presented in Fig. 14, 15, and 16, respectively. Supplemental corrosion data in these acids are provided in Tables 10, 11, 12 and in the Appendices to this article. Table 13 lists data for several alloys in HBr and HI solutions. Corrosion data for unalloyed titanium in highly concentrated and SO_3-fuming H_2SO_4 media can be found in Ref 8. It should be noted that the grade 7 (or 11) titanium alloy exhibits substantially greater resistance to dilute uninhibited reducing acids than any other commercial titanium alloy. General corrosion rates for as-annealed high-strength titanium alloys in uninhibited boiling HCl solutions are plotted in Fig. 17, 18, and 19 (Ref 14). Figure 20 suggests that aging has little effect on the general resistance of a titanium alloy to HCl (Ref 14). The beneficial effect of molybdenum alloying additions on alloy corrosion resistance is apparent from these results.

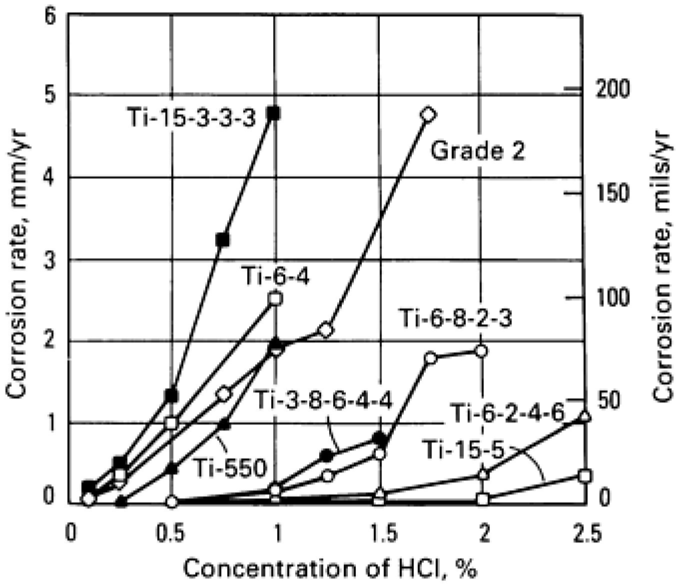

Fig. 20 General corrosion of aged titanium alloys in naturally aerated HCl solutions

Hydrofluoric acid solutions can aggressively attack titanium alloys over the full range of concentrations and temperatures, because the fluoride ion (F^-) forms highly stable, soluble complexes with titanium. Although the addition of oxidizing species, such as HNO_3, will tend to reduce corrosion and retard hydrogen uptake in HF solutions, significant rates of attack still prevail. Inhibition of corrosion can be achieved in very dilute acid fluoride solutions when an excess of complexing metal ions (for example, Fe^{3+}, Al^{3+}, and Cr^{6+}) is present (Ref 101, 102). In the absence of these complexing metal ions, solutions containing more than 20 ppm F^- may attack titanium when solution pH falls below 6 to 7.

Titanium alloys exhibit good resistance to most mildly reducing acid solutions whether they are inhibited or not. These environments include sulfurous acid, aqueous hydrogen sulfide solutions, boric acid, or carbonic acid. Near-nil corrosion rates can be expected over the full concentration range to temperatures well beyond their boiling points (Ref 26, 80, and 103).

Inhibition of Reducing Acid Corrosion. Although strong reducing acids may seriously corrode titanium alloys in pure form, the presence of certain oxidizing species (cathodic depolarizers) in these acids can effectively inhibit general corrosion; this expands the useful range of application of these alloys. These species may be prime constituents of a process stream, naturally occurring background contaminants (such as dissolved oxygen), intentionally added inhibitors, or ferrous corrosion products.

The inhibitors commonly encountered in industrial service are listed in Table 14. Many of these effective inhibitors are multivalent metal ions in their highest valence states. Inhibitor potency at levels as low as 100 ppm or below is typically observed, as indicated by the data presented in Table 15 and those listed under the respective acids in the Appendices to this article. The beneficial influence of minute ferric ion concentrations on the useful resistance of titanium grades 2, 7, and 12 in HCl media is shown in Fig. 21. Nitric acid or nitrate additions effectively inhibit titanium alloy corrosion on HCl media, but more limited inhibition is observed in H_2SO_4 and H_3PO_4 solutions containing nitric acid or nitrates.

Table 14 Species that inhibit the corrosion of titanium alloys in reducing acids

Inhibitor category	Species	Relative inhibitor potency
Oxidizing metal cations	Ti^{4+}, Fe^{3+}, Cu^{2+}, Hg^{4+}, Ce^{4+}, Sn^{4+}, VO_2^+, Te^{4+}, Te^{6+}, Se^{4+}, Se^{6+}, Ni^{2+}	High
		High
		Low
Oxidizing anions	ClO_4^{2-}, $CR_2O_7^{2-}$, MoO_4^{2-}, MnO_4^{2-}, WO_4^-, IO_3^-, VO_4^{3-}, VO_3^-, NO_3^-, NO_2^-, $S_2O_3^{2-}$	Very High
		Very high
		Moderate
Precious metal ions	Pt^{2+}, Pt^{4+}, Pd^{2+}, Ru^{3+}, Ir^{3+}, Rh^{3+}, Au^{3+}	High
		High
Oxidizing organic compounds	Picric acid, *o*-dinitrobenzene, 8-nitroquinoline, *m*-nitroacetanilide, trinitrobenzoic acid, and certain other nitro, nitroso, and quinone organics	Moderate-high
Others	O_2, H_2O_2, ClO_3^-, OCl^-	Moderate

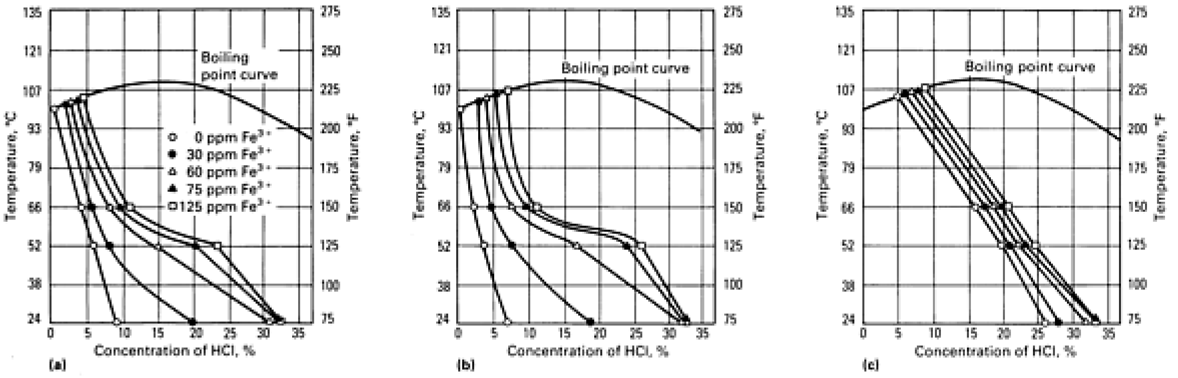

Fig. 21 Effect of minute Fe^{3+} ion concentrations on the useful corrosion resistance of grades 2 (a), 12 (b), and 7 (c) titanium in naturally aerated HCl solutions. 0.127-mm/yr (5-mils/yr) isocorrosion lines are shown.

Because the performance of titanium alloys in reducing acids is highly influenced by the presence of many inhibiting species, the nature and background chemistry of a reducing acid environment should be thoroughly examined before determining alloy suitability. Titanium is often selected for normally aggressive reducing acid solutions, such as the hydrometallurgical acid-leaching process streams for metallic ores, because of the beneficial effect of these inhibitive ions (Ref 106).

Anodic protection is also an effective means of passivating and protecting titanium alloys in reducing acids. Table 16 shows that impressed anodic potentials can significantly reduce the corrosion rate of unalloyed titanium in various hot, concentrated acids. Generally, an increase in anodic potential will decrease the corrosion rate as long as the anodic pitting potential is not exceeded for titanium in the electrolyte. Information on the mechanism of and apparatus for anodic protection is available in the article "Anodic Protection" in this Volume.

Table 16 Effect of impressed anodic potentials on the corrosion of unalloyed titanium in hot reducing acids

Salt Solutions. Titanium alloys are highly resistant to practically all salt solutions over the pH range of 3 to 11 and to temperatures well in excess of boiling. Titanium withstands exposure to solutions of chlorides (Ref 26, 109), bromides, iodides, sulfites, sulfates, borates, phosphates, cyanides, carbonates, bicarbonates, and ammonium compounds. Corrosion rate values for titanium alloys in these various salt solutions are generally less than 0.03 mm/yr (1.2 mils/yr) and can be found in the Appendices to this article as reported by various sources (Ref 8, 26, 80, 109, and 110).

Oxidizing anionic salts such as nitrates, hypochlorites, chlorites, chlorates, perchlorates, molybdates, chromates, permanganates, and vanadates further extend titanium alloy passivity into stronger acidic and alkaline solutions. Similar beneficial effects on the low-pH (acidic) side can be expected from oxidizing cationic salts, such as ferric, cupric, and nickelous chlorides or sulfates. In fact, titanium is often the most practical metal for handling hot, oxidizing, acidic chloride conditions.

Titanium alloys are frequently selected because of their superior resistance to the chlorides typically found in many process streams, brines, and seawater. In hot chloride media, susceptibility to pitting is usually not an issue, but crevice corrosion may be possible, depending on pH and temperature (see the section "Crevice Corrosion" in this article). Special attention must be given to nonoxidizing acidic or hydrolyzable salt solutions as temperatures and concentrations increase. To avoid general or localized HCl attack resulting from salt hydrolysis, special concentration-temperature guidelines for titanium should be observed for concentrated $AlCl_3$ (Ref 8, 109), $ZnCl_2$ (Ref 111), $MgCl_2$ (Ref 112), and $CaCl_2$ solutions. Guidelines for titanium grades 2, 7, and 12 in hot concentrated $MgCl_2$ and in concentrated sea salt and NaCl slurries are presented in Fig. 22 and 23, respectively, and in Fig. 24 for concentrated $CaCl_2$ brines. Grades 12 and 7 and higher molybdenum-containing titanium alloys exhibit superior resistance to general and localized corrosion in these high-temperature acid salt solutions.

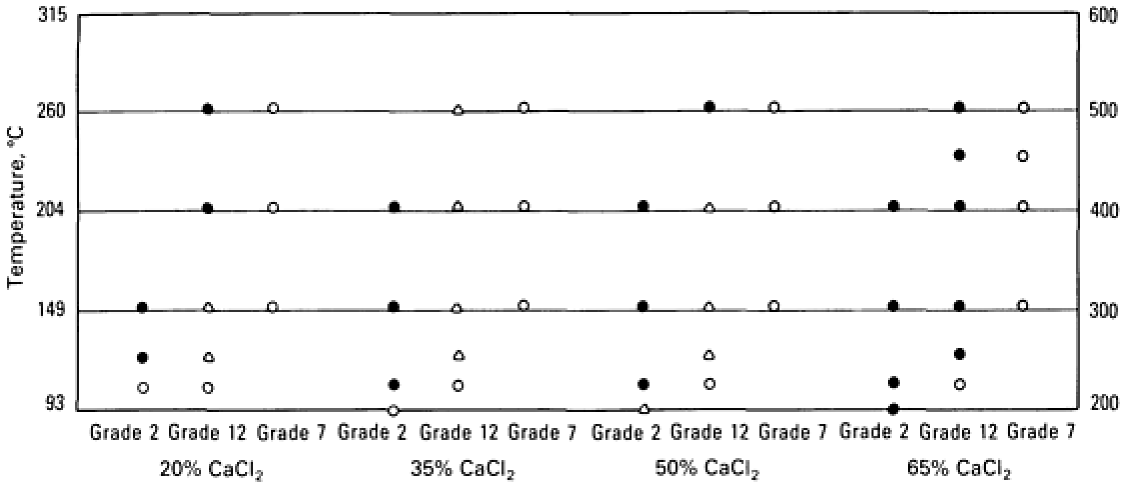

Fig. 24 Temperature guidelines for avoiding localized attack of grades 2, 7, and 12 titanium in concentrated $CaCl_2$ solutions in the absence of crevices. • denotes susceptibility to localized attack; △ indicates incipient edge attack.

Alkaline Media. Titanium alloys are generally very resistant to alkaline media, including solutions of NaOH, KOH, $Ca(OH)_2$, $Mg(OH)_2$, and NH_4OH (Ref 26). Near-nil corrosion rates can be expected in boiling solutions of the latter three alkalies up to saturation. As shown in Table 17, titanium exhibits low corrosion rates in NaOH and KOH solutions at subboiling temperatures. However, significant increases in corrosion are noted as the concentrations of these two strong alkalies increase at higher temperatures. Potassium hydroxide tends to be more aggressive than sodium hydroxide under these conditions.

Table 17 Corrosion of unalloyed titanium in highly alkaline solutions

Medium	Concentration, %	Temperature		Corrosion rate	
		°C	**°F**	**mm/yr**	**mils/yr**

Source: Ref 8, 26, 67, 80

Although corrosion rates are relatively low in alkaline media, titanium alloys may experience excessive hydrogen pickup and eventual embrittlement under certain conditions. For α and near-α alloys, hydrogen embrittlement is possible when temperatures exceed 80 °C (175 °F) and pH is 12 or more. The presence of dissolved oxidizing species in hot caustic

solutions, such as chlorate, hypochlorite, or nitrate compounds, can extend resistance to hydrogen uptake to somewhat higher temperatures.

Organic Compounds. As indicated in Table 18, titanium alloys are highly resistant to most organic compounds, including alcohols, ketones, ethers, aldehydes, and hydrocarbons. The traces of moisture (ppm levels) normally present in industrial organic process streams are sufficient to maintain the protective oxide film of titanium. Totally anhydrous organic streams may prevent oxide film repair and should be avoided. In the special case of absolute methanol, at least 1.5% H_2O must be added to prevent depassivation and SCC (Ref 113, 114, 115, 116). Higher molecular weight alcohols are generally quite benign toward titanium alloys.

Table 18 Corrosion of unalloyed titanium in organic media

Medium	Concentration, %	Temperature, °C (°F)	Corrosion rate	
			mm/yr	**mils/yr**

Chlorinated hydrocarbons generally do not pose any problems for most titanium alloys (Table 18). A few high-strength alloys may be susceptible to SCC under specific circumstances (see the section "Stress-Corrosion Cracking" in this article). If significant quantities of water are also present, many chlorinated hydrocarbons may undergo hydrolysis to form HCl at higher temperatures. Titanium alloy performance will depend on the temperature and the extent of HCl formation and concentration in the aqueous phase.

Titanium alloys are generally very resistant to organic acids. Nil corrosion can be expected in concentrated solutions of very weak organic acids such as adipic, hydroxyacetic, acetic, terephthalic, tannic, stearic, maleric, tartaric, benzoic, butyric, and succinic acids to temperatures in excess of 100 °C (212 °F). Table 19 provides a selection of corrosion rates derived from several sources. Corrosion rates can become significant in the stronger, nonaerated organic acids as acid concentration and temperature increase. These acids include formic, lactic, citric, trichloroacetic, and, especially, oxalic acid (see data in the Appendices to this article). Grades 7 and 12 exhibit much greater resistance to these acids than unalloyed titanium.

Table 19 Corrosion of titanium alloys in various organic acids

Acid	Concentration, %	Alloy	Temperature, °C (°F)	Corrosion rate	
				mm/yr	**mils/yr**
Acetic	0-99.5	Grades 2, 7, 12	Boiling	nil	
Adipic	67	Grade 2	240 (465)	nil

Trichloroacetic	100	Grade 2	Boiling	14.6	575

Source: Ref 8, 26, 80, 103, and 109

Solution aeration is often sufficient to inhibit corrosion on unalloyed titanium in the stronger organic acids, such as formic, lactic, and citric (Ref 8, 26, and 80). Addition of oxidizing species (Table 14) may also effectively inhibit corrosion in the more aggressive organic acids, such as oxalic.

Gases. The oxide film on titanium alloys provides an effective barrier to attack by most gases in wet or dry condition, including oxygen, nitrogen, dry HCl, SO_2, NH_3, HCN, CO_2, CO, and H_2S (Ref 117). This protection extends to temperatures in excess of 150 °C (300 °F). The outstanding resistance of titanium alloys to rural, marine, and urban atmospheric exposure has been documented (Ref 78).

Titanium alloys experience no significant corrosion degradation in oxygen or sulfur-bearing gases below 300 °C (570 °F). Excessive surface oxidation and eventual interstitial embrittlement may occur above 340 to 370 °C (645 to 700 °F) after prolonged, continuous exposure to air, depending on alloy composition. Embrittlement is the result of the enhanced diffusion rate of interstitial oxygen into the metal at higher temperatures such that time to failure will also depend on metal section thickness and state of stress.

Titanium alloys exhibit reasonably good oxidation resistance to temperatures of approximately 550 °C (1020 °F) in short-term (less than several hours) air exposures. Studies have shown that aluminum, silicon, and niobium improve the oxidation resistance of titanium but that vanadium, iron, and certain other β-stabilizing elements may increase oxidation

rates (Ref 8, 118). Other sources suggest that oxidation rates (kinetics) depend on gas composition, temperature, and exposure time (Ref 8). Below approximately 200 °C (390 °F), a logarithmic dependence with time is typical, but a parabolic rate law (Ref 8, 118) and a logarithmic rate law (Ref 8, 119, and 120) have both been measured between 200 and 700 °C (390 and 1290 °F). The growth of thermal oxide films on unalloyed titanium in the air at 400 to 700 °C (750 to 1290 °F) is plotted in Fig. 25 as a function of time. Above 700 °C (1290 °F), a linear dependence of rate with time is typical, indicating little protective effect by the surface oxide.

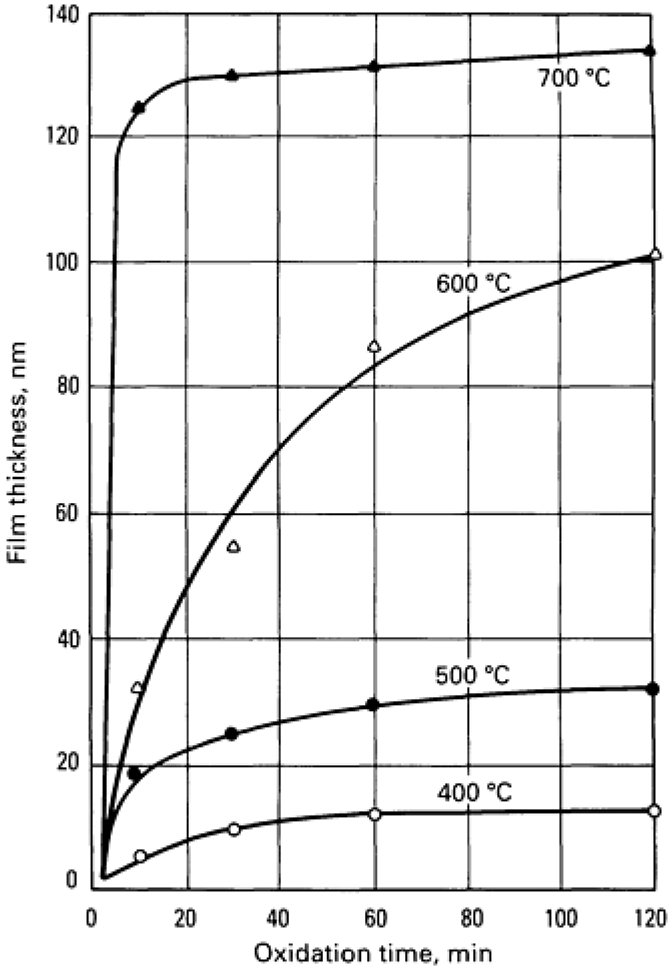

Fig. 25 Growth of thermal oxide films on unalloyed titanium in air. Source: Ref 120

Although the ignition of titanium alloys in normal air is generally not of concern in typical mill product forms (except powders), ignition is possible in enriched oxygen atmospheres. Figure 26 shows that ignition may occur when oxygen content exceeds 35 vol%. Thresholds for the ignition of unalloyed titanium in pure oxygen gas are plotted in Fig. 27 as a function of pressure and temperature. Ignition thresholds in low-temperature gaseous oxygen are provided in Fig. 28. Titanium alloys exhibit impact sensitivity in liquid oxygen (Ref 123). Ignition is not easily achieved unless the oxide film is mechanically damaged and fresh metal surfaces are exposed.

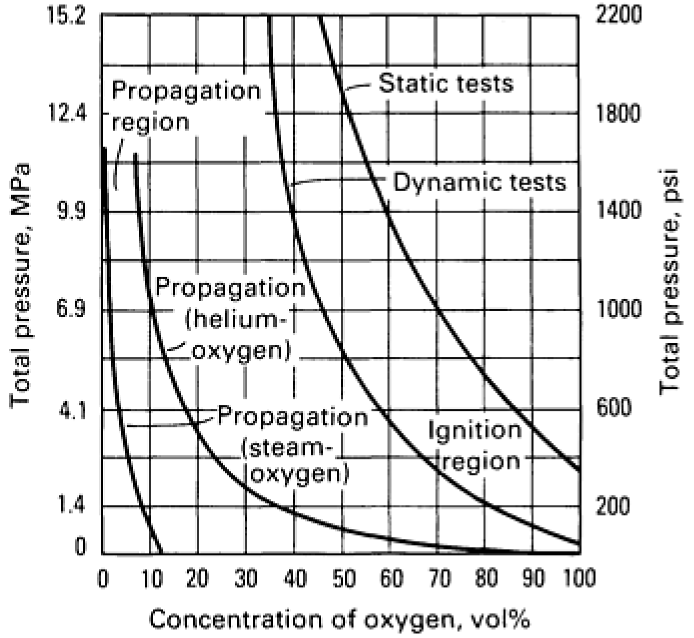

Fig. 26 Ignition and crack propagation limits for unalloyed titanium in various oxygen gas mixtures. Source: Ref 121, 122

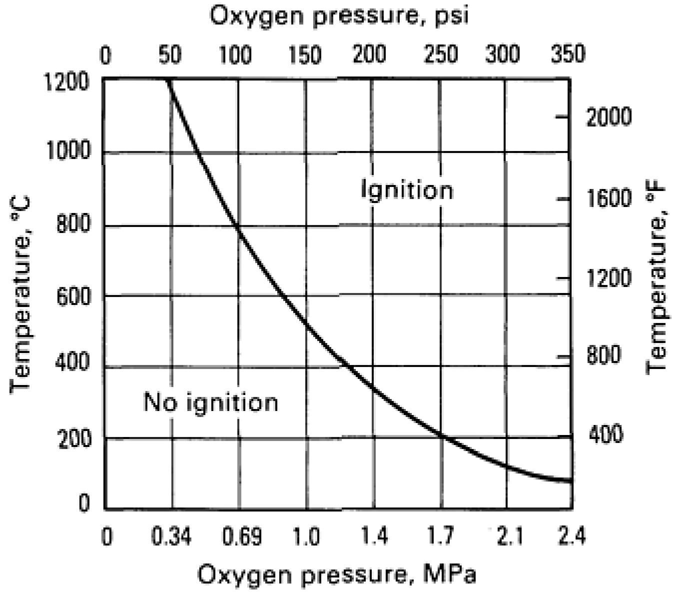

Fig. 27 Ignition limits for ruptured unalloyed titanium in pure oxygen gas atmospheres. Source: Ref 122

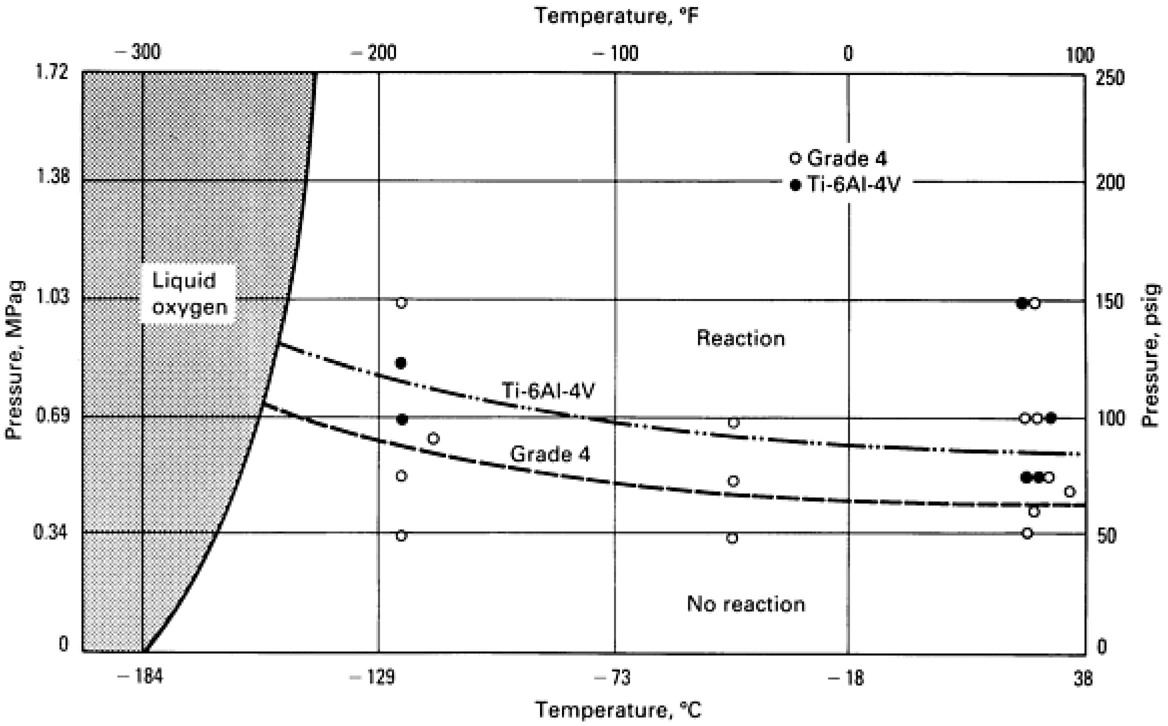

Fig. 28 Ignition limits for grade 4 titanium and Ti-6Al-4V alloy in low-temperature pure oxygen atmospheres. Source: Ref 67, 121

Ignition and burning of titanium alloys can be avoided in oxygen-rich atmospheres by proper equipment design, surface coatings, and/or avoidance of mechanical damage to exposed titanium surfaces (Ref 106). Recommended guidelines for preventing ignition of titanium powders have also been established (Ref 124).

Titanium alloys exhibit very low reaction rates in pure nitrogen atmospheres below 650 °C (1200 °F) because of the formation of a protective nitride surface film. Reaction and diffusion rates are significantly lower than those observed in oxygen (Ref 8).

Although titanium is the preferred metallic material for handling wet chloride and bromine gas environments, rapid, dangerous, exothermic halogenation reactions may occur with titanium in dry chlorine and bromine gas environments. A minimum water content (or oxygen content) in these cases is necessary to maintain total alloy passivity, as indicated in Fig. 29 and 30. The critical water content depends on gas temperature and flow rate. Mechanical damage to metal surfaces to expose fresh metal facilitates reaction with dry chlorine, but thicker oxide films (thermal oxides) tend to retard initiation of the reaction. Titanium alloys cannot be fully passivated in liquid bromine, because of the extremely low solubility of water in this medium.

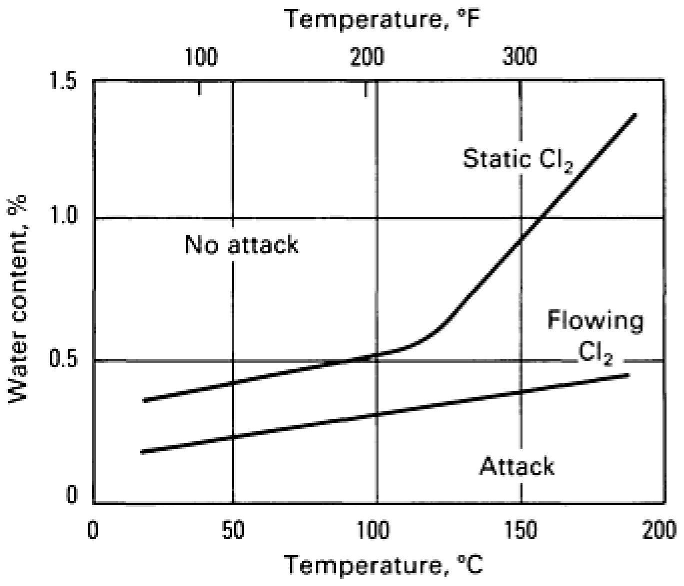

Fig. 29 Effect of temperature and gas flow on the critical water content required to passivate titanium in pure chlorine gas. Source: Ref 125

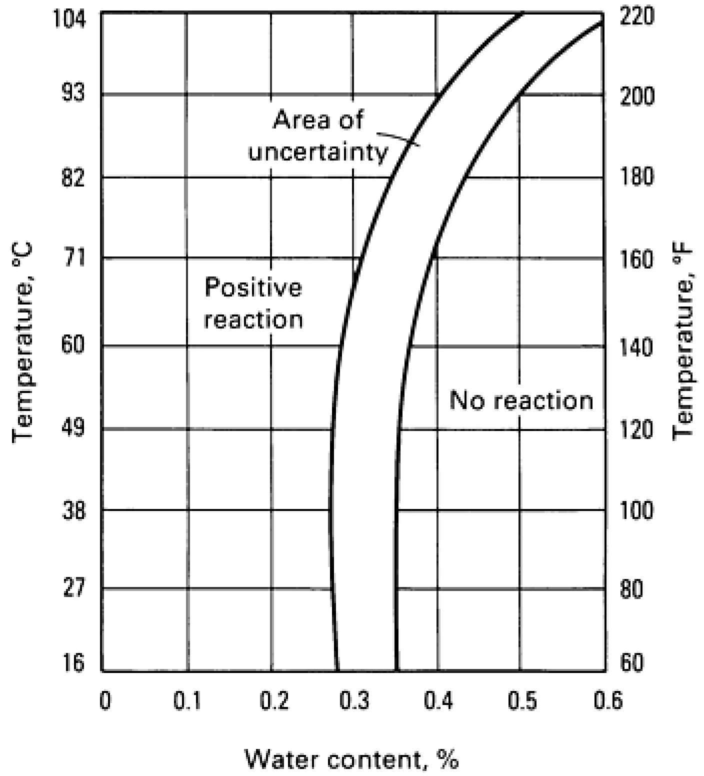

Fig. 30 Water content necessary to maintain passivity of unalloyed titanium in static chlorine gas atmospheres. Source: Ref 126

Rapid, pyrophoric reactions with titanium alloys are also possible in anhydrous N_2O_4 gas atmospheres (Ref 94, 95, and 96). Small water additions (Ref 127) or the presence of 0.6 to 1.0 wt% nitric acid effectively inhibits metal attack.

Liquid Metals and Fused Salts. Titanium exhibits good resistance to many liquid metals at moderately elevated temperatures, at which corrosion rate increases with temperature and flow rate (Ref 8, 67, 80, and 109). As shown in Table 20, these metals include molten aluminum, sodium, potassium, sodium-potassium mixtures, magnesium, tin, and lead. In contrast, useful performance of titanium in molten lithium, bismuth, zinc, gallium, cadmium, and mercury is limited to relatively low temperatures. Liquid mercury below 150 °C (300 °F) does not appear to affect titanium unless wetting of freshly exposed (mechanically damaged) surfaces occurs (Ref 67). As discussed in the earlier section on SCC, liquid cadmium, silver, and mercury may cause SCC of titanium alloys.

Table 20 Corrosion of unalloyed titanium in liquid metals

Liquid metal	Temperature		Corrosion rate	
	°C	**°F**	**mm/yr**	**mils/yr**
Bismuth-lead	300	570	<0.1	<4
Bismuth-lead	600	1110	0.13-1.3	5-50
Gallium	400	750	0.1	4

Tin	600	1110	0.1-1.0	4-40
Aluminum	750	1380	<0.1	<4
Aluminum	850	1560	≫0.1	≫4
Cadmium	500	930	>1.0	>40
Zinc	445	830	≫1.0	≫40

Titanium exhibits relatively high rates of attack in molten chloride salts, increasing with both temperature and the presence of oxygen. Aggressiveness of attack follows the order: KCl > NaCl > LiCl (Ref 8, 109). High rates of metal dissolution have also been reported in fused sodium carbonate, sodium hydroxide, sodium peroxide, and sodium bisulfate (Ref 109).

Crevice Corrosion in Specific Media

Titanium alloys generally exhibit superior resistance to crevice corrosion as compared to stainless steel and nickel-base alloys (Ref 128). Nevertheless, the susceptibility of titanium alloys to crevice corrosion should be considered when tight crevice exist in hot aqueous chloride, bromide, iodide, or sulfate solutions. Crevice test results indicate that the initiation of crevice corrosion often lacks reproducibility, consistency, and regularity. These test data must be judged relatively to their statistical significance (that is, number of data points). Factors that affect crevice attack significantly include alloy composition, pH, temperature, halide concentration, presence of oxidizing species (cathodic depolarizes), sample surface condition, type of gasket, type of crevice (gasket-to-metal, metal-to-metal, deposit-to-metal), and the crevice geometry, particularly crevice gap (tightness) (Ref 1, 23, 26, 129, 130, and 131).

Chlorides. The susceptibility of titanium alloys to crevice corrosion in hot, concentrated chloride solutions increases significantly as temperatures increase and pH decreases. Figure 31 shows pH-temperature limits for the crevice corrosion of titanium grades 2, 7, and 12. These guidelines have been found to be applicable to most chloride salt solutions, including seawater, over a wide range of chloride concentrations (>0.1%). The limits for grade 2 are applicable to all unalloyed grades as well.

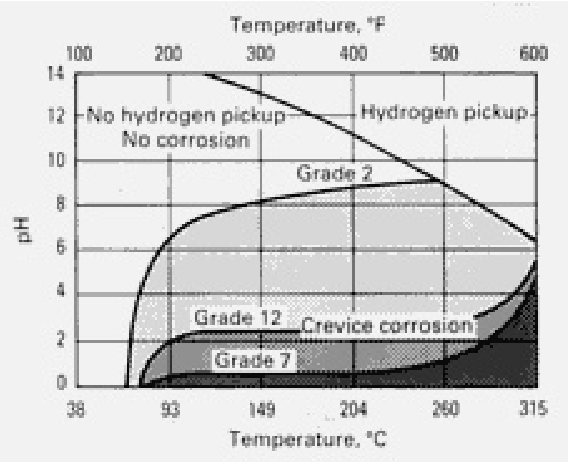

Fig. 31 Temperature-pH limits for crevice corrosion of grades 2, 7, and 12 titanium in saturated NaCl brines. Crevice corrosion will occur in the shaded area. Source: Ref 26, 132

Crevice attack of titanium alloys will generally not occur below a temperature of 70 °C (160 °F) regardless of solution pH or chloride concentration or when solution pH exceeds 10 regardless of temperature. As indicated in Fig. 31 and Table 21, grade 12 provides crevice corrosion resistance when brine pH falls between 3 and 11 to temperatures as high as 300 °C (570 °F). The grade 7 (or 11) alloy extends this resistance to brine pH values as low as 0.6 to 0.7, depending on brine composition and temperature. The grade 7 alloy is considered to be the most crevice corrosion resistant titanium alloy available commercially, and it is often preferred for hot low-pH salt solutions.

Table 21 Resistance of titanium alloys to crevice corrosion in boiling salt solutions

Tight metal-to-gasket crevices were tested.

Solution	pH	Alloy/resistance[(a)]		
		Grade 2	**Grade 12**	**Grade 7**
Saturated $ZnCl_2$	3.0	F	R	R
10% $MgCl_2$	4.2	F	R	R
10% $CaCl_2$	3.0	F	R	R
10% KCl	3.0	F	R	R
Saturated NaCl	3.0	F	R	R
Saturated NaCl + Cl_2	1-2	F	F	R
10% NH_4Cl	4.1	F	R	R
10% $FeCl_3$	0.6	F	F	R
10% Na_2SO_4	2.0	F	R	R

(a) F, failed; R, resistant.

The crevice corrosion resistance of grade 12 titanium was extensively tested in concentrated near-neutral NaCl, NaCl-$MgCl_2$, and NH_4Cl brines at high temperatures. Studies were conducted to assess this alloy for potential application in hypersaline geothermal brine (Ref 132), high-level nuclear waste storage (Ref 134, 135, and 136), oil refineries (Ref 137), and salt evaporator brine heaters (Ref 133). In all cases, crevice testing involving Teflon gasket-to-metal and metal-to-metal crevices for extended periods revealed no evidence of significant attack to temperatures as high as 250 °C (480 °F). In saturated NH_4Cl solution, no gasket-to-metal or under-salt-deposit attack was noted to 177 °C (350 °F) and at pH 3 to 7. Similar performance is noted for grade 7 titanium under these conditions.

It should be cautioned that deviations from normal crevice corrosion guidelines can be expected in certain acidic salts that may hydrolyze to form HCl at high temperatures when highly concentrated (Ref 111, 112). These salts include $MgCl_2$, $CaCl_2$, $ZnCl_2$, and $AlCl_3$. The grade 7 alloy is generally most resistant in these situations (Ref 112).

Teflon gasket-to-metal crevices of various high-strength titanium alloys were also tested in hot NaCl brines. The data, detailed in Ref 13, produced the ranking of alloy resistance shown in Table 22. Relative alloy crevice corrosion resistance generally parallels alloy resistance in reducing acid media. Titanium alloys containing at least 4 wt% Mo exhibit significantly increased crevice corrosion in high-temperature NaCl media down to relatively low pHs. The beneficial effect of higher molybdenum content is confirmed in Teflon gasket-to-metal crevice tests performed on the Ti-3-8-6-4-4 alloy under simulated deep oil well (downhole) conditions (Ref 138). Testing to 300 °C (570 °F) in a pH solution consisting of 250 g/L NaCl, 1 g/L S, and 103-kPa (15-psi) H_2S revealed no susceptibility to crevice attack and indicated superior resistance to grade 12 titanium under these conditions.

Table 22 Ranking of titanium alloy crevice corrosion resistance in NaCl brines at temperatures ≥90 °C (195 °F)

Alloy	Maximum pH at which attack occurred
Least resistant	
Ti-6-4	≥5
Grade 2	≥5
Ti-4-3-1	5
Ti-550	3
Grade 12	2
Transage 210	2
Ti-6-2-4-6	2
Ti-3-8-6-4-4	1
Ti-15-5	<1
Most resistant	

The crevice corrosion resistance of grade 9 titanium appears to be essentially the same as that for unalloyed titanium in hot NaCl brines. On the other hand, the greater aluminum content of the grade 5 alloy results in slightly reduced crevice resistance as compared to unalloyed grades.

Studies have addressed the effect of chloride concentration on crevice corrosion initiation on unalloyed titanium (Ref 130). Threshold temperatures of 250, 200, and 150 °C (480, 390, and 300 °F) were indicated for chloride concentrations of 0.01, 0.1, and 1%, respectively, in neutral (pH 7) NaCl brine. Unpublished results suggest that 0.01% Cl^- at 90 °C (195 °F) and 0.10% Cl^- at 70 °C (160 °F) may be threshold conditions for crevice attack in aerated, pH 3 to 5 solutions given tight Teflon gasket-to-metal crevices.

Tests have shown that crevice tightness and type of gasket are critical to crevice corrosion initiation. Teflon gasket-to-metal crevices are generally more susceptible to crack initiation than silicone rubber, neoprene rubber, asbestos, and polyvinyl chloride (PVC) gasket-to-metal crevices (Ref 23, 129). Certain polymeric sealants, such as styrol-acrylic copolymer or methacrylate polymers, may significantly increase susceptibility to crevice attack, especially when the sealant contains chloride salts (Ref 23, 129). On the other hand, metal-to-metal crevices are generally least susceptible to attack. In addition, it has been found that the incubation time for crevice corrosion on NaCl brine may be reduced, and attack aggravated, by impressed anodic potentials (Ref 23, 129). As reviewed in the previous section on crevice corrosion, certain dissolved oxidizing species (cathodic depolarizers) in the brine may similarly decrease crevice attack incubation period while increasing attack rate.

Bromides and Sulfates. Unpublished test results suggest that the pH-temperature guidelines for crevice corrosion of titanium in saturated NaCl (Fig. 31) are applicable in saturated NaBr solutions. However, the rate of crevice attack is measurably lower than that in chlorides at corresponding pH and temperature values.

For example, crevice testing of unalloyed titanium in saturated Na_2SO_4 solutions revealed attack in neutral solutions at temperatures above 110 °C (230 °F) and only below pH 6 at 104 °C (220 °F) with no attack at 93 °C (200 °F) as low as pH 3. Teflon gasket-to-metal crevices were also exposed to a simulated acid sulfate galvanizing solution for 38 days at temperatures of 66, 82, and 100 °C (150, 180, and 212 °F). The pH 1.3 solution consisted of 100 g/L Na_2SO_4, 120 g/L $ZnSO_4$, 0.6 g/L Fe^{3+} (as $Fe_2(SO_4)_3$), and 0.008% Cl^-. Grade 2 titanium proved to be fully resistant, except at boiling (100 °C, or 212 °F). Grade 7 and 12 titanium alloys resisted crevice attack under all conditions tested. All results indicate that threshold temperatures for crevice corrosion in sulfate solution are measurably higher than those in chloride brines.

Anodic Pitting in Specific Media

Anodic Breakdown Pitting. Titanium exhibits relatively high anodic breakdown potentials, E_b, in aqueous solution as compared to most engineering metals. This is the basis for its use as dimensionally stable anodes for chlor-alkali cells, anodes for recovery of metals or metal oxides from solutions, zinc and nickel plating anode baskets, aluminum anodizing racks, and platinum anode substrates for impressed cathodic protection systems. In sulfate and phosphate media, anodic pitting potentials of titanium alloys are typically in the range of +80 to +100 V (versus Ag/AgCl reference electrode). For this reason, dilute sulfuric and phosphoric acid solutions (and their salts) are typical electrolytes for anodizing titanium to grow protective surface oxides and/or produce colored surfaces.

In halide salt solutions, titanium alloys exhibit somewhat lower but yet reasonably high pitting potentials. Table 23 reveals that the anodic break-down pitting potential decreases measurably with increasing temperature. Values of +9 to +10.5 V (versus Ag/AgCl) can be expected in room-temperature chloride solutions, decreasing to approximately +1.2 V at 175 to 250 °C (345 to 480 °F). These values are dependent on sample surface condition. For example, abraded or sandblasted surfaces exhibit somewhat lower values than as-pickled surfaces. In one study, increasing alloy aluminum content was shown to reduce anodic pitting potential in titanium alloys (Ref 139, 140). Pitting potentials were determined for a 20% NH_4Cl solution under stagnant and flowing (1 m/s, or 3.3 ft/s) conditions (Ref 143). Values were measured at +9 to +10 V at 20 to 40 °C (70 to 100 °F), decreasing into the range of +4.0 to +5.5 V at 120 °C (250 °F). Increased flow rate indicated a minor negative effect on pitting potential. A relatively minor effect by pH and chloride concentration is also observed in NaCl brine (Ref 142).

Table 23 Anodic breakdown pitting potentials, E_b, for titanium alloys in chloride solutions

Alloy	Solution	pH	Temperature		E_b, V[(a)]	Ref
			°C	**°F**		
Grade 2	1 *N* NaCl	7	25	75	+11.0	139
Grade 5	1 *N* NaCl	7	25	75	5.2	139
Grade 2	Saturated NaCl[(b)]	1, 7	25	75	9.6	. . .
Grade 12	Saturated NaCl[(b)]	1, 7	25	75	9.6	. . .
Grade 7	Saturated NaCl[(b)]	1, 7	25	75	9.6	. . .
Grade 5	Saturated NaCl[(b)]	1, 7	25	75	8.9	. . .
Grade 2	Saturated NaCl	1, 7	95	200	5.0-6.5	. . .
Grade 12	Saturated NaCl	1, 7	95	200	5.0-5.7	. . .
Grade 7	Saturated NaCl	1, 7	95	200	5.2-7.0	. . .
Grade 5	Saturated NaCl	1, 7	95	200	2.5-3.4	. . .
Grade 2	1 *N* NaCl	7	125	255	~4.4	140

Grade 2	1 *N* NaCl	7	175	345	~1.2	140
Grade 2	1 *N* NaCl	7	200	390	~1.2	140
Grade 12	Seawater	8	245	475	2.3	141
Grade 12	O_2-saturated seawater	8	245	475	3.3	141
Grade 2	1 *N* KCl + 0.2 *M* H_2SO_4	. . .	25	75	80.0	142

(a) Measured versus Ag/AgCl reference electrode.

(b) Similar values were obtained in synthetic seawater (pH 8).

It was shown that pitting potentials of titanium can be raised in chloride solutions by addition of sulfate ions (Ref 144). Above a critical sulfate concentration, titanium exhibits pitting potential values similar to those obtained in pure sulfate media (Table 23).

As shown in Fig. 32, anodic pitting potential values are significantly lower in bromide solutions, and they decrease with increasing temperature. The dependence of pitting potential on bromide concentration at room temperature is given by (Ref 142):

$$E_b \text{ (versus SCE)} = 1.1 - 0.43 \log [\text{Br}]$$

At room temperature, anodic pitting potentials of +0.90 to +1.4 V have been reported for titanium grades 2 and 5 (Ref 139, 142). One study has reported values for grade 1, 2, and 3 titanium ranging between +1.8 to +2.2 V in 1% NaBr (pH 6) solution at room temperature, decreasing to +1.0 to +1.2 V at 100 °C (212 °F) (Ref 145). As Fig. 32 suggests, pitting potentials may fall to potentials as low as +0.6 to +0.8 V at temperatures above 130 to 150 °C (265 to 300 °F). Thus, pitting of titanium alloys may be possible in pure bromide solutions at higher temperature if highly oxidizing conditions prevail.

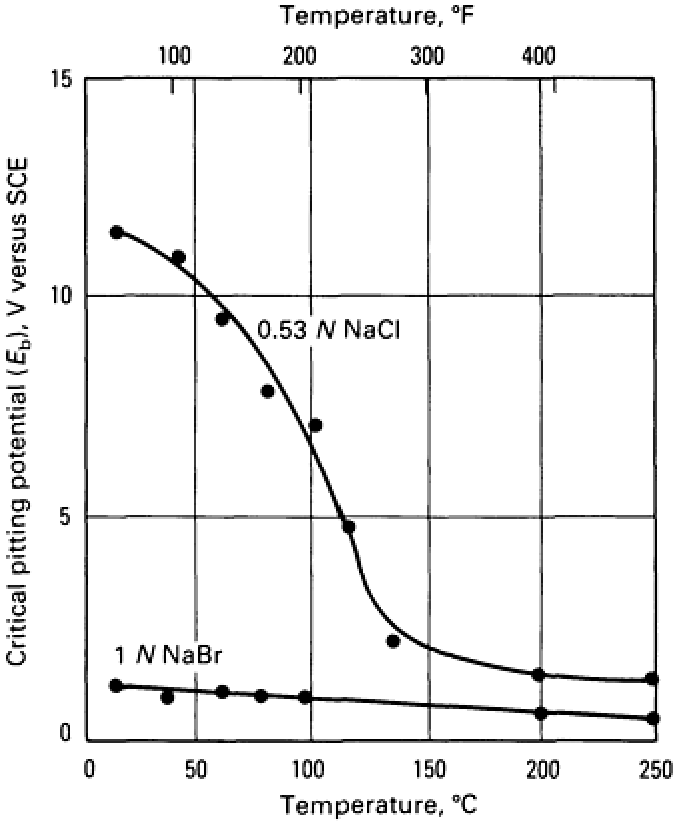

Fig. 32 Effect of temperature on the anodic pitting potential E_b of grade 2 titanium in dilute NaCl and NaBr solutions. Source: Ref 142

However, additions of various oxidizing anions may inhibit pitting in NaBr solutions by significantly raising anodic pitting potentials (Ref 142). Critical concentrations of these inhibitive anions have been determined, and the relative efficiency of inhibition decreases in the order $SO_4^{2-} > NO_3^- > CrO_4^{2-} > PO_4^{3-} > CO_3^{2-}$.

Studies in room-temperature iodide solutions have revealed anodic pitting potentials of +1.7 to +1.8 V, with little effect of acidification indicated (Ref 139, 146). Above 40 to 50 °C (100 to 120 °F), values near +0.5 V (versus SCE) are reported.

Repassivation potentials, E_p, represent conservative measures of anodic pitting tendency because they represent minimum potentials below which pitting cannot be sustained. The values presented in Table 24 show that titanium alloys will not experience spontaneous pitting attack in aqueous chloride media, even if oxidizing species are present. Unalloyed titanium exhibits the highest E_p value, which decreases as alloy aluminum content increases. Increasing iron content over the range of 0.02 to 0.20% results in a minor (several tenths of a volt) decrease in E_p values in unalloyed titanium (Ref 11).

Table 24 Repassivation potentials of as-annealed titanium alloys in boiling chloride media

Alloy	Repassivation potential, V[(a)]		
	5% NaCl (pH 3.5)	**3% HCl**	**Saturated NaCl**
Grade 1	. . .	. . .	+7.0
Grade 2	+6.7	+5.8	+5.7
Ti-6-4	+2.3	+1.7	. . .

Grade 7	. . .	. . .	+5.6

Source: Ref 147

(a) Measured versus Ag/AgCl reference electrode.

Like anodic pitting potentials, repassivation potentials are significantly lower in bromide and iodide media. Room-temperature E_p values of +1.2 and +0.95 V are measured for grades 2 and 5 titanium, respectively (Ref 139), whereas values of +0.9 V in dilute KBr solutions have been reported (Ref 146). Repassivation potentials for grades 2 and 5 titanium in dilute room-temperature iodide solutions have been measured to be +1.8 and +1.5 V, respectively (Ref 139, 146).

Hydrogen Damage in Specific Media

Gaseous Hydrogen. Absorption of hydrogen by titanium alloys in gaseous hydrogen is highly dependent on temperature, gas pressure, gas moisture or oxygen content, metal surface condition, alloy composition, and the nature of the surface oxide formed on the metal (Ref 148). In the absence of surface oxide film interferences, the hydrogen concentration in titanium is directly proportional to the square root of the hydrogen gas partial pressure (Ref 8, 149). Hydrogen absorption is a fully reversible process in that vacuum may remove absorbed hydrogen given sufficient temperatures to promote kinetics and overcome oxide film diffusion barriers. The ability of anodic and thermal oxide films on titanium to retard hydrogen absorption significantly in high-temperature hydrogen gas has been demonstrated (Ref 148, 149, 150, and 151).

As shown in Table 25, absorption of hydrogen by grade 2 titanium in dry hydrogen gas dramatically increases as both pressure and temperature increase. Table 25 also reveals the protective effect of surface oxides (as-pickled and anodized surfaces) and the detrimental effect of iron surface contamination. Similar results for unalloyed titanium are given in Table 26, in which hydrogen gas pressures of 4.1 to 6.2 MPa (600 to 900 psi) and temperatures of 100 to 300 °C (212 to 570 °F) were tested. These results also demonstrate the beneficial effects of gas moisture content. It has been shown that at least 2% H_2O content in 5.5-MPa (800-psi) hydrogen gas at 315 °C (600 °F) effectively retards hydrogen uptake in commercially pure titanium (Ref 150).

Table 25 Hydrogen absorption in grade 2 titanium after 96-h exposures in pure, dry hydrogen

Temperature		Hydrogen pressure		Freshly pickled	Hydrogen absorption, ppm/specimen surface preparation		
°C	**°F**	**MPa**	**psi**		**Pickled + 2-month exposure**	**Iron-contaminated**	**Anodized**

Cathodic Hydrogen Uptake. As discussed in the section "Hydrogen Damage" in this article, titanium may absorb hydrogen if there is a mechanism for generating atomic hydrogen on the metal surface. This mechanism may involve an impressed cathodic current, galvanic coupling to active metals, or severe, continuous mechanical damage of titanium surfaces. In these situations, the factors of potential, current density, metal temperature, solution pH and chemistry, and alloy composition and surface condition all significantly influence the rate at which hydrogen is absorbed.

Figure 33 shows that unalloyed titanium may absorb hydrogen in near-neutral brines (seawater) at 25 and 100 °C (75 and 212 °F) when cathodic potentials are more active (negative) than -0.75 V versus SCE. This charging produces only thin, innocuous surface hydride films (Fig. 7) on unalloyed titanium as long as potentials remain more noble than -1.0 V and temperatures are below 80 °C (175 °F). For example, grade 2 titanium galvanically coupled to aluminum alloy 6063 in a process water electrolyte at 65 °C (150 °F) generated surface hydrides only. However, accelerated hydriding of unalloyed titanium may occur at impressed potentials cathodic (negative) to -1.0 V even at room temperature. The potential threshold indicated in Fig. 33 applies to α-β and β titanium alloys as well; however, significantly higher rates of hydrogen absorption and penetration can be expected at any given temperature under hydrogen charging conditions. This results from the significantly higher solubility and diffusion coefficients for hydrogen in the β phase (Ref 36, 38).

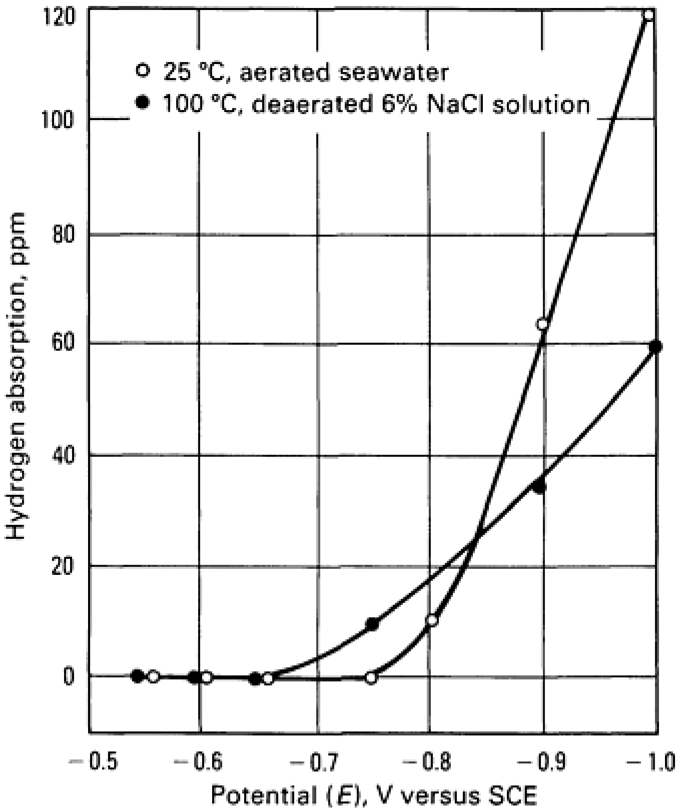

Fig. 33 Cathodic potential thresholds for absorption of hydrogen by unalloyed titanium in neutral brines. Source: Ref 41, 42

Increasing temperature and decreasing pH have both been shown to accelerate significantly the rate of hydrogen absorption of titanium alloys during cathodic charging (Ref 39, 44, 46, 152, 153, and 154). These studies indicate that the rate of hydrogen absorption and surface hydride layer growth initially follow a parabolic rate law; this suggests that hydrogen diffusion is rate controlling at temperatures less than and equal to 100 °C (212 °F) (Ref 155). Linear rate behavior has been observed in long-term charging exposures (Ref 46). Dramatic increases in hydrogen absorption rate during cathodic charging are noted when electrolyte pH levels are reduced to 2 or below (Ref 29, 39, 46, 150, and 152).

The presence of hydrogen recombination poisons, such as sulfide, arsenate, or antimony species, substantially increases hydrogen uptake during charging (Ref 152). This effect of sulfide has been observed in a few oil refinery heat exchangers in which grade 2 titanium tubes were galvanically coupled to carbon steel tubesheets and components in hot (≥80 °C, or 175 °F) sulfide-containing aqueous process streams. Severe hydriding (Fig. 6) and eventual embrittlement of the tubes occurred. Elimination of the detrimental couple with the active metal (steel) has been achieved by designing with more galvanically compatible passive alloys (including all-titanium design) or use of dielectric joints. In comparison, grade 2 titanium galvanically coupled to carbon steel in neutral sulfide-free electrolytes results in very minor increases in hydrogen uptake to temperatures as high as 120 °C (250 °F) (Ref 29, 44).

The surface condition of titanium also influences hydrogen absorption rates during cathodic charging. Studies consistently reveal that as-pickled and as-received surfaces are much less amenable to hydrogen uptake than abraded, vapor-blasted, or sandblasted surfaces (Ref 29, 39, and 45). Furthermore, anodized and, particularly, thermally oxidized surfaces are highly effective barriers to hydrogen uptake in titanium during charging (Ref 26, 42, and 47).

Stress-Corrosion Cracking in Specific Media

In the following sections, SCC titanium alloys in a variety of environments will be discussed. Most of the discussion will concentrate on environments that were identified through the use of precracked, notched test specimens (category 2), as in Ref 48. Mention also will be made of the few environments in which smooth specimens are sufficient for the identification of SCC.

Although the protection oxide film of titanium exhibits a high degree of stability and integrity in many aggressive environments, even to the extent that essentially no corrosion occurs, SCC has been identified in several environments. The SCC literature for titanium alloys is summarized in Table 27. Table 27 lists the environments that are known to cause SCC and the alloys that have been found to be susceptible. Each of these environments and the metallurgical factors that influence SCC susceptibility are discussed in the following sections.

Table 27 Environments known to promote SCC of commercial titanium and titanium alloys

Medium	Temperature		Susceptible materials
	°C	**°F**	
Oxidizers			
Nitric acid, RFNA	Room		Unalloyed titanium, Ti-8Mn, Ti-6Al-4V, Ti-5Al-2.5Sn, Ti-2Fe-2Cr-2Mo
Nitrogen tetroxide (no excess NO)	30-75	85-165	Ti-6Al-4V
Organic compounds			
Methanol (chloride, bromide)	Room		Ti-6Al-4V
			Ti-6Al-4V, Ti-8Al-1Mo-1V, grade 4

. . .	340	650	Ti-8Al-1Mo-1V

Red Fuming Nitric Acid. The first reported observation of titanium SCC occurred in red fuming nitric acid (Ref 156). Cracking was observed for commercially pure titanium in a room-temperature environment containing 20% NO_2. Later investigators indicated that SCC occurred in as little as 6.5% NO_2 with less than 0.7% H_2O. Intergranular cracking was observed on smooth specimens, which indicates the high sensitivity to SCC in this medium. In addition to commercially pure titanium, cracking was observed on Ti-8Mn and Ti-6Al-4V, even in red fuming HNO_3 without free NO_2. Work on inhibitors showed than 1.5 to 2.0% H_2O completely inhibits SCC. It was also shown that 1% NaBr inhibits SCC (Ref 156). The work on water as an inhibitor is especially interesting because it is of importance in a number of other environments that promote SCC.

Nitrogen Tetroxide. As titanium use in aerospace increased, it was found that titanium alloys were highly resistant to corrosion attack in nitrogen tetroxide (N_2O_4), an oxidizer used with hydrazine rocket fuels. Unfortunately, SCC was rather dramatically revealed in an explosion during proof testing of a Ti-6Al-4V storage vessel. The vessel that exploded had been exposed to N_2O_4 at 40 °C (100 °F) at a stress level of 620 MPa (90 ksi). Testing revealed that titanium alloys would crack in NO-free N_2O_4 (that is, N_2O_4 with excess dissolved oxygen, or red N_2O_4) but would not crack in NO-containing N_2O_4 (oxygen free, or green N_2O_4) (Ref 127).

Methanol. Prior to the discovery of SCC in N_2O_4, methanol was found to cause stress cracking of titanium alloys. Methanol and NaBr were shown to be extremely corrosive to titanium, and in some cases, they promoted intergranular SCC of smooth specimens (Ref 157). Soon after this discovery, it was shown that methanol/HCl and methanol/H_2SO_4 mixtures also caused SCC of commercially pure titanium--once again on smooth specimens (Ref 158). Stress-corrosion cracking in methanol was dramatically rediscovered when a Ti-6Al-4V pressure vessel exploded during proof testing with methanol. This led to a flurry of research to discover the nature of this cracking phenomenon and the metallurgical factors that promoted cracking.

Two types of SCC are observed in methanol solutions and are characterized by the failure mode exhibited. In the first type, intergranular fracture is evident. This type of fracture is common for commercially pure titanium and β titanium alloys, such as Ti-13V-11Cr-3Al, that are exposed to methanol containing a halide ion, such as Cl^- or Br^-. Susceptibility to SCC measured as time to failure of smooth samples indicates that:

- Increasing the halide content decreases time to failure
- Water additions to a critical level decrease time to failure
- Higher halide concentrations increase the critical level of water for maximum susceptibility to SCC
- Water levels beyond the critical level reduce and can inhibit cracking susceptibility

Details of this failure mode are presented in Ref 113, 114, 115, 116 and 159, 160, 161.

The effects of both cathodic and anodic polarization have also been investigated. Anodic polarization increases the susceptibility of titanium to SCC in methanol/halide mixtures. On the other hand, cathodic polarization dramatically reduces SCC susceptibility, as shown in Fig. 34. Potentials more negative than -250 mV versus Ag/AgCl prevent cracking in methanol (Ref 161).

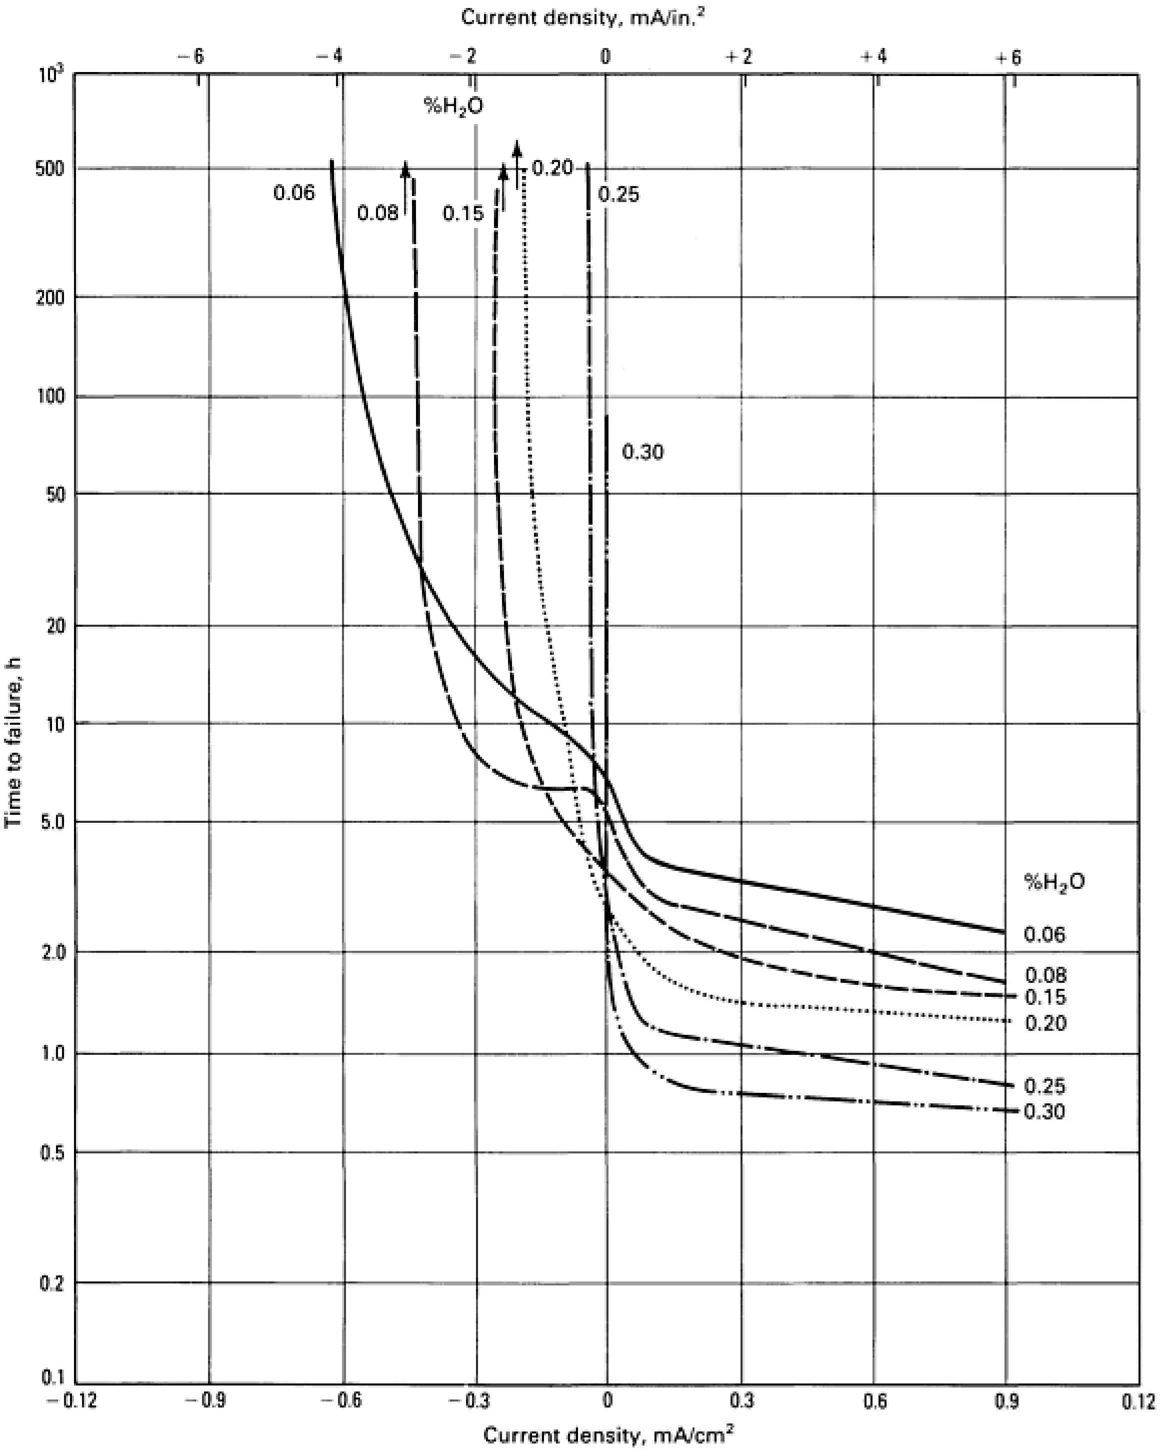

Fig. 34 Time to failure versus applied current and water content for cold-rolled and annealed Ti-6Al-4V stressed to 75% of yield strength in a methanol/HCl mixture. For 0.08% H_2O, 0.15% H_2O, and 0.20% H_2O, there was no failure in time shown.

Metal ion additions have also been examined and found to affect methanol SCC. In general, additions that have altered the cathodic reaction, such as palladium, chromium, iron, and gold, have accelerated cracking. This is shown in Fig. 35 for palladium.

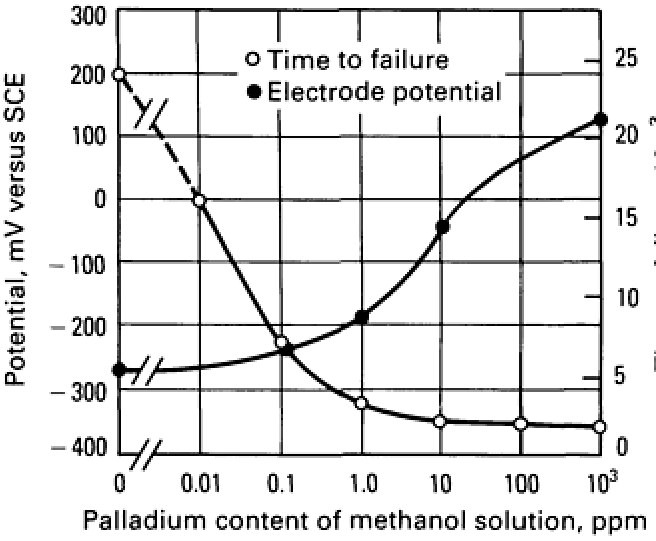

Fig. 35 Effect of palladium on time to failure and electrode potential for commercially pure titanium in methanolic solutions

The other fracture mode, typical of highly alloyed titanium, is characterized by transgranular α-phase cleavage. Alloys such as Ti-8Al-1Mo-1V typify this failure mode. In tests using precracked specimens, cracking changes from intergranular in stage I cracking (SCC initiation, Fig. 8) to transgranular in stage II (SCC propagation). Most of the α and α-β alloys susceptible to SCC in neutral aqueous solutions (discussed later) exhibit this mode of failure. In contrast, β titanium alloys, such as Ti-11.5Mo-6Zr-4.5Sn, exhibit intergranular fracture in stage II. Stage II is the region in which crack velocity is essentially independent of stress intensity (SCC propagation).

In general, halide additions increase crack velocity in stage II. It has also been reported that additions of sulfuric acid and acetic accelerate cracking. Application of cathodic potential between -1.5 and -1.0 V versus SCE has been shown to prevent crack initiation (stage I). Anodic potentials appear to increase crack velocity. As indicated earlier, small water additions prevent methanol SCC initiation. This effect is shown in Fig. 36. Little work has been performed on the effect of temperature on methanol SCC; however, the data available indicate that crack velocities increase with temperature.

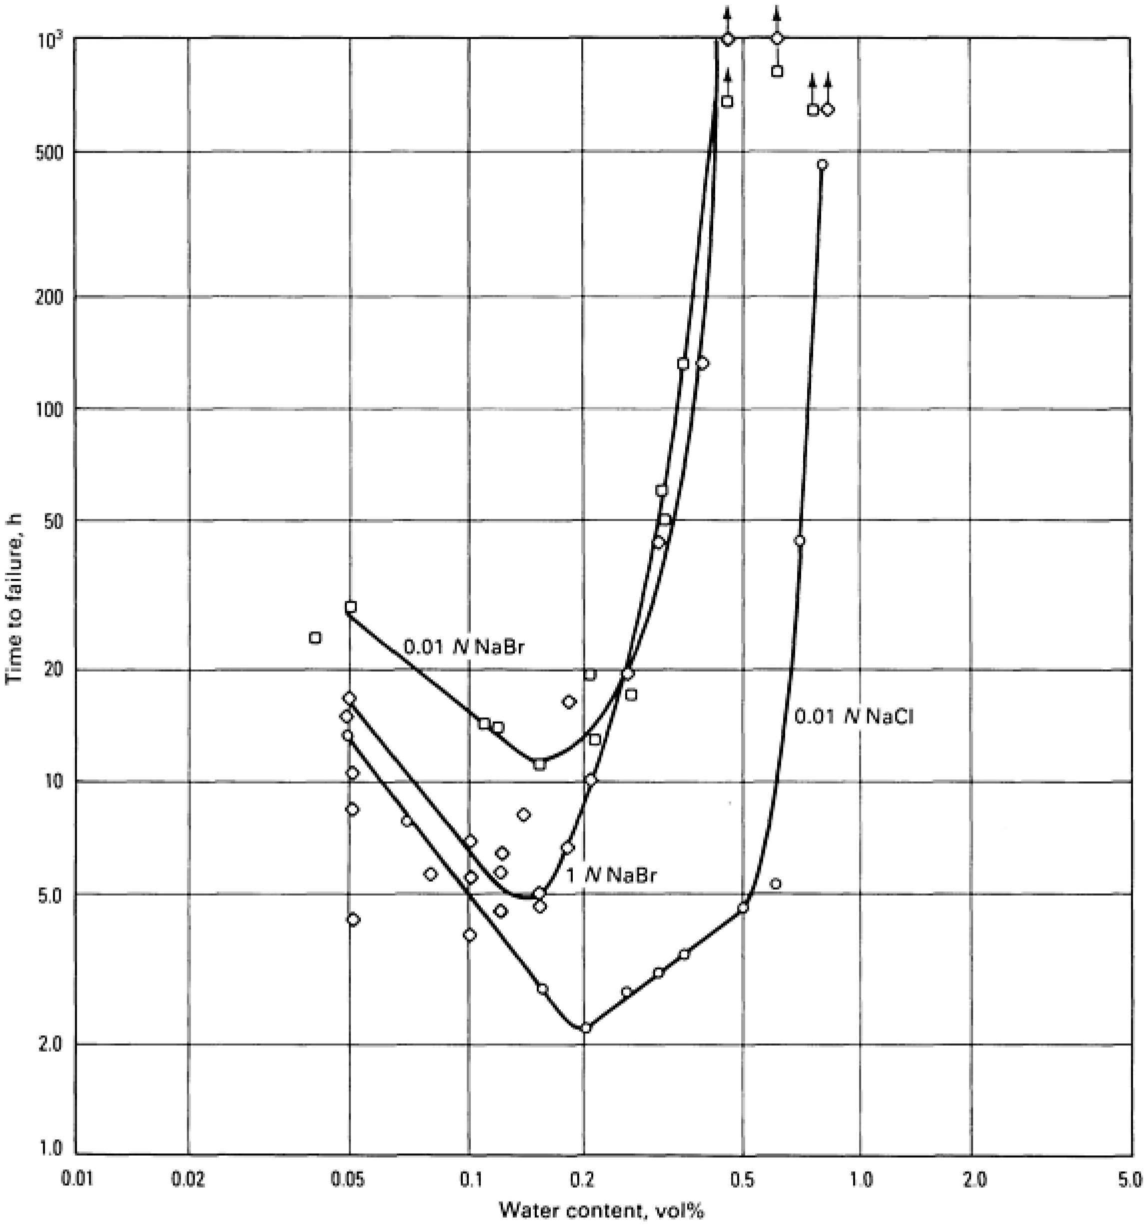

Fig. 36 Effect of bromide and chloride additions on SCC of cold-rolled and annealed commercially pure titanium stressed to 75% of yield strength in methanol/water solutions. Arrows indicate no failure in time shown.

Titanium alloys known to be susceptible to aqueous SCC (discussed later) are also susceptible to methanol SCC, and the alloys most susceptible to seawater are also most susceptible to methanol. In addition, the alloys that are susceptible to SCC in distilled water are not beneficially affected by the inhibiting effect of water (Fig. 37).

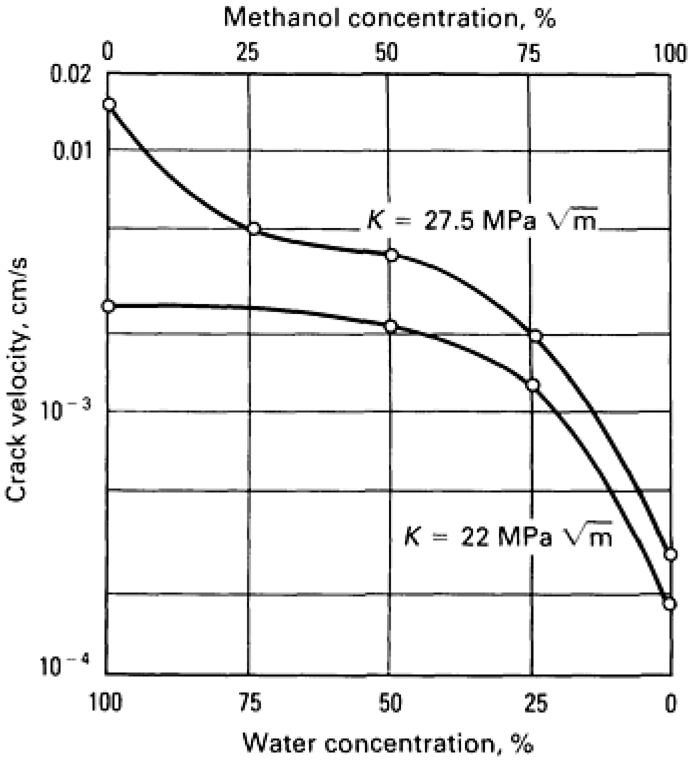

Fig. 37 Effect of water on crack velocity for Ti-8Al-1Mo-1V in methanolic solutions

Other Alcohols. Very little work has been performed on SCC in alcohols other than methanol.The studies that have been reported on alloys other than commercially pure titanium show that certain α-β alloys, such as Ti-6Al-4V, may be susceptible to cracking in anhydrous ethanol. Cracking in ethylene glycol has also been reported for Ti-8Al-1Mo-1V. Other work indicates that cracking susceptibility significantly diminishes as the number of carbon atoms in the alcohol increases.

Halogenated Hydrocarbons. No testing of commercially pure titanium has been performed in common hydrocarbons. However, widespread use of titanium alloys in the aerospace industry has prompted considerable study of SCC in halogenated hydrocarbons common to aerospace processing. Stress-corrosion cracking of certain titanium alloys has been identified in the following hydrocarbons:

- Carbon tetrachloride
- Methylene chloride
- Methylene iodide
- Trichloroethylene
- Trichlorofluoromethane
- Trichlorofluoroethane
- Octafluorocyclobutane

In most of these environments, precracked specimens (category 2) are required to identify SCC.

Carbon tetrachloride (CCl_4) SCC was first noted in Ti-8Al-1Mo-1V (Ref 162, 163, 164, and 165). The threshold stress intensity was approximately the same as that observed for SCC in 3.5% NaCl. Crack velocities in CCl_4 were approximately ten times faster than velocities in methanol. Studies on dynamically loaded smooth specimens (category 3) also showed that Ti-5Al-2.5Sn was susceptible to SCC in CCl_4 at stresses approaching the tensile strength of the alloy.

The other hydrocarbons identified were found to cause cracking in Ti-8Al-1Mo-1V and Ti-5Al-2.5Sn, alloys known to be susceptible to SCC in distilled water (Ref 165, 166). No other alloys were found to be similarly affected.

Freons include any of a number of fluorinated hydrocarbons commonly used as refrigerants. Titanium alloys Ti-8Al-1Mo-1V and Ti-5Al-2.5Sn have been found to exhibit threshold stress intensities in commercial freons below air threshold stress intensities (Ref 166). The alloy Ti-6Al-4V was also identified as susceptible when exposed in the solution-treated and aged condition.

Hot Salts. In the late 1950s, cracking of a titanium alloys was discovered during routine creep testing. The failure was eventually traced to chlorides from fingerprints on the creep specimen. These findings were reproduced in several laboratory studies for a host of titanium alloys. Nearly all titanium alloys were found to be susceptible to this cracking phenomenon (termed hot salt cracking) with the exception of the commercially pure grades of titanium. With this discovery, a great deal of concern was expressed with regard to the multitude of existing applications similar to this laboratory environment. However, after much investigation, it was found that no failure in the field could be attributed to hot salt cracking.

Several complete descriptions of host salt cracking can be found in th literature (Ref 167, 168, 169, 170, 171, 172, 173, 174, and 175). Hot salt cracking is primarily influenced by temperature, stress, time, and the alloy itself. Cracking is observed in the temperature range from 285 to 425 °C (545 to 800 °F). In general, susceptibility increases with stress and/or temperature and does not occur below 260 °C (500 °F) or above 540 °C (1000 °F).

Cracking is normally characterized by extensive branching and is not necessarily associated with the regions of highest stress intensity; therefore, category 2 specimens are not required to initiate cracking. Indeed, it is often difficult to initiate cracks in precracked notches. Statically loaded beam specimens (category 1) have been used in most of the laboratory investigations.

The alloys that are most susceptible to hot salt cracking are α alloys with more than 3% Al, such as Ti-5Al-2.5Sn. Commercially pure titanium is apparently immune (Ref 176). Alpha-beta alloys are less susceptible to cracking, although alloys with high aluminum contents are most susceptible. Apparently, the least resistant titanium alloy is Ti-8Al-1Mo-1V. Alloys with higher molybdenum content, such as Ti-4Al-3Mo-1V, are most resistant (Ref 169). The combined effect of time, temperature, and stress is shown in the Larsen-Miller diagram in Fig. 38 for several alloys. From Fig. 38, it is clear that alloy type and microstructural condition are important.

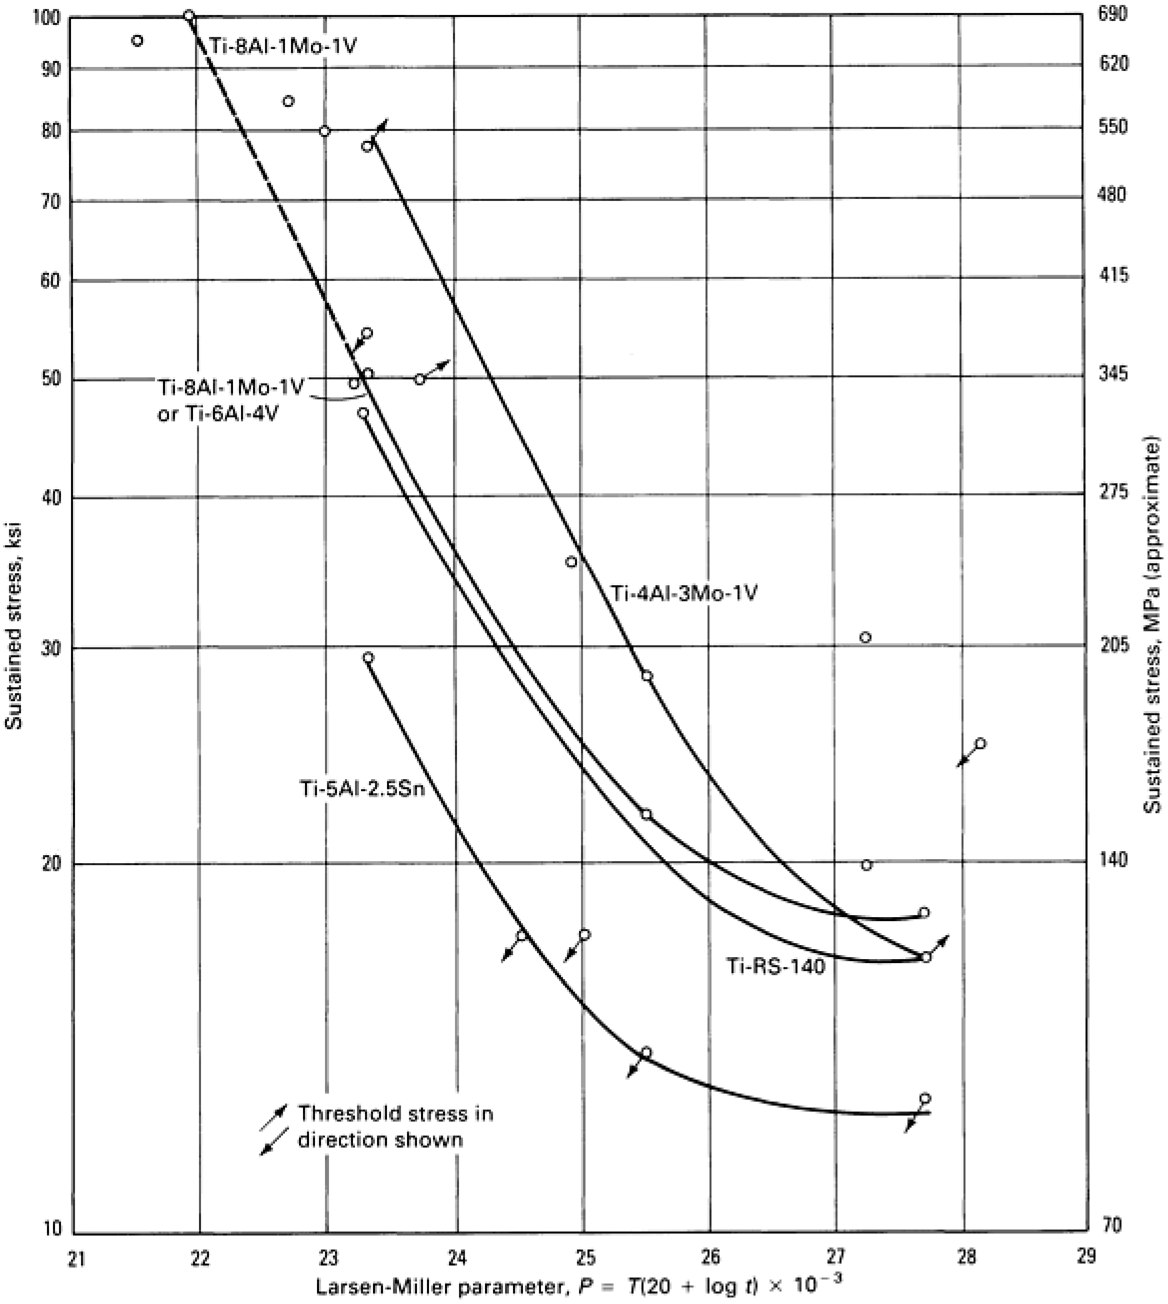

Fig. 38 Larsen-Miller plot for hot salt cracking of several annealed α-β titanium alloys. *T* is temperature (°R), and *t* is exposure time (hours).

Oxygen has been reported as necessary for hot salt cracking. At least one study has shown that cracking will not occur in Ti-5Al-2.5Sn when the environmental pressure is reduced below 10 μm (Ref 169). Although the role of water (moisture) has not been clearly established, it appears that water is also a necessary environmental component in the cracking process (Ref 170, 171).

Chloride, bromide, and iodide salts have all been shown to produce similar cracking. Fluoride and hydroxide salts have not. The cation associated with the salt has also been reported to affect cracking susceptibility. The severity of attach has been shown to increase as follows (Ref 170, 171):

$$MgCl_2 > SrCl_2 > CsCl > CaCl_2 > KCl > BaCl_2 > NaCl > LiCl$$

Table 28 lists titanium alloys in order of their susceptibility to hot salt cracking. This list is taken from Ref 177 and has not met with unanimous agreement.

Table 28 Relative resistance of titanium alloys to hot salt cracking

Ti-5Al-2.5Sn	**Least resistant**
Ti-7Al-12Zr	
Ti-5Al-5Sn-5Zr	
Ti-8Al-1Mo-1V	
Ti-8Mn	
Ti-5Al-5Sn-5Zr-1Mo-1V	Moderately resistant
Ti-6Al-4V	
Ti-6Al-6V-2Sn	
Ti-5Al-2.75Cr-1.25Fe	
Ti-13V-11Cr-3Al	
Ti-4Al-3Mo-1V	Most resistant
Ti-2.25Al-1Mo-11Sn-5Zr-0.25Si	
Ti-2Al-4Mo-4Zr	
Ti-8Mo-8V-2Fe-3Al	
Ti-11.5Mo-6Zr-4.5Sn	

Cracking is normally intergranular in nature, but it depends largely on alloy type. Alpha alloys exhibit both transgranular and intergranular fracture, depending on whether the material was annealed above or below the β transus, respectively. Alpha-beta alloys exhibit predominantly intergranular fracture (Ref 171, 173, 176, and 178).

From a practical standpoint, hot salt cracking appears to be a phenomenon that is restricted to the laboratory. As indicated earlier, no in-service failure has been attributed to hot salt cracking. The likely reason for this is the critical relationship among environment, stress level, and alloy type. Unless all of the conditions are met simultaneously and for extended time, cracking will not occur.

Molten Salts. It would appear that Ti-8Al-1Mo-1V is the only titanium alloy tested for SCC in molten salt environments. Cracking has been observed in pure chloride and bromide eutectic melts at temperatures between 300 and 500 °C (570 and 930 °F). In general, increasing temperature increases crack velocity. Cathodic protection has been observed to inhibit or stop cracking.

Nitrate salts below 125 °C (255 °F) do not induce cracking even when Cl^-, Br^-, or I^- anions are present. At higher temperatures in pure molten nitrates, cracking can occur only when halides are present (Ref 164).

Liquid/Solid-Metal Embrittlement. Several metals, both in liquid and solid form, have been found to induce cracking in contact with titanium alloys (Ref 127, 164, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, and 190). The first reported incidence stemmed from a cracked compressor disk in contact with cadmium-plated steel bolts (Ref 179). Initial speculation hinted that the exposure temperature may have been above the melting point of cadmium, leading to liquid-metal embrittlement. However, later work found that cracking would occur well below the melting point of cadmium (Ref 186), such as at room temperature for Ti-6Al-4V.

Those metals known to cause cracking of titanium alloys include cadmium, mercury, zinc, and certain silver brazing alloys. The titanium alloys that are known to be susceptible to cracking in cadmium include commercially pure titanium (ASTM grade 3) with more than 0.2% oxygen, Ti-4Al-4Mn, Ti-8Mn, Ti-31V-11Cr-3Al, Ti-6Al-4V, and Ti-8Al-1Mo-1V. It is likely that most other titanium alloys are susceptible, but have not been tested.

Alloys tested and found to crack in mercury include commercially pure titanium (ASTM grade 4, ~0.3% oxygen), Ti-8Mn, Ti-13V-11Cr-3Al, Ti-6Al-4V, and Ti-8Al-1Mo-1V. As with cadmium, other alloys are probably susceptible, but have not been tested.

Zinc, in both solid and liquid form, has been reported to cause cracking of titanium alloys. However, there is conflicting evidence in the literature as to whether this is actually the case.

Silver and silver brazing alloys have been shown to cause cracking in titanium alloys that are particularly sensitive to SCC. These alloys include Ti-8Al-1Mo-1V, Ti-5Al-2.5Sn, and Ti-7Al-4Mo (Ref 187, 188). As with cadmium, both solid and liquid forms of silver may produce cracking. Susceptibility for Ti-6Al-4V is considered to be above 345 °C (650 °F).

Aqueous Environments. Under certain metallurgical conditions, several titanium alloys have been shown to be susceptible to SCC in distilled water. These include Ti-8Al-1Mo-1V, Ti-5Al-2.5Sn, and Ti-11.5Mo-6Zr-4.5Sn. Microstructural variation for each alloy affects the degree of susceptibility. For example, mill-annealed Ti-8Al-1Mo-1V is less susceptible than step-cooled Ti-8Al-1Mo-1V. Testing has been performed with category 2 type specimens where crack velocity and threshold stress intensity are determined. In these alloys, the degree of susceptibility is highly dependent on heat treatment.

Test results in neutral-pH environments with category 2 type specimens indicate that titanium alloys exhibit a threshold stress intensity, K_{ISCC}, below which cracks will not propagate. The individual effects of ionic species, concentration, potential, pH, and so on, have been extensively studied and are discussed below.

Ionic Species. The anions Cl^-, Br^-, and I^- are the only species shown to promote and/or induce SCC in titanium alloys. The few alloys susceptible to cracking in distilled water become more susceptible, while alloys that are not susceptible in distilled water may become susceptible when these species are present. Anions such as NO_3^-, SO_4^{2-}, OH^-, F^-, $Cr_2O_4^{2-}$, and PO_4^{3-} may reduce sensitivity.

In general, cations do not alter SCC sensitivity. However, oxidizing cations, such as Fe^{3+} or Cu^{2+}, can increase K_{ISCC} in more susceptible alloys. This effect is analogous to anodic polarization, which is discussed in the section "Potential and pH" in this article.

Concentration. As shown in Fig. 39, increasing the concentration of anions that promote SCC generally increases crack velocity (Ref 164, 191, and 192) and decreases K_{ISCC}. Additions of SO_4^{2-} and NO_3^- to distilled water can completely inhibit SCC in alloy/heat-treatment combinations that are moderately susceptible, such as mill-annealed Ti-8Al-1Mo-1V. More susceptible combinations, such as step-cooled Ti-8Al-1Mo-1V, are not similarly affected.

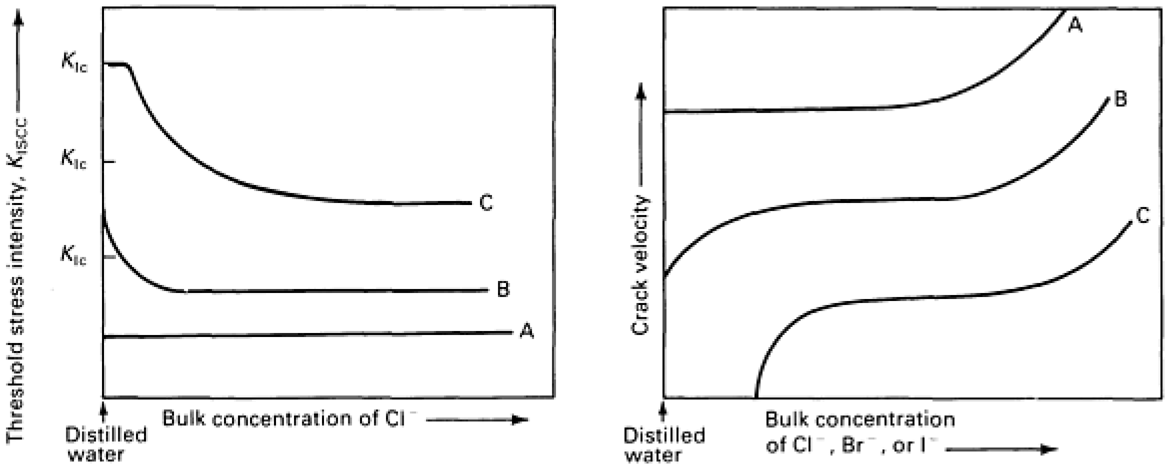

Fig. 39 Effect of halide ion concentration on K_{ISCC} and crack velocity in aqueous solutions. A, highly susceptible; B, moderately susceptible; C, slightly susceptible

Potential and pH. It is difficult to discuss the effect of potential and pH on SCC independently. In neutral brines containing halides, K_{ISCC} varies significantly with potential. Both cathodic and anodic polarization increase K_{ISCC}. Within a narrow potential region, K_{ISCC} reaches a minimum. Both the start and breadth of this range are dependent on the alloy and its metallurgical condition. In general, the range of maximum susceptibility (minimum K_{ISCC}) occurs at approximately -500 mV versus SCE. Examples of this behavior are shown in Fig. 40.

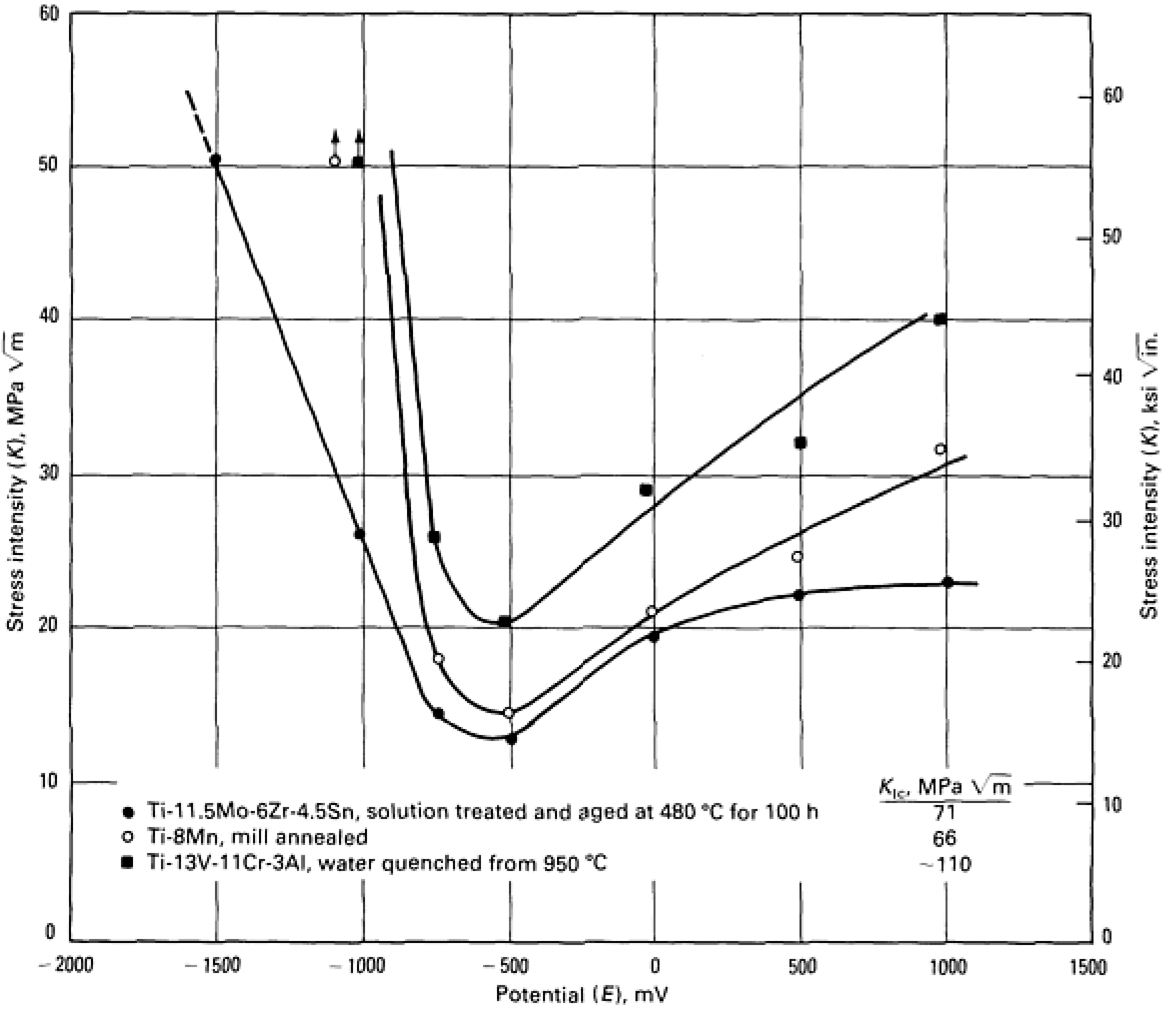

Fig. 40 Stress-corrosion cracking of β titanium alloys as a function of potential in 0.6 *M* KCl at 24 °C (75 °F). Source: Ref 164

Stress-corrosion crack velocity is also affected by potential. For alloys such as Ti-13V-11Cr-3Al, crack velocity increases linearly with anodic polarization (Ref 192). The slope of the crack velocity curve depends on the alloy type and metallurgical condition, and application of sufficient cathodic potential can halt a stress-corrosion crack.

In acidic solutions, potential effects are somewhat different (Ref 193). First, cathodic polarization will not stop a propagating crack. Second, lowering pH usually decreases K_{ISCC} and increases crack velocity at a constant potential, as shown in Fig. 41. In alkaline solutions, SCC is similar to that found in neutral solutions (Ref 194, 195).

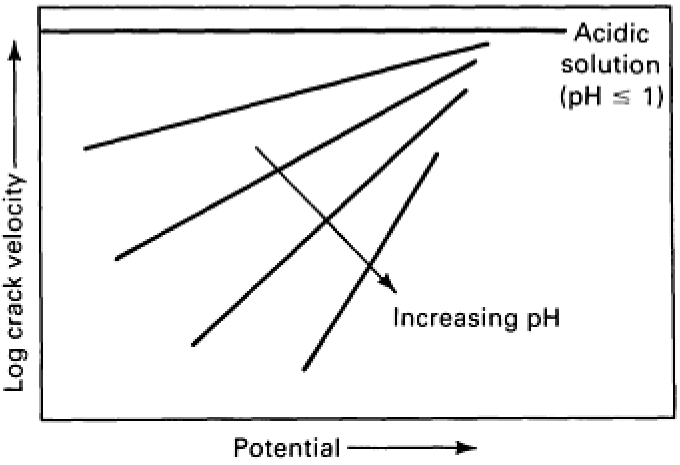

Fig. 41 Stage II crack velocity as a function of pH and potential in aqueous solutions

Temperature. Limited published data were available on the effect of temperature on SCC in aqueous environments (Ref 164, 191). Within a narrow temperature range (0 to 93 °C, or 32 to 200 °F), K_{ISCC} in NaCl solution was found to be independent of temperature for Ti-8Al-1Mo-1V. However, crack velocity was found to be strongly dependent on temperature.

Experimentation with category 1 and category 2 specimens has shown that the β alloy Ti-3Al-8V-6Cr-4Mo-4Zr does not crack in NaCl brines up to 205 °C (400 °F) (Ref 196). Tests above that temperature in NaCl brines containing H_2S may produce cracking with category 3 specimens.

Hydrogen Sulfide. Tests in acidic NaCl brine environments containing hydrogen sulfide employing category 1 specimens indicate that titanium alloys are immune to SCC at stress levels up to their yield strength (Ref 138). It is, however, unclear whether the category 1 type specimens are capable of determining SCC susceptibility in these environments. As noted in the previous section, elevated-temperature tests in H_2S brines indicate that Ti-3Al-8V-6Cr-4Mo-4Zr is susceptible to SCC. Unfortunately, no similar tests in environments with H_2S have been reported. Therefore, H_2S may not be the species responsible for SCC in this alloy.

Metallurgical Effects. In addition to environmental effects, the metallurgical condition of a particular titanium alloy will influence its susceptibility to SCC. Both chemistry and heat treatment (microstructure) play a part in these effects.

In α alloys, the two most important alloying elements are aluminum and oxygen. Binary titanium-aluminum alloys have been extensively studied. In this investigation, it has been established that 5% Al is necessary for SCC to occur in aqueous environments. As the aluminum level is increased, K_{ISCC} decreases and crack velocity increases (Ref 193, 197). The most susceptible heat treatments in aluminum-containing alloys are those that produce the α_2 phase.

Binary titanium-oxygen alloys also exhibit a critical level of oxygen below which SCC does not occur, because of the transition from wavy to planar slip (Ref 198). This level, generally taken as less than 0.20 to 0.25%, represents the break between ASTM grade 2 and ASTM grade 3. Titanium-aluminum-oxygen alloys generally suffer from the cumulative effects of both aluminum and oxygen on SCC (Ref 198). Tin additions to titanium-aluminum alloys generally cause a loss in SCC resistance. This is clearly demonstrated by Ti-5Al-2.5Sn, one of the more susceptible titanium alloys.

The α-β titanium alloys are considerably more difficult to generalize with regard to SCC behavior. This stems from the wide variety of microstructures that can be produced and the number of alloying elements involved.

Stress-corrosion cracking of Ti-8Al-1Mo-1V has been extensively studied because of its sensitivity to microstructure. The martensitic structures produced by quenching from high-temperature solution treatment are immune to SCC (Ref 190, 191). Lower-temperature solution treatment produces an equiaxed α-β structure that is susceptible to SCC. The degree of susceptibility is determined by the grain size, volume fraction, and mean free path of the susceptible α phase.

Tempered martensitic structures, produced by annealing a martensitic microstructure, are also susceptible to SCC (Ref 190). Basket-weave or Widmanstätten microstructures produced by working and/or heat treatment above the β transus generally exhibit better toughness both in and out of an aqueous environment.

In general, titanium alloys with higher aluminum, oxygen, and tin contents are the most susceptible to SCC; the effect of aluminum is shown in Fig. 42. Molybdenum is usually beneficial in increasing SCC resistance. Microstructural effects in these alloys are similar to those discussed for Ti-8Al-1Mo-1V.

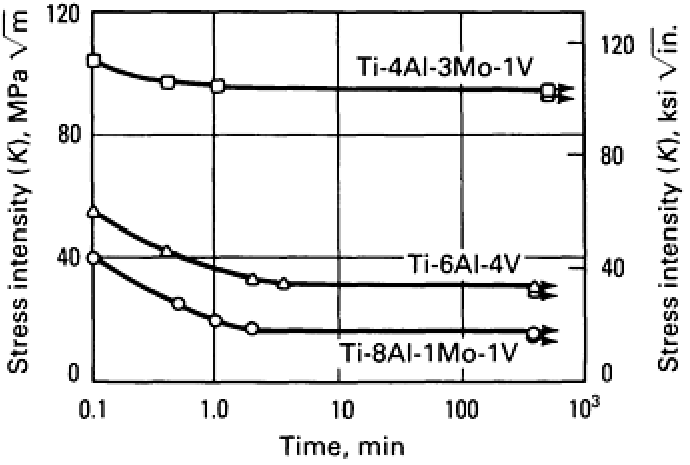

Fig. 42 Effect of alloy composition on SCC resistance of mill-annealed titanium alloys in aqueous 3.5% NaCl solution at 24 °C (75 °F)

With the exception of Ti-13V-11Cr-3Al, all of the commercial β titanium alloys are immune to SCC in the β-phase condition (Ref 199, 200, 201, and 202). However, aging decomposes the β phase and produces a variety of phases. The ω phase, produced by low-temperature aging of many β alloys, does not induce SCC susceptibility. Aging at higher temperatures produces the α phase, which nearly always leads to SCC. The degree to which a given β alloy in the $\beta + \alpha$ condition is susceptible appears to be related to the alloy chemistry and to the quantity and morphology of the α phase.

Aging at higher temperatures produces a coarser, α which is less susceptible to SCC than the finer α. Alloys containing molybdenum are less susceptible to SCC, especially those without tin.

Galvanic Corrosion in Specific Media

In their normal passive condition, titanium alloys are most often the cathode when galvanically coupled to most common engineering alloys in service. As a result, galvanic corrosion of titanium is very rare and occurs only under very unusual conditions. This rare situation could occur in a medium such as reducing acid, in which titanium is actively corroding. In this case, coupling to a more active metal (Ref 203) or a more noble metal could accelerate titanium alloy corrosion only if full passivation is not achieved. Coupling titanium alloys to a more noble material is most often very beneficial, resulting in establishing passivity when titanium is marginally active (corroding) or further maintaining passivity of titanium at more noble potentials. This form of anodic protection explains the excellent galvanic compatibility of titanium with noble metals (precious metals) and graphite composites in most environments.

Titanium alloys exhibit relatively noble corrosion potentials in the many environments in which full passivity is achieved. This is evident from Table 2. Similar data in natural seawater from other sources indicate that corrosion potentials for titanium and its alloys fall in the range of +0.1 to -0.3 V versus SCE (Ref 41, 44, 204, 205, and 206). Deaeration, increasing temperature (Ref 206), and sunlight (Ref 207) were all shown to cause a slight shift in titanium corrosion potential in the active direction.

In all cases, these referenced sources reveal that titanium exhibits corrosion potentials that are very similar to those of other more resistant alloys in the passive conditions, including the stainless steels and nickel-base alloys. The minor potential differences between these resistance, alloys result in very small, benign galvanic interactions as long as passive alloy conditions exist. Thus, galvanic compatibility can be expected in most environments when a titanium alloy is coupled to another resistant alloy, assuming both exist in a fully passive condition. The data in Table 29 for stainless steel and nickel-base alloys coupled to titanium in marine environments support this point.

Table 29 Corrosion rates of various metals galvanically coupled to titanium in marine exposures

Coupled material	Corrosion rate after indicated exposure, mm/yr (mils/yr)				
	193 days at half tide			**56 months in sea air**	
	Uncoupled	**Coupled[(a)]**	**Coupled[(b)]**	**Uncoupled**	**Coupled[(b)]**

AISI type 316 stainless steel	nil	nil	nil	nil	nil

(a) Area ratio of titanium to other metal: 1 to 7.

(b) Area ratio of titanium to other metal: 7 to 1.

However, when a titanium alloy is coupled to a metal that is active (corroding or pitting) in an environment, accelerated anodic attack of the active metal may ensue. Depending on the environment, active metals may include carbon steel, aluminum, zinc, copper alloys, or stainless steels that are active or pitting.

The effect of enhanced galvanic corrosion of various copper alloys coupled to commercially pure titanium in ambient temperature seawater is illustrated in Fig. 43 and 44. These sources and others reveal a wide variation in the extent of galvanic corrosion of copper alloys and steel (Ref 43, 69, 208, 209, and 210). The degree of galvanic attack depends on many (often interacting) factors, including cathode-to-anode surface area ratio, concentration of dissolved cathodic depolarizers such as oxygen and atomic hydrogen, temperature (Ref 44, 208), medium flow velocity and flow characteristics (that is, turbulence, angle of impingement), and medium chemistry. The presence of sulfide, increasing cathode-to-anode area, oxygen content, and flow velocity all aggravate the galvanic attack of copper alloys in seawater. As shown in Fig. 45, deaeration of NaCl brines drastically reduces galvanic attack (compare to Fig. 43). Discussions of galvanic interactions between titanium and a wide array of engineering alloys in flowing seawater are presented in Ref 74.

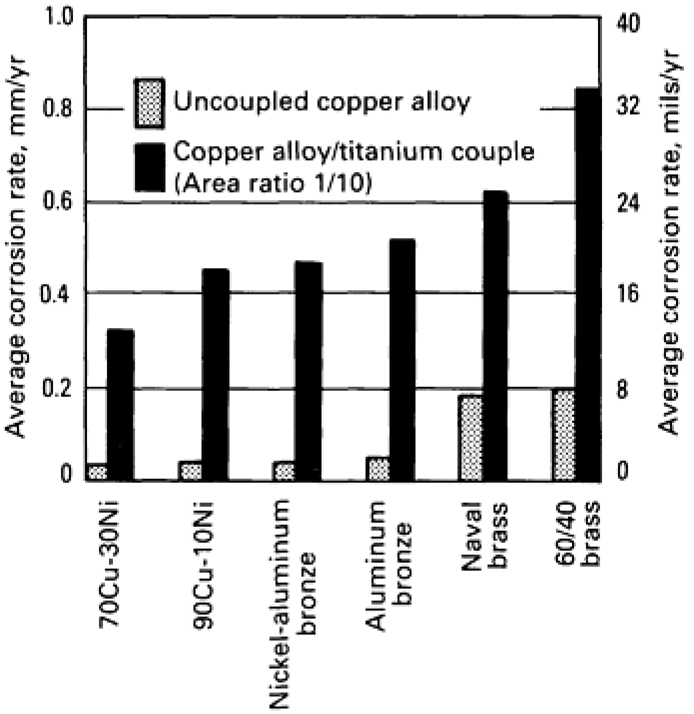

Fig. 43 Corrosion of various copper alloys that were galvanically coupled to titanium in aerated seawater at 25 °C (77 °F). Compare with Fig. 45. Source: Ref 41, 44

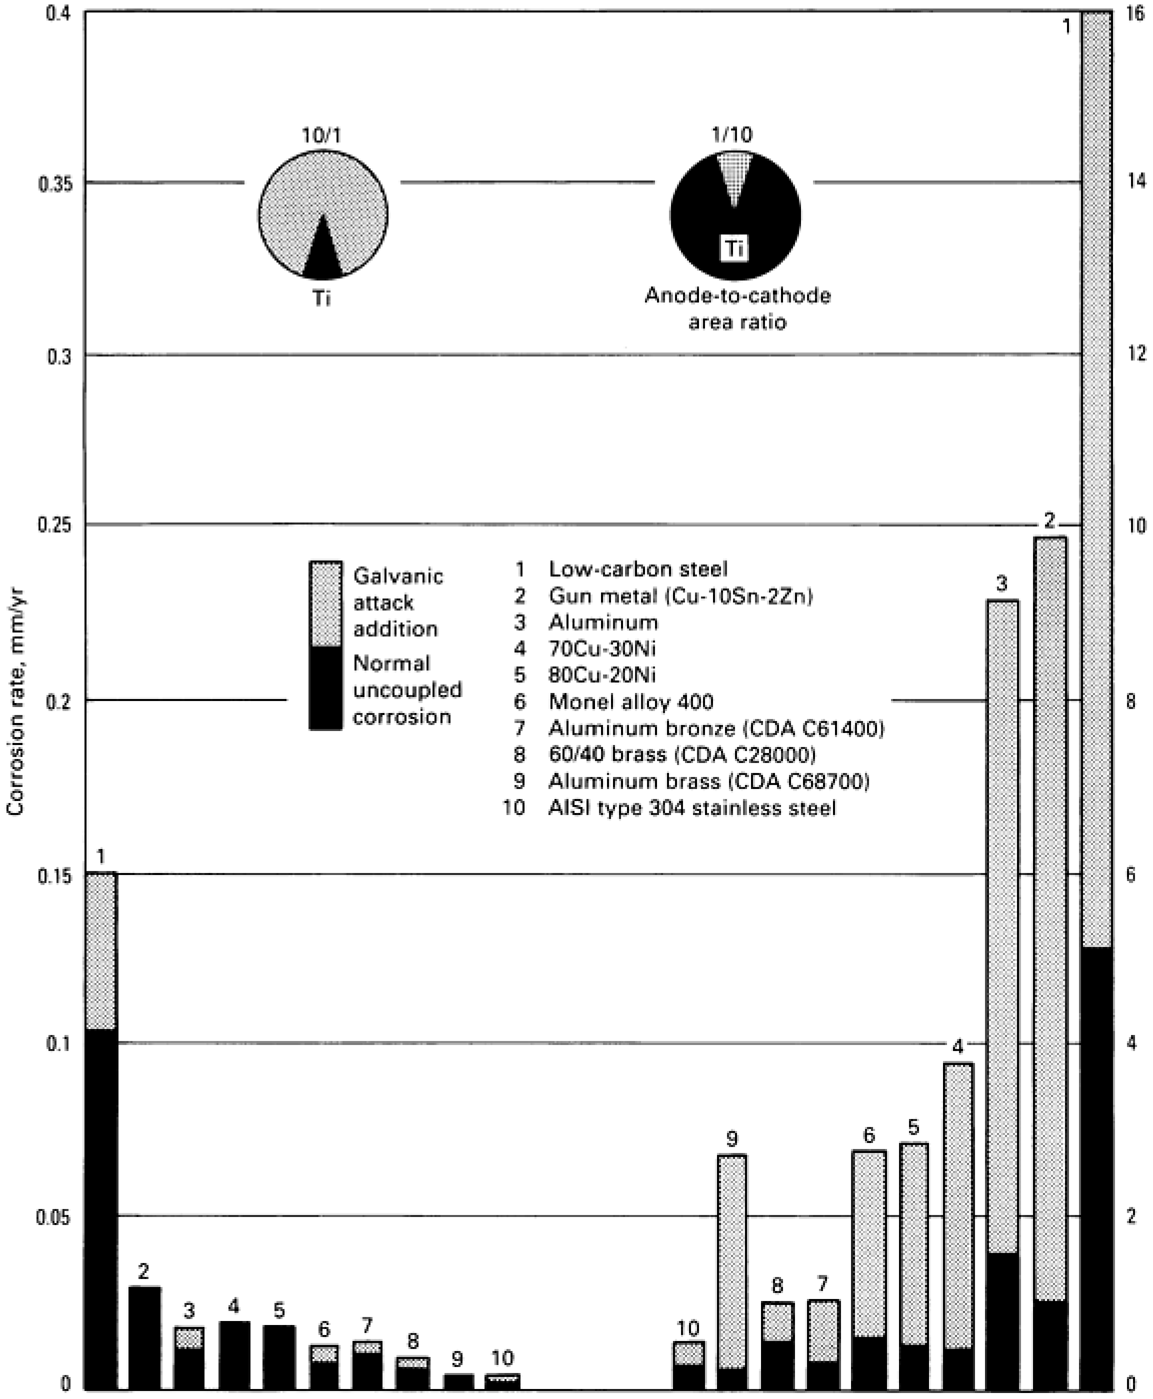

Fig. 44 Corrosion of dissimilar metals coupled to titanium in flowing ambient-temperature seawater. Source: Ref 56

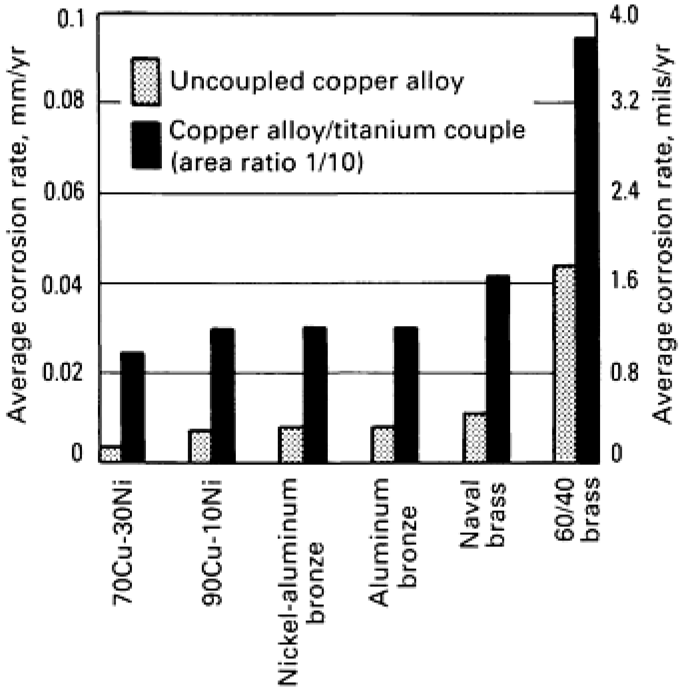

Fig. 45 Corrosion of copper alloys that were galvanically coupled to titanium in boiling, deaerated 6% NaCl at 100 °C (212 °F). Compare with Fig. 43, which shows corrosion rates in aerated seawater. Source: Ref 44

As a result of the relatively high polarization resistance (2.6 × 10^6 $\Omega \cdot cm^2$) and hydrogen overvoltage of titanium in ambient seawater, the cathodic behavior of titanium is similar to that of the 18-8 stainless steels (Ref 211). Therefore, the galvanic effects of titanium on active metals are quite similar to those for 18-8 stainless, as observed in salt spray tests (Ref 212). Although these cathode characteristics tend to mitigate galvanic current, they also result in increased cathodic current throwing power in conductive electrolytes; therefore, the effective surface area of titanium involved in a galvanic couple may be quite large. For example, studies show that the effective length of titanium (and stainless steel) condenser tubing involved in the galvanic attack of copper alloy tubesheets in seawater is in excess of 6 m (20 ft) (Ref 208, 211, and 213). This differs significantly from the two-tube diameter effective length rule used for copper alloys in seawater. Thus, significant cathodic polarization of titanium may occur in nonoxidizing media, such as seawater, when coupled to a more active metal. This often leaves the galvanic couple in cathodic control.

Effective design strategies for limiting or avoiding galvanic attack of active metals include:

- Coupling to more compatible (passive) alloys (including all-titanium design)
- Use of dielectric (insulating) joints between dissimilar metals
- Cathodic protection of the active metal by either impressed current or sacrificial anode means (Ref 44, 208, and 210)

Coating of titanium cathode surfaces may also mitigate galvanic current, assuming that the galvanic couple is in cathodic control.

Erosion-Corrosion in Specific Media

Unalloyed titanium and grade 5 titanium have both been shown to withstand silt-free flowing seawater to velocities as high as 30 m/s (100 ft/s) (Ref 41, 57, 214, 215, 216, 217, and 218). In fact, high-speed water wheel tests in seawater indicate erosion rates for grade 5 titanium of approximately 0.013 mm/yr (5 mils/yr) at 46 m/s (150 ft/s) (Ref 216). Jet impingement tests also involving seawater velocities of 46 m/s (150 ft/s) reveal rates of 0.03 to 0.06 mm/yr (1.2 to 24 mils/yr) for commercially pure titanium, with values of approximately 0.03 mm/yr (1.2 mils/yr) for welded and unwelded grade 5 titanium samples alike (Ref 218). Extremely low erosion rates are also reported for grade 2 titanium at various

seawater locations, as shown in Table 30. The superior erosion-corrosion resistance of titanium has also been reported in other media (Ref 103).

Table 30 Erosion-corrosion of grade 2 titanium in seawater at various locations

Location	Flow rate		Type of test	Test duration, months	Erosion-corrosion rate

Studies involving sand and emery particle-laden seawater indicate satisfactory erosion-corrosion resistance to flow rates of approximately 6 m/s (20 ft/s) (Ref 57). Data generated from rotating disk tests are presented in Table 31. The immunity of titanium to erosion-corrosion in silt-laden seawater flowing at approximately 2 m/s (6.5 ft/s) has been demonstrated in more than 20 years of power plant surface condenser tube service (Ref 69, 72). The outstanding resistance of titanium alloys to cavitation damage has also been documented (Ref 217, 219, and 220), and it has been confirmed that the harder higher-strength titanium alloys are more resistant to cavitation (Ref 221).

Table 31 Erosion-corrosion of titanium grade 2 in seawater containing suspended solids

Flow rate		Seawater suspension	Test duration, h	Erosion-corrosion rate	
m/s	**ft/s**			**mm/yr**	**mils/yr**

Source: Ref 57

Testing in a hypersaline geothermal brine further demonstrated the superior erosion-corrosion characteristics of titanium alloys (Ref 132, 222, and 223). Expanded brine (104 °C, or 220 °F; pH 2.5 to 4.5) impinged on high-strength ferrous, nickel, cobalt, and titanium alloy samples at a velocity of 240 m/s (800 ft/s). Grade 5 titanium uniquely experienced no detectable erosive wear after 120 h of exposure.

The relative erosion resistance of unalloyed titanium was investigated in two special versions of a rotating drum test involving erosive wear by wet TiO_2 filter cake solids and feed slurry (Ref 224). Titanium exhibited minor metal loss, being measurably superior to the steels, stainless steels, and nickel alloys tested. The superior erosion-corrosion resistance of titanium compared to Hastelloy alloy C was noted in a high-velocity gas scrubber venturi device in which a chloride-rich solution was used to scrub hot (315 °C, or 600 °F) process gas (Ref 224).

Erosion-corrosion testing in coal-water slurries representative of those associated with coal-washing plants also affirmed the superior performance of unalloyed titanium as compared to carbon steel, Ni-hard cast iron, and stainless steel alloys (Ref 225). Test results revealed that titanium was inert to attack to slurry velocities of 5 m/s (16 ft/s) but that types 304 and 316, alloy 904L, and type 440C stainless steels exhibited significant wear above 2 m/s (6.5 ft/s). Unalloyed titanium that was thermally oxidized at 700 °C (1290 °F) provided full wear resistance to velocities as high as 8 m/s (26 ft/s) in these rotary tests.

Extensive erosion-corrosion testing of Ti-6Al-4V, Ti-5Al-2.5Sn, and Ti-7Al-4Mo alloys has been conducted in high-velocity wet stream environments for application in low-pressure steam turbine blading in power plants. These alloys have demonstrated superior resistance to 403 stainless steel (12 to 13% Cr steel) in operating turbines and in water droplet erosion and water jet impingement tests (Ref 220). Full erosion resistance of Ti-6Al-4V blades to velocities of 440 to 530 m/s (1450 to 1740 ft/s) at 10% steam moisture has been noted in turbines. In fact, these studies suggest useful erosion resistance of Ti-6Al-4V in approximately 8% steam moisture to 549 m/s (1800 ft/s), and in 11% steam moisture to 488 m/s (1600 ft/s) (Ref 220). Single-shot water jet impingement testing has shown that annealed Ti-7Al-4Mo alloy is significantly more erosion resistant than 12% Cr steel, type 303 stainless steel, or Stellite alloy 6 at jet velocities of 610 and 915 m/s (2000 and 3000 ft/s).

Expanding and Enhancing the Corrosion Resistance of Titanium

The general corrosion resistance of titanium can be improved or expanded by one or a combination of the following strategies:

- Alloying
- Inhibitor additions to the environment
- Precious metal surface treatments
- Thermal oxidation
- Anodic protection

Alloying. Perhaps the most effective and preferred means of extending resistance to general corrosion into reducing environments has been by alloying titanium with certain elements. Beneficial alloying elements include precious metals (>0.05 wt% Pd) (Ref 226, 227, 228, and 229), nickel (≥0.5 wt%) (Ref 226, 229, 230, 231, and 232), and/or molybdenum (≥4 wt%) (Ref 13, 229, 233, and 234). These additions facilitate cathodic depolarization by providing sites of low hydrogen overvoltage, which shifts alloy potential in the noble direction where oxide film passivation is possible. Relatively small concentrations of certain precious metals (of the order of 0.1 wt%) are sufficient to expand significantly the corrosion resistance of titanium in reducing acid media.

These beneficial alloying additions have been incorporated into several commercially available titanium alloys, including the titanium-palladium alloys (grades 7 and 11), Ti-0.3Mo-0.8Ni (grade 12), Ti-3Al-8V-6Cr-4Zr-4Mo, Ti-15Mo-5Zr, and Ti-6Al-2Sn-4Zr-6Mo. As shown by the corrosion data in this article, these alloys all offer expanded application into hotter and/or stronger HCl, H_2SO_4, H_3PO_4, and other reducing acids as compared to unalloyed titanium. The high-molybdenum alloys offer a unique combination of high strength, low density, and superior corrosion resistance.

Inhibitor Additions. Various oxidizing species can effectively inhibit the corrosion of titanium in reducing acid environments when present in very small concentrations. Typical potent inhibitors for titanium alloys in aggressive reducing acids are listed in Table 14. Many of these inhibitors are effective at levels as low as 20 to 100 ppm, depending on acid concentration and temperature. If not normally present in a given corrosive acid stream, minute additions of a process-compatible inhibitive species may be considered to protect titanium components. These can be especially practical when process streams are recycled.

Minute additions of water may be required to maintain titanium alloy passivity in certain anhydrous environments. This has been highly effective in certain anhydrous organic compounds, absolute methanol, red fuming nitric acid, dry hydrogen or chlorine gas, and nitrogen tetroxide.

Precious Metal Surface Treatments. Precious metals such a platinum and palladium have been ion plated, ion implanted, or thermal diffused into titanium alloy surface to achieve improved resistance to reducing acids (Ref 235). This approach has not been used commercially for industrial components because of high cost, coating application limitations, and the limitations (mechanical and corrosion damage) normally associated with very thin surface films. However, ion plated platinum or gold surface films impart significant improvements in titanium alloy oxidation resistance of temperatures up to 650 °C (1200 °F) (Ref 236, 237).

Thermal Oxidation. Protective thermal oxide films can form when titanium is heated in air at temperatures of 600 to 800 °C (1110 to 1470 °F) for 2 to 10 min. The rutile TiO_2 film formed measurably improves resistance to dilute reducing acids as well as absorption of hydrogen under cathodic charging (Ref 47) or gaseous hydrogen conditions. Corrosion studies in hot, dilute HCl solutions have confirmed its superior protective benefits as compared to as-pickled, polished, or anodized surfaces on unalloyed titanium (Ref 47, 238). Corrosion and hydrogen uptake resistance was afforded by thermal oxidation in molten urea at 200 °C (390 °F) (Ref 238). Enhanced protection from dry chlorine attack can also be expected. Like anodizing, thermal oxidation offers no improvements in titanium resistance in highly alkaline or oxidizing aqueous media.

Although the thermal oxide has proved to be protective in relatively short-term tests in dilute reducing acids, long-term performance has not been fully demonstrated. Mechanical damage and plastic strain of thermally oxidized components must be avoided for effective protection. The oxide has been successfully applied on tubing and small components, but may be impractical for large components or where component distortion may occur during heating.

Anodic Protection. Titanium alloys can be effectively protected in reducing acid media by impressed anodic (direct current) potentials. Sustained impressed potentials in the range of + 1 to +4 V versus the standard by hydrogen electrode (SHE) are usually adequate to measure full passivation of titanium in many acids, as indicated in Table 16. Limited use of anodic protection by impressed currents has been made in concentrated H_2SO_4 and H_3PO_4 solutions in which a very wide range of impressed potentials can be applied. The added cost of impressed current systems, challenges with protecting complex component geometries, and stray current problems have inhibited its application. Also, titanium surfaces exposed to alternating wet/dry or vapor-phase conditions are not protected by this method.

Other Surface Treatments. Surface films of titanium nitrides and carbides are highly resistant to reducing acids. Studies have shown that the dense adherent nitride films produced by reactive plasma ion plating provided superior protection in deaerated H_2SO_4 solutions when compared to several other film-forming methods (Ref 239). Methods of applying nitride surface films to titanium include ion implantation (Ref 240), ion plating, sputter deposition, or thermal diffusion (nitrogen gas or molten cyanide bath). Because of the cost and limitations of film application and the inherent thin film performance limitations, these films are generally not used for corrosion resistance only. The improved water resistance offered by these hard films is generally the primary incentive.

The crevice corrosion resistance of titanium alloys can be enhanced by the following strategies:

- Alloying titanium
- Precious metal surface treatments
- Other metallic coatings
- Thermal oxidation
- Noble alloy contact
- Surface pickling (for smeared surface iron)

Alloying. The crevice corrosion resistance of titanium alloys tends to parallel general corrosion resistance in reducing acids. Thus, alloying with certain precious metals, such as palladium (Ref 131, 226, 241), nickel (Ref 23, 133, 226, 231, and 232), and/or molybdenum (Ref 13, 138), also significantly improves the resistance of titanium to crevice corrosion (Ref 242).

The commercially available titanium alloys that exhibit superior crevice corrosion resistance include grades 7, 11, and 12. In addition, high-strength titanium alloys containing at least 4 wt% Mo offer an excellent combination of improved crevice corrosion resistance, low density, and high strength (Ref 13). Proper alloy selection depends largely on pH, temperature, and other conditions, as discussed previously in this article.

Selection of a more resistant titanium alloy is generally preferred from a long-term reliability and cost standpoint over surface treatment options for less resistant titanium alloys. On the other hand, localized surface treatments may be cost-effective when very heavy alloy wall sections are involved or when it is necessary to upgrade existing equipment components.

Surface films of many precious metals and/or their oxides offer significant improvements in the crevice corrosion resistance of titanium. In Fact, these treatments can offer crevice resistance approaching that of the grade 7 or 11 titanium alloy. The most common precious metals applied to titanium surfaces are palladium, platinum, and ruthenium, and their oxides. Thermal diffusion coatings of palladium (Ref 235), platinum, and ruthenium are readily applied by firing in an air furnace after coating titanium with modified metal chloride solutions (Ref 243). The resultant coating is typically a mixture of titanium and precious metal oxides, depending on firing temperature (Ref 235). Thermal palladium surface treatments have been successfully used in oil refinery tubular exchangers (Ref 244).

Other methods of applying these precious metals on titanium surfaces include electroplating, brush plating, and ion implantation. Electroplating or brush plating provides precious metal layer thicknesses of the order of 0.01 mm (0.4 mils). Brush plating is a special technique for achieving localized electroplating of surfaces (Ref 245). Palladium implantation generates palladium-rich surface layers of the order of 0.5 μm (0.02 mil) or less. These surface layers have been shown to be effective in hot, concentrated chloride brines (Ref 246).

Other Metallic Coatings. The application of certain metals and their oxides within titanium alloy crevices can effectively inhibit crevice corrosion initiation in hot chloride media. These metals include nickel and copper, their oxides,

and the Fe_2O_3 and MoO_3 oxides (Ref 247, 248). In finely powdered form, these materials can be painted on creviced titanium surfaces in slurry form. Alternative, these powders can be formulated into sealants, such as silicone or ethylene propylene diene monomer (EPDM) rubber. For example, a 5 wt% addition of nickel metal/NiO powder (50/50) blended into EPDM gaskets for chlor-alkali cell anode components is known to prevent the crevice corrosion of unalloyed titanium in hot, low-pH, chlorine-saturated NaCl brines. It has been shown that unalloyed titanium anodized in a molybdate solution also provides crevice corrosion resistant metal surfaces (Ref 248).

Thermal Oxidation. Crevice corrosion resistance is afforded from thermal oxide films formed when titanium alloys are heated in air to 500 to 800 °C (930 to 1470 °F) for 2 to 10 min. Increasing the temperature (or time) within this range results in thicker, more protective oxide films. In hot NaCl brines, thermally oxidized titanium has proved its superior resistance to anodized or as-pickled titanium in both metal-to-metal and metal-to-gasket crevices (Ref 47, 129). Avoidance of mechanical damage or plastic metal strain is necessary for good protection. Thermal oxide films may exhibit limitations at higher temperatures and in low-pH brine, and they are better considered for situations in which only borderline crevice conditions exist for unalloyed titanium.

Noble Alloy Contact. Crevice corrosion of unalloyed titanium or other titanium alloys can be averted in metal-to-metal crevice situations. If a more noble alloy is one member of the metal-to-metal crevice, the titanium metal surface can be anodically protected by the galvanic couple achieved in the crevice. More noble metals include the precious metals, more resistant titanium alloys such as grade 7 or 12, or copper alloys. For example, it is well known that unalloyed titanium tubes that are roll expanded into copper alloy tubesheets resist tube joint crevice corrosion in high-temperature seawater (Ref 41, 44). Similarly, the more noble grade 7 titanium alloy will protect unalloyed titanium with which it is in direct contact; this provides resistance similar to that of grade 7 titanium. For example, a grade 7-grade 2 titanium sheet crevice will resist crevice attack in boiling chlorine-saturated NaCl brines, in which a grade 2-grade 2 joint would undergo crevice corrosion. This principle also applies to treated titanium surfaces in contact with untreated unalloyed titanium.

Surface Pickling. If the presence of galled or smeared surface iron is suspected on titanium equipment, it should removed to prevent possible pitting or hydrogen uptake in titanium exposed to hot chloride brines. This surface iron contamination can be removed with a light (~5 min) pickle in near-ambient temperature 35 vol% HNO_3-5 vol% HF or 12-1 HNO_3-HF solution, followed by water flushing. This procedure will remove less than 0.03 mm (1.2 mils) from the titanium alloy surface. Studies have shown that pickling in dilute HNO_3-HF solutions is much more effective in removing surface iron contamination than either anodizing (Ref 47) or pure HNO_3 exposures.

Appendix 1: General Corrosion Data for Unalloyed Titanium

This appendix is a compilation of general corrosion rate values for unalloyed titanium (ASTM grades 1 to 4). These values were derived from various published sources (Ref 8, 26, 67, 80, 85, 86, 109, and 127) and from unpublished in-house laboratory tests. These data should be used only as a guideline for alloy performance. Rates may very depending on changes in medium chemistry, temperature, length of exposure, and other factors. Also, total alloy suitability cannot be assumed from these values alone, because other forms of corrosion, such as localized attack, may be limiting. The text should be consulted to assess overall alloy suitability more thoroughly for a given set of environmental conditions. In complex, variable, and/or dynamic environments, *in situ* testing may provide more reliable data. In the following table, temperatures are given only in centigrade, and corrosion rates are reported only in millimeters per year.

Medium	Concentration, %	Temperature, °C	Corrosion rate, mm/yr
Acetaldehyde	75	149	0.001

Appendix 2: General Corrosion Data for Titanium Alloys

This appendix is a compilation of general corrosion rate values for commercial titanium alloys other than the unalloyed grades. These values were derived from various published sources (Ref 13, 26, 68, 80, 109, 133, and 138) and from unpublished in-house laboratory tests. These data should be used only as a guideline for alloy performance. Rates may vary depending on changes in medium chemistry, temperature, length of exposure, and other factors. Total alloy

suitability cannot be assumed from these values alone, because other forms of corrosion, such as localized attack, may be limiting. The text should be consulted to assess overall alloy suitability more thoroughly for a given set of environmental conditions. In complex, variable, and/or dynamic environments, *in situ* testing may provide more reliable data. In the following table, temperatures are given only in centigrade, and corrosion rates are reported only in millimeters per year.

Medium	Alloy	Concentration, %	Temperature, °C	Corrosion rate, mm/yr
Acetic acid	Grade 9	99.7	Boiling	nil
Acetic acid + 5% formic acid	Grade 12	58	Boiling	nil

Corrosion of Zirconium and Hafnium

T.L. Yau and R.T. Webster, Teledyne Wah Chang Albany

Introduction

ZIRCONIUM was first identified by Klaproth in 1789. In 1824, Berzelius made the first impure metal by reducing potassium fluorozirconate with potassium. In 1925, van Arkel and de Boer prepared the first high-purity zirconium by using an iodide decomposition process. The commercial Kroll process was developed in 1946 at the Bureau of Mines in Albany, OR.

Although zirconium is sometimes described as an exotic or rare element, it is in fact plentiful. It is ranked 19th in abundance of the chemical elements occurring in the earth's crust, and it is more abundant than many common metals, such as nickel, chromium, and cobalt. The most important source for zirconium is zircon ($ZrSiO_4$), which occurs in several regions throughout the world in the form of beach sand.

In 1940, Gillett discovered the excellent corrosion resistance of zirconium in a large number of acids and alkalies. This property was confirmed by Kroll in 1946 when ductile zirconium became available. Kroll predicted that zirconium would find uses in hydrochloric acid (HCl) applications. Hydrochloric acid is regarded as the most corrosive of the common acids. Indeed, one of the earliest applications for zirconium was in the handling of HCl.

About the time of Kroll's work, Kaufman and Utermeyer found that the early measurements of the thermal neutron cross section of zirconium were incorrect, because the metal that was tested contained hafnium. Hafnium occurs naturally with zirconium in ores (the corrosion of hafnium is discussed in section "Corrosion Resistance of Hafnium" in this article). When the hafnium was removed, zirconium was found to have a very low thermal neutron cross section. This high transparency to thermal neutrons, coupled with excellent corrosion resistance and good mechanical properties, makes zirconium very useful in nuclear power applications, especially as cladding for uranium fuel and for other reactor internals.

Nuclear applications account for a large portion of all the zirconium consumed. The excellent corrosion resistance of zirconium to strong acids and alkalies, salts, seawater, and other agents has attracted increasing attention for applications in chemical-processing equipment. Zirconium is used as a getter in vacuum tubes, as an alloying element, and in the manufacture of such diverse items as surgical appliances, photoflash bulbs, and explosive primers. Along with niobium, zirconium is superconductive at low temperatures and is used to make superconductive magnets.

Physical and Mechanical Properties of Zirconium

Typical physical and mechanical properties of zirconium are given in Table 1 for comparison with the properties of other structural metals. First, the density of zirconium is lower than that of iron or nickel. Second, zirconium has a low coefficient of thermal expansion. The coefficient of thermal expansion of zirconium is about two-thirds that of titanium, about one-third that of AISI type 316 stainless steel, and about one-half that of Monel. Third, zirconium has high thermal conductivity--about 18% better than that of type 316 stainless steel.

Table 1 Typical physical and mechanical properties of zirconium

Physical Properties	
Atomic number	40
Atomic weight, amu	91.22
Atomic radius, Å	
0 charge	1.60-1.62
4+ charge	0.80-0.90
Density, g/cm^3 (lb/in.^{3})	6.510 (0.235)
Crystal structure	
α **phase**	Hexagonal close-packed (below 865 °C, or 1590 °F)
β **phase**	Body-centered cubic (above 865 °C or 1590 °F)
$\alpha + \beta$ **phase**	. . .
Melting point, °C (°F)	1852 (3365)

Zirconium forms intermetallic compounds with most metallic elements, and only a limited number of alloys have been developed. For nuclear service, it is desirable to have zirconium alloys with improved strength and corrosion resistance in high-temperature water or steam. The most common alloys--Zircaloy-2 and Zircaloy-4--contain the strong αstabilizers tin and oxygen, as well as the βstabilizers iron, chromium, and nickel. The other alloys of commercial importance are Zr-2.5Nb and Zr-1Nb. In zirconium, niobium is a mild βstabilizer.

Zirconium ores generally contain a few percent of its sister element, hafnium. Hafnium has chemical and metallurgical properties similar to those or zirconium, although its nuclear properties are markedly different. Hafnium is a neutron absorber, but zirconium is not. As a result, there are nuclear and non-nuclear grades of zirconium and zirconium alloys. The nuclear grades are essentially hafnium free, and the non-nuclear grades may contain up to 4.5% Hf. Properly speaking, the alloy names Zircaloy, Zr-2.5Nb, and Zr-1Nb apply to nuclear grade materials. American Society for Testing and Materials (ASTM) specifications for non-nuclear grades list UNS R60704 as the alloy corresponding closely to Zircaloy-4 and UNS R60705 and R60706 as the alloys corresponding closely to Zr-2.5Nb. Properties and design specifications for zirconium alloys are given in Tables 2, 3, 4, and 5.

Table 2 Chemical compositions of zirconium alloys

Alloy	Composition, %								
	Zr + Hf, min	**Hf, max**	**Fe + Cr**	**Sn**	**H, max**	**N, max**	**C, max**	**Nb**	**O, max**

(a) 85% joint efficiency was used to determine the allowable stress value for welded tube. Filler metal shall not be used in the manufacture of welded tube.

Corrosion Resistance of Zirconium

Zirconium is a reactive metal, as evidenced by its redox potential of -1.53 V versus the normal hydrogen electrode at 25 °C (75 °F). It has a high affinity for oxygen. When zirconium is exposed to an oxygen-containing environment, an adherent, protective oxide film forms on its surface. This film is formed spontaneously in air or water at ambient temperature and below. Moreover, this film is self-healing and protects the base metal from chemical and mechanical attack at temperatures to 300 °C (570 °F). As a result, zirconium is very resistant to corrosive attack in most mineral and organic acids, strong alkalies, saline solutions, and some molten salts. Zirconium is not attacked by oxidizing media unless halides are present.

There are a few media that will attack zirconium. Among them are hydrofluoric acid (HF), ferric chloride ($FeCl_3$), cupric chloride ($CuCl_2$), aqua regia, concentrated sulfuric acid (H_2SO_4), and wet chlorine gas. Table 6 lists media for which corrosion test data have been reported for zirconium and its alloys. The data in Table 6 should be viewed as a guide to application of zirconium in chemical process media. Corrosion resistance should be determined *in situ* if possible because the process medium may differ greatly from the reported media.

Table 6 Corrosion resistance of zirconium alloys in various media

Specific Media

Water and Steam. Corrosion and oxidation of unalloyed zirconium in water and steam are reported to be irregular (Ref 1, 2). This behavior is probably caused by variations in the impurity content in the metal. Nitrogen and carbon impurities are particularly harmful. The corrosion rate of zirconium increases markedly when nitrogen and carbon concentrations exceed 40 and 300 ppm, respectively (Ref 1, 2).

Test results for a large number of heats of high-quality crystal bar zirconium are plotted in Fig. 1. The irregular behavior of unalloyed zirconium corrosion can be seen in the curves for 315 and 360 °C (600 and 680 °F). The data for corrosion resistance at 315 °C (600 °F) must be plotted as a band because there is too much scatter in the data. The curve at 360 °C (680 °F) has three bands extending upward from it; each band represents a change in corrosion rate from the basic rate indicated by the single line and represents data from a different set of test specimens. The irregular corrosion behavior of unalloyed zirconium stimulated alloy development programs. Zircaloy-2, Zircaloy-4, Zr-2.5Nb and Zr-1Nb are the most important alloys used in water-cooled nuclear reactors because they have the most reliable corrosion resistance in high-temperature water and steam.

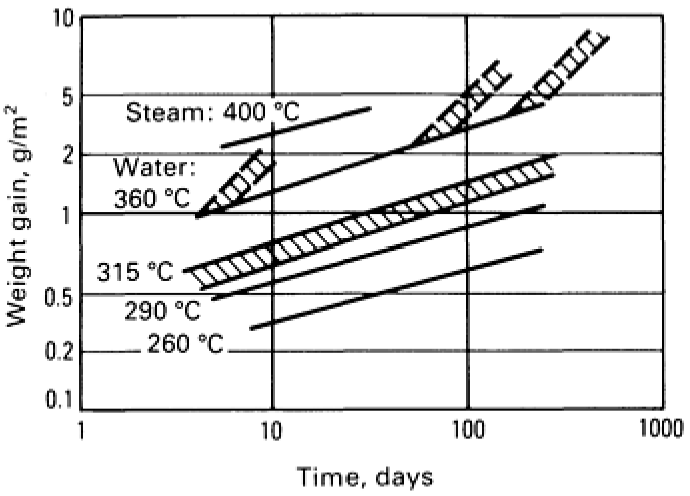

Fig. 1 Corrosion of arc-melted crystal bar zirconium in pressurized water and in steam. Source: Ref 2

Zircaloy-2 is superior to unalloyed zirconium in high-temperature water and steam. A tightly adherent oxide film forms on this alloy at a rate that is at first quasi-cubic but after an initial period undergoes a transition to linear behavior. Unlike the oxide film on unalloyed zirconium, the oxide film on Zircaloy-2 remains dark and adherent throughout transition and in the post-transition region. Test results for Zircaloy-2 in water and steam are plotted in Fig. 2.

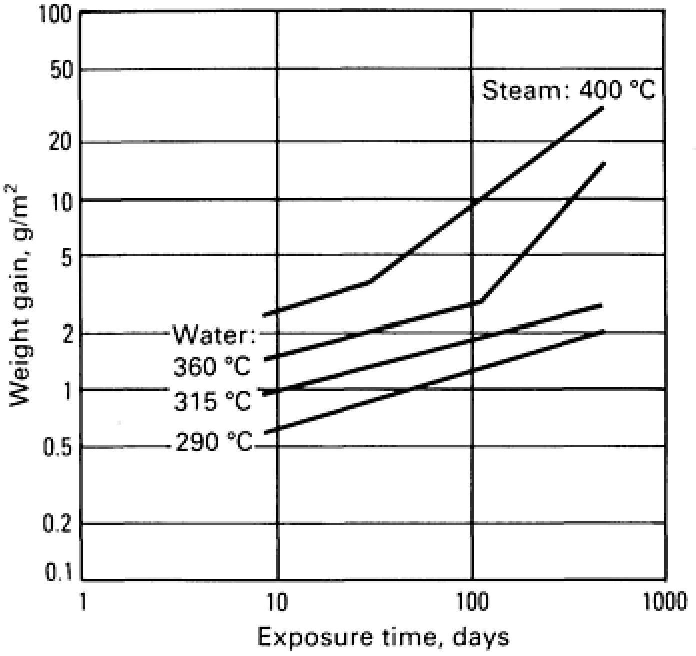

Fig. 2 Corrosion of Zircaloy-2 in pressurized water and in steam. Source: Ref 2

Zircaloy-4 differs in composition from Zircaloy-2 only in having no nickel and a slightly greater iron content. Both variations are intended to reduce hydrogen pickup in reactor operation. The corrosion behavior of Zircaloy-4 is very similar to that of Zircaloy-2 (compare Fig. 3 and Fig. 2). However, hydrogen pickup for Zircaloy-4 is significantly lower, particularly when the alloy is exposed to water at 360 °F). At this temperature, hydrogen pickup for Zircaloy-4 is about 25% of theoretical, or less than half that for Zircaloy-2. In addition, hydrogen pickup for Zircaloy-4 is less sensitive to hydrogen overpressure than that for Zircaloy-2 (Fig. 4). For both Zircaloys, hydrogen pickup is markedly decreased when dissolved oxygen is present in the corrosion medium (Ref 1).

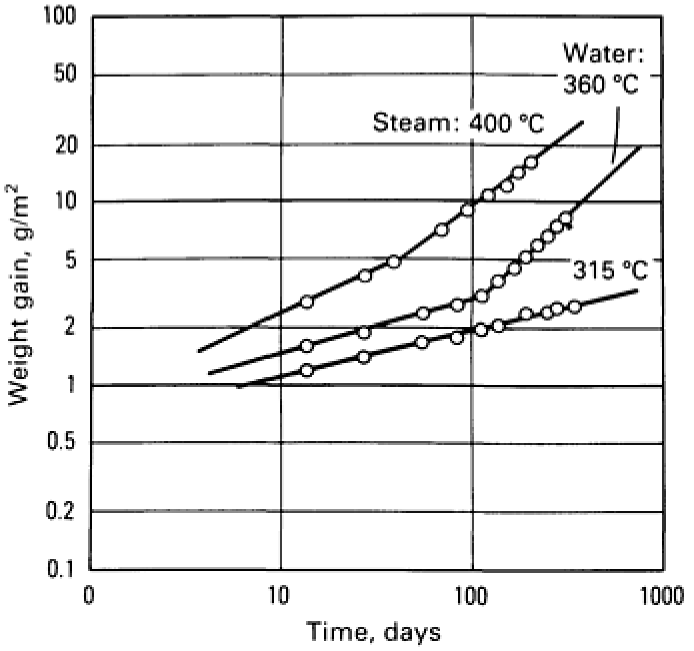

Fig. 3 Corrosion of Zircaloy-4 in pressurized water and in steam. Source: Ref 2

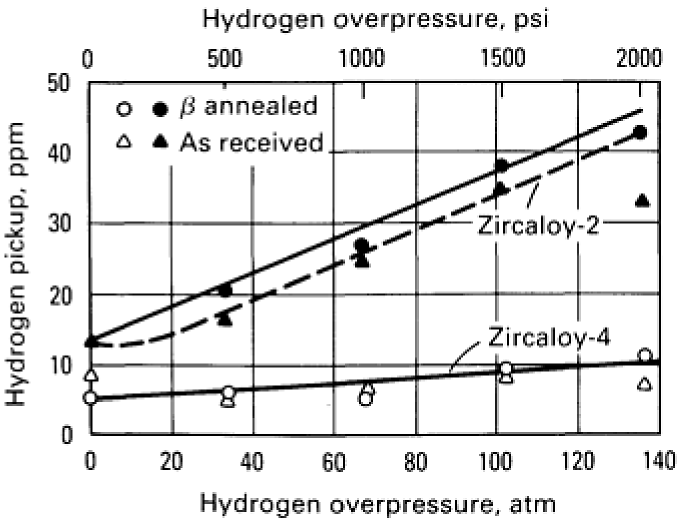

Fig. 4 Hydrogen pickup versus hydrogen overpressure for Zircaloy-2 and Zircaloy-4. Specimens were immersed for 14 days in water pressurized by admitting compressed hydrogen into the vapor space above the waterline. Water temperature: 343 °C (650 °F). Source: Ref 2

Alloy Zr-2.5Nb is considered to be somewhat less resistant to corrosion than the Zircaloys. Nevertheless, Zr-2.5Nb is acceptable for many applications. An example is the use of Zr-2.5Nb pressure tubes in the primary loops of some reactors. The corrosion resistance of Zr-2.5Nb can be substantially improved by heat treatments (Ref 3, 4). Also, Zr-2.5Nb is superior to Zircaloys in steam at temperatures above 400 °C (750 °F) (Ref 5).

Salt Water. Zirconium has excellent corrosion resistance to seawater, brackish water, and polluted water. The corrosion properties of zirconium grades Zr702 and Zr704 in natural seawaterare given in Ref 6. Specimens with or without crevice attachment of Zr702 were placed in the Pacific Ocean at Newport, OR, for up to 129 days. All welded and nonwelded specimens exhibited negligible corrosion rates. Marine biofouling was observed; however, no corrosion was found beneath the marine organisms or within the crevices. Laboratory tests were performed on Zr702 and Zr704 in boiling seawater for 275 days and in 200 °C (390 °F) seawater for 29 days. Both alloys were resistant to general, pitting, and crevice corrosion.

Tests of U-bend specimens with or without steel coupling of Zr702, nickel-containing Zr704, and nickel-free Zr704 were conducted in boiling seawater for 365 days. Results are reported in Table 7. No cracking was observed during the testing period. Overstressing of the tested U-bend indicated that all specimens were still ductile except for the welded nickel-containing Zr704 with steel coupling. Steel-coupled nickel-containing Zr704 showed much higher hydrogen and oxygen absorption and formed hydrides, particularly in the weld heat-affected zone. Chemical analyses and metallographic examinations on other U-bends did not show evidence of hydride formation.

Table 7 Hydrogen and oxygen analyses of zirconium-steel coupled U-bend test specimens

365-day test in boiling seawater

Specimen	Condition	Hydrogen/oxygen content, ppm	
		Hydrogen	**Oxygen**
Zr702-steel	Unwelded	6	1350
Zr704 (nickel-containing)-steel	Unwelded	8	1480
Zr704 (nickel-free)-steel	Unwelded	9	1440
Zr702-steel	Welded	8	1250
Zr704 (nickel-containing)-steel	Welded	450	5000
Zr704 (nickel-free) steel	Welded	5	1480

Source: Ref 6

Sulfuric acid is a corrosive and complicated acid. It has a wide range of strengths, changing from the reducing character of dilute solutions to the oxidizing character of concentrated solutions. The resistance of most engineering metals and alloys depends greatly on the acid concentration and temperature. The usefulness of many materials is restricted to some specific conditions, such as low concentrations, high concentrations, or low temperatures.

The corrosion of zirconium in H_2SO_4 solutions is rather straightforward (Fig. 5). It can be seen that zirconium resists attack by H_2SO_4 at all concentrations up to 70% and at temperatures to boiling and above. In 70 to 80% H_2SO_4, the corrosion resistance of zirconium depends strongly on temperature. In highly concentrated H_2SO_4, the corrosion rate of zirconium increases rapidly with concentration.

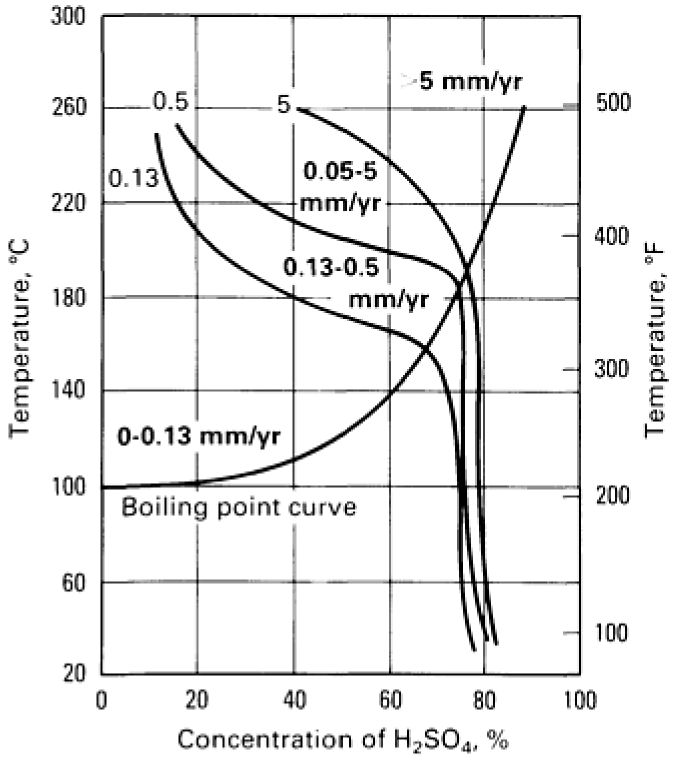

Fig. 5 Isocorrosion diagram for zirconium in H_2SO_4

In the range in which zirconium shows corrosion resistance in H_2SO_4, a protective film is formed on zirconium that is predominantly cubic zirconium oxide (ZrO_2) with only traces of the monoclinic phase (Ref 7). Zirconium corrodes in highly concentrated H_2SO_4 (for example, 80%) because loose films are formed that prove to be zirconium disulfate tetrahydrate ($Zr(SO_4)_2 \cdot 4H_2O$) (Ref 8). Also, at the higher acid concentrations, films that flake off are formed, and they are probably partly zirconium hydride (Ref 8).

The two most attractive regions for the use of zirconium in H_2SO_2 can be seen in Fig. 5. The first region is the concentration range of 40 to 60% H_2SO_4, and the second is the dilute H_2SO_4 at elevated temperatures. In these two regions, iron- and nickel-base alloys corrode rapidly, or their resistance depends strongly on concentration, temperature, or aeration. The comparative corrosion rates of zirconium and several iron- and nickel-base alloys in H_2SO_4 are given in Table 8. As demonstrated in Table 8, stainless steels have very poor corrosion resistance in hot H_2SO_4. In general, stainless steels provide useful service only at low temperatures in dilute or highly concentrated H_2SO_4. Nickel-base alloys have higher corrosion resistance than stainless steels in H_2SO_4 (Table 8). However, the corrosion resistance of Alloy B-2 (UNS N10665) in H_2SO_4 decreases greatly at elevated temperatures. For example, the corrosion rate of Alloy B-2 in 10% H_2SO_4 increases from 0.025 to 26 mm/yr (1 to 1022 mils/yr) when temperature changes from 102 to 225 °C (215 to 435 °F). Furthermore, the corrosion resistance of Alloy C-276 (UNS N10276) is sensitive to temperature and concentration.

(a) Boiling point

The corrosion resistance of zirconium in H_2SO_4 can be further understood from electrochemical measurements. The anodic polarization curves of zirconium in 4.9 to 72.5% H_2SO_4 at near-boiling temperatures are shown in Fig. 6. All polarization curves in this article were obtained according to ASTM G 5 (Ref 9). As indicated in Fig. 6. zirconium experiences a passive-to-transpassive transition in H_2SO_4 with an increasing potential. Zirconium does not have the active region in H_2SO_4, as is the case with common metals and alloys.

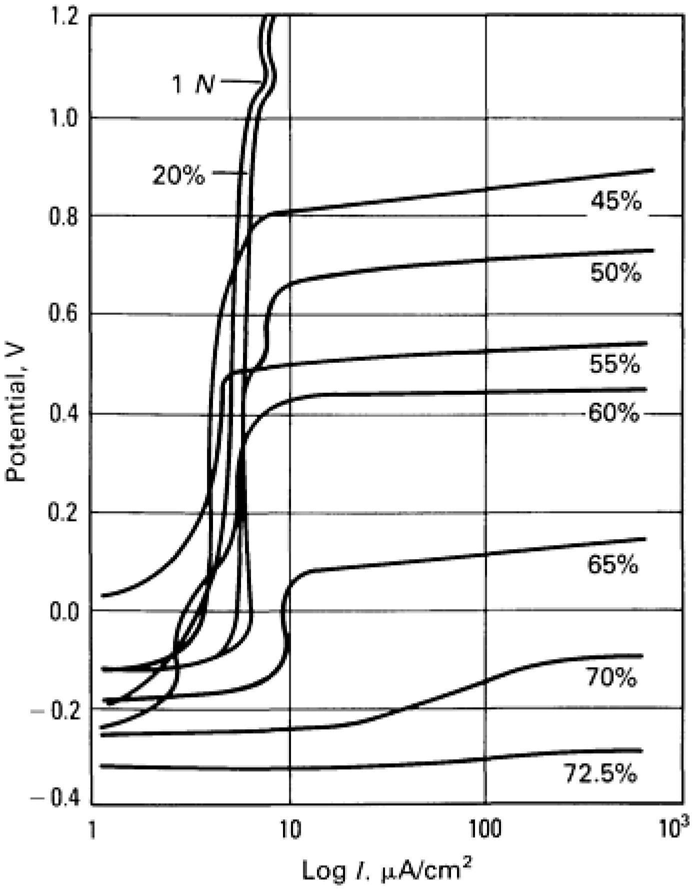

Fig. 6 Anodic polarization curves for zirconium in various concentrations of H_2SO_4(wt%). Applied potential is given in volts versus the saturated calomel electrode. Temperature: near boiling point

Figure 6 shows that the transpassive (breakdown) potential of zirconium in H_2SO_4 decreases with increasing concentration. As shown in Fig. 7, in less than 65% H_2SO_4, zirconium can tolerate some amounts of strong oxidizing agents, such as ferric (Fe^{3+}), cupric (Cu^{2+}), and nitrate ions (NO_3^-) without a reduction in corrosion resistance,as confirmed by immersion test results (Ref 10). Moreover, in 20% or less H_2SO_4, zirconium can tolerate a great amount of strong oxidizing agents. Consequently, zirconium equipment is often used in steel pickling. In more than 65% H_2SO_4, zirconium becomes sensitive to the presence of oxidizing agents (Ref 7).

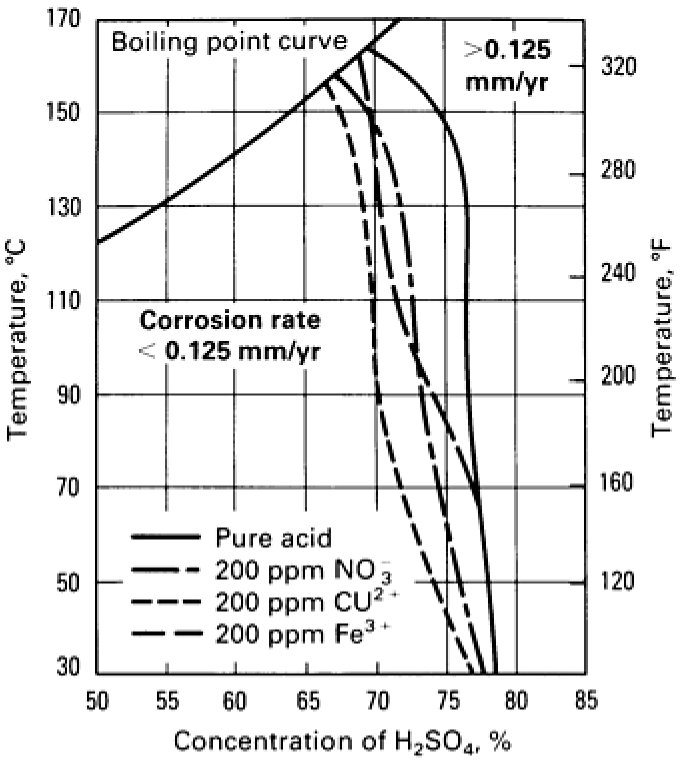

Fig. 7 Effect of 200 ppm of various impurities on the 0.125-mm/yr isocorrosion line for zirconium in H_2SO_4

Zirconium weld metal may corrode preferentially when H_2SO_4 concentration is approximately 55% and higher. Heat treatment at 775 ± 15 °C (1425 ± 25 °F) for 1 h per 25.4 mm (1 in.) of thickness was found to restore the corrosion resistance to the same high resistance of the parent metal (Ref 11, 12, 13).

The acid concentration limit is very important when zirconium is used to handle H_2SO_4 at elevated temperatures in the marginal concentration region, such as 60% or more. When the limit is exceeded, zirconium may corrode rapidly. In less than 65% H_2SO_4, the vapor phase is almost entirely water vapor (Ref 14). Also, the concentration change is negligible when the system is under a pressurized condition (Ref 15). Consequently, acid concentration can change significantly, because of, for example, imperfect sealing of a system. In a nonpressurized system, the acid concentration can exceed the concentration limit. Acid concentration can easily change when the system is under vacuum because the water vapor is continuously taken away.

The results of the impurity effect study can be found in Ref 10 and 16. General conclusions include:

- Ferric, Cu^{2+}, and NO_3^- ion impurities in H_2SO_4 degrade at acid concentrations above 65%
- Chloride ions (Cl^-) alone do not change the corrosion resistance of zirconium in H_2SO_4
- When heavy-metal ions and halide ions coexist in H_2SO_4 (for example, when $FeCl_3$ is present), the optimum acid concentration range for zirconium is 60 to 65%, as demonstrated in Table 9
- Zirconium can tolerate only very small amounts of fluoride ions (F^-) in H_2SO_4 even at low acid concentrations. Fluoride ions must be complexed using inhibitors--such as silica (SiO_2), aluminum nitrate ($Al(NO_3)_3$), and zirconium sponge--when zirconium equipment is used to handle H_2SO_4-F^- solutions

Table 9 Inhibiting effect of SO_4^{2-} on the corrosion of zirconium in boiling H_2SO_4 containing $FeCl_3$

Medium	Temperature		Corrosion rate[a]	
	°C	°F	mm/yr	mils/yr
40% H_2SO_4 + 2% $FeCl_3$	115	240	5[b]	199[b]
50% H_2SO_4 + 2% $FeCl_3$	124	225	2	80
55% H_2SO_4 + 2% $FeCl_3$	131	270	2.1	83
60% H_2SO_4 + 2% $FeCl_3$	141	285	0.66	26
70% H_2SO_4 + 2% $FeCl_3$	166	330	0.84	33

(a) Calculated from four 1-day cycles.

(b) Localized corrosion.

When the corrosion resistance limits of zirconium in H_2SO_4 are exceeded, a pyrophoric surface layer may be formed on zirconium under some specific conditions (Ref 17, 18). The pyrophoric surface layer on zirconium formed in 77.5% H_2SO_4 + 200 ppm Fe^{3+} at 80 °C (175 °F) consisted of γ-hydride, ZrO_2, zirconium sulfate, and fine metallic particles (Ref 18). The combination of γ-hydride and metallic particles is suggested to be responsible for the pyrophoricity. Treating in hot air or steam can be used to eliminate this tendency (Ref 18).

Hydrochloric acid is regarded as the most difficult to handle of the common acids for metallic materials (Ref 19). The presence of even a small amount of HCl in a medium may cause pitting and stress-corrosion cracking (SCC) of common metals and alloys.

Zirconium is totally resistant to attack in all concentrations of HCl to temperatures well above boiling (Ref 10, 20, 21). The isocorrosion diagram for zirconium in HCl is shown in Fig. 8. Moreover, zirconium is not as susceptible to hydrogen embrittlement in HCl as tantalum is (Ref 22, 23). As discussed in Ref 23, tantalum lost 33% and 18% of its ductility after 1000 h in 11 *M* HCl and 11 *M* HCl + 7% gallium chloride ($GaCl_3$), respectively, at 70 °C (160 °F). Under the same testing conditions, zirconium remained unattacked and retained 100% of its ductility.

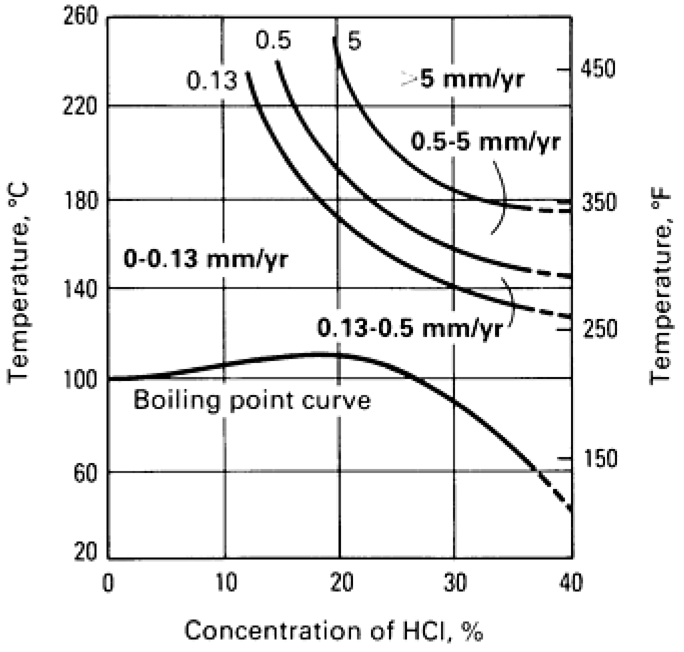

Fig. 8 Isocorrosion diagram for zirconium in HCl

The comparative corrosion rates of zirconium and several iron- and nickel-base alloys in boiling 20% HCl are given in Table 10. Table 10 shows that zirconium outperforms other tested alloys. Normally, stainless steels and high-performance alloys can be considered only for handling very dilute and/or low-temperature HCl (Ref 24, 25).

Table 10 Corrosion rates of zirconium and stainless alloys in boiling 20% HCl

Alloy	Test duration, h	Corrosion rate	
		mm/yr	**mils/yr**
Zr702	28	0.018	0.7
Type 304	0.5	>8890	$>3.5 \times 10^5$
Type 310	0.5	>2795	$>1.1 \times 10^5$
Type 316	0.5	1145	$>4.5 \times 10^4$
Hastelloy B-2	28	0.43	17

Although HCl is highly reducing, the anodic polarization curves of zirconium still do not have the active region (Fig. 9). This corrosion property explains the resistance of zirconium to crevice corrosion in chloride-containing environments.

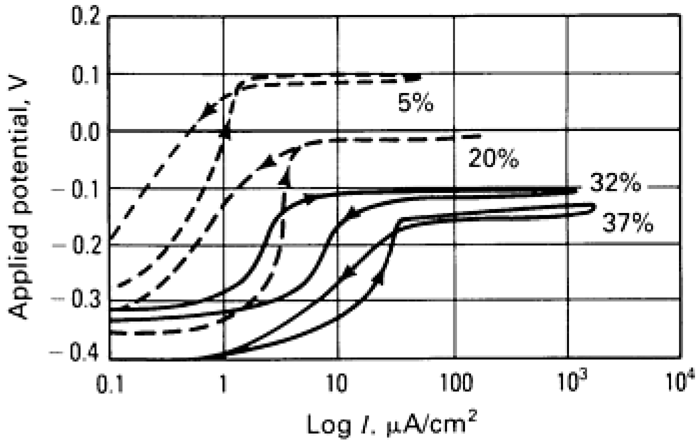

Fig. 9 Potentiodynamic curves for zirconium in various concentrations of HCl. Applied potential is given in volts versus the saturated calomel electrode.

However, Fig. 9 shows that zirconium can suffer pitting and/or SCC when it is anodically polarized to a potential at or exceeding the pitting potentials. The same types of corrosion problems can be developed in HCl when strong oxidizing ions, such as Fe^{3+}, are present. Figure 10 illustrates the detrimental effect of Fe^{3+} in 20% HCl at 100 °C (212 °F). It can be seen that the presence of Fe^{3+} polarizes the zirconium surface to a potential exceeding the pitting potential. Thus, local breakdown of the passive surface at preferred sites occurs, and a condition develops that favors pitting and/or cracking. Maintaining zirconium at a potential in its passive region, which is arbitrarily set at 50 to 100 mV below the corrosion potential, can counteract the detrimental effects resulting from the presence of Fe^{3+} (Ref 26).

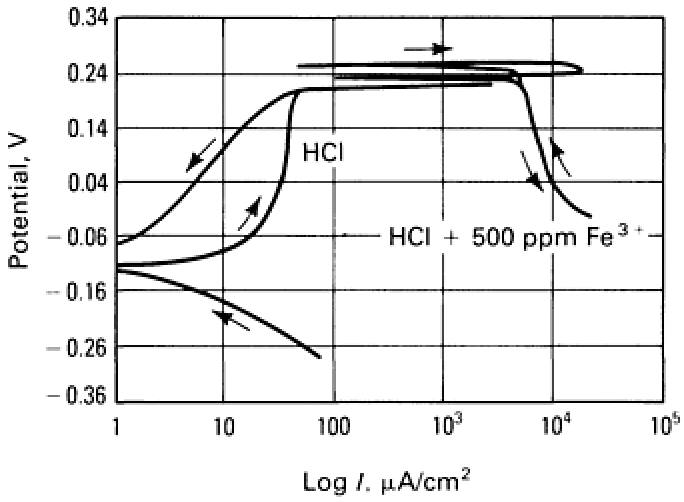

Fig. 10 Anodic polarization curves for zirconium in 20% HCl with and without 500 ppm Fe^{3+}. Test temperature: 100 °C (212 °F). Potential is given in volts versus the standard hydrogen electrode.

Zirconium resists other halogen acids except HF. Zirconium has corrosion rates of less than 0.13 mm/yr (<5 mils/yr) in boiling 20, 45, and 48% hydrobromic acid (HBr) and less than 0.025 mm/yr (<1 mil/yr) in boiling 47% hydroiodic acid (HI). The results of pitting potential measurements indicate that zirconium has lower pitting tendency in 1 *N* HBr or 1 *N* HI than in 1 *N* HCl:

Solution	Pitting potential, mV versus SCE
1 *N* HCl	140
1 *N* HBr	420
1 *N* HI	670

Nitric acid (HNO_3), due to its passivating power, is not considered to be a difficult acid for metallic materials to handle. However, HNO_3 becomes highly corrosive when its temperature is high or when impurities, such as heavy-metal ions, are present.

The excellent corrosion resistance of zirconium in HNO_3 has been known for over 30 years (Ref 20, 27, 28). Below the boiling point and at 98% HNO_3 and up to 250 °C (480 °F) and at 70% HNO_3, the corrosion rate of zirconium is less than 0.13 mm/yr (<5 mils/yr) (Fig. 11). Recent autoclave tests showed that the corrosion rates of zirconium were less than 0.025 mm/yr (<1 mil/yr) in 80% HNO_3 and 90% HNO_3 at 120 and 150 °C (250 and 300 °F) (Ref 29). Moreover, the corrosion rates were still under 0.025 mm/yr (<1 mil/yr) when zirconium was tested in boiling 30% to 70% HNO_3 with up to 1% $FeCl_3$, 1% NaCl, 1% seawater, 1% Fe^{3+}, or 1.45% stainless steel at 205 °C (400 °F) (Ref 29). These results indicated that the presence of heavy-metal ions and Cl^- in HNO_3 has little effect on the corrosion resistance of zirconium.

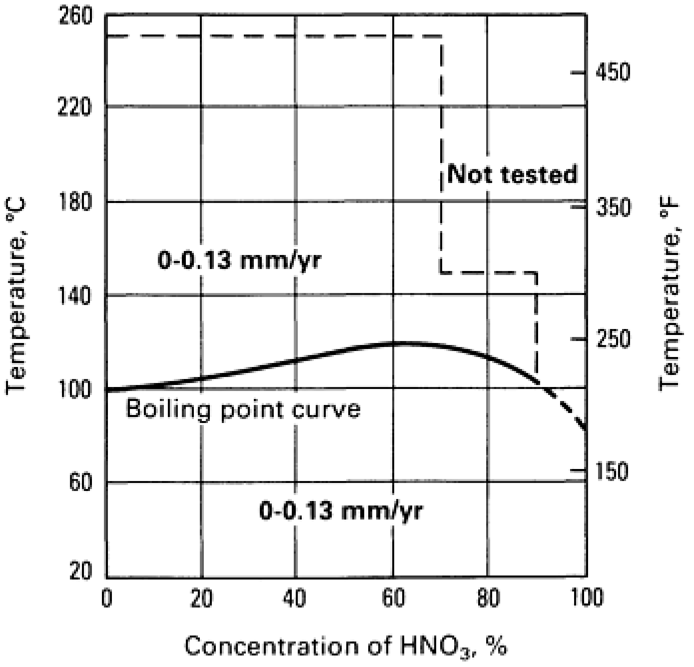

Fig. 11 Isocorrosion diagram for zirconium in HNO_3

Zirconium is normally susceptible to pitting in acidic oxidizing chloride solutions. However, NO_3^- ions effectively inhibit the pitting of zirconium (Ref 30, 31, 32). The minimum ratio of NO_3^- /Cl^- required to inhibit pitting of zirconium

was determined to be 1 (Ref 30, 31) or 5 (Ref 32). Nevertheless, the presence of appreciable amounts of HCl should be avoided, because zirconium is not resistant to aqua regia.

In the production of HNO_3, ammonia (NH_3) is oxidized with air over platinum catalysts. The resulting nitric oxide (NO) is further oxidized into nitrogen dioxide (NO_2), then absorbed in water to form HNO_3. Acid of up to 70% concentration is produced at temperatures to 204 °C (400 °F) by the process. As indicated in Table 11, all tested alloys except zirconium corrode rapidly in 65% HNO_3 at 204 °C (400 °F).

Table 11 Corrosion rates of zirconium and stainless alloys in 65% HNO_3 at 204 °C (400 °F)

Alloy	Test duration, h	Corrosion rate	
		mm/yr	**mils/yr**
Zr702	48	0.008	0.3
Type 304	3	>380	>1.5×10^4
Type 310	20	>305	>1.2×10^4
Type 316	20	>380	>1.5×10^4
Hastelloy B-2	0.25	>1.4×10^4	>5.5×10^5

The polarization curves of zirconium in HNO_3 are shown in Fig. 12. A passive-to-active transition similar to that which occurs in H_2SO_4 takes place with increasing acid concentration. However, corrosion potentials are very noble because of the oxidizing nature of HNO_3. Common oxidizing agents, such as oxygen and Fe^{3+} ions, will not affect the corrosion resistance of zirconium. The polarization curves do suggest that, although corrosion rates are low, zirconium may be sensitive to stress in concentrated HNO_3. This is consistent with the observation of SCC in U-bend specimens in more than 70% HNO_3 (Ref 33). The slow strain rate technique can reveal cracking of zirconium in less than 70% HNO_3 (Ref 34).

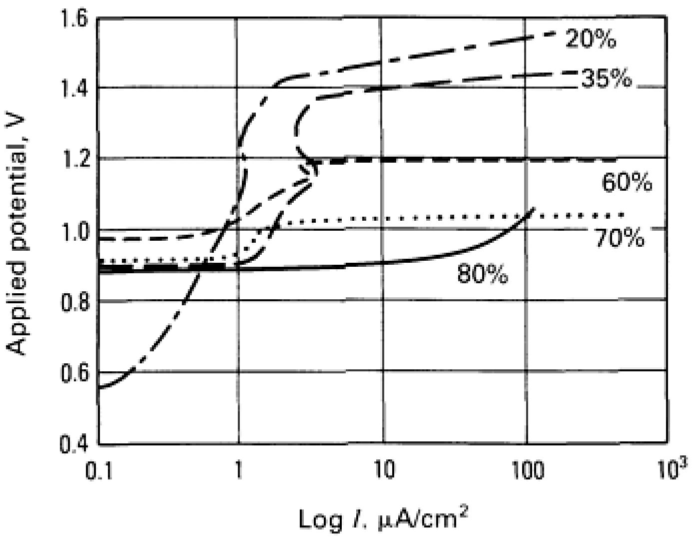

Fig. 12 Anodic polarization curves for zirconium in various concentrations of HNO_3. Applied potential is given in volts versus the saturated calomel electrode.

The primary concern in the use of zirconium for HNO_3 service is cracking in concentrated HNO_3. Results of C-ring tests indicate that zirconium specimens will have a long life when they are stressed below the yield point (Ref 33). Cracking can be prevented by avoiding high sustained tensile stresses or by applying other preventive measures (Ref 35).

Other concerns include the accumulation of chlorine gas in the vapor phase and the presence of noncomplexed F^- ions (Ref 29). Chlorine gas can be generated by the oxidation of chlorides by HNO_3. Areas that can trap chlorine gas should be avoided for zirconium equipment when Cl^- is present in HNO_3. The corrosion of zirconium in HNO_3-F^- solutions can be controlled by adding an inhibitor, such as zirconium sponge, zirconium nitrate ($Zr(NO_3)_4 \cdot 5H_2O$, or phosphorus pentoxide (P_2O_5), to convert F^- ions into noncorrosive complex ions.

Phosphoric acid (H_3PO_4) is less corrosive than other mineral acids. Many materials demonstrate useful resistance in H_3PO_4 at least at low temperatures. As usual, corrosion rates increase with temperature, concentration, and impurities in the acid. Areas such as the liquid-level line or the condensing zone are particularly vulnerable to attack.

Zirconium resists attack in H_3PO_4 at concentrations up to 55% and temperatures exceeding the boiling point. Above 55% H_3PO_4, the corrosion rate could increase greatly with temperature (Fig. 13). The most interesting area for zirconium would be dilute H_3PO_4 at elevated temperatures. As indicated in Table 12, zirconium outperforms tested stainless alloys in 20% H_3PO_4 at 150 °C (300 °F).

Table 12 Corrosion rates of zirconium and stainless alloys in 20% H_3PO_4 at 150 °C (300 °F)

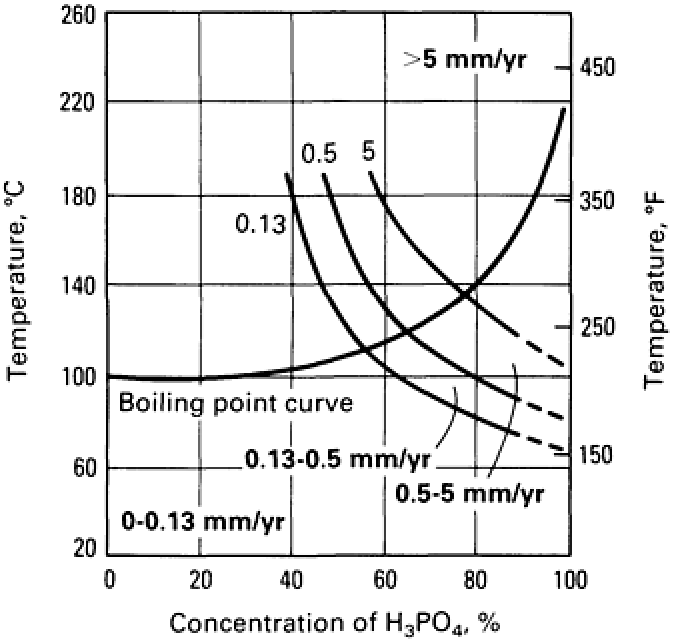

Fig. 13 Isocorrosion diagram for zirconium in H_3PO_4

Figure 14 shows the anodic polarization curves of zirconium in H_3PO_4 at near-boiling temperatures. As the concentration increases, the passive range diminishes gradually, and the passive current increases progressively. It appears thatzirconium passivates more slowly in H_3PO_4 than in other mineral acids.

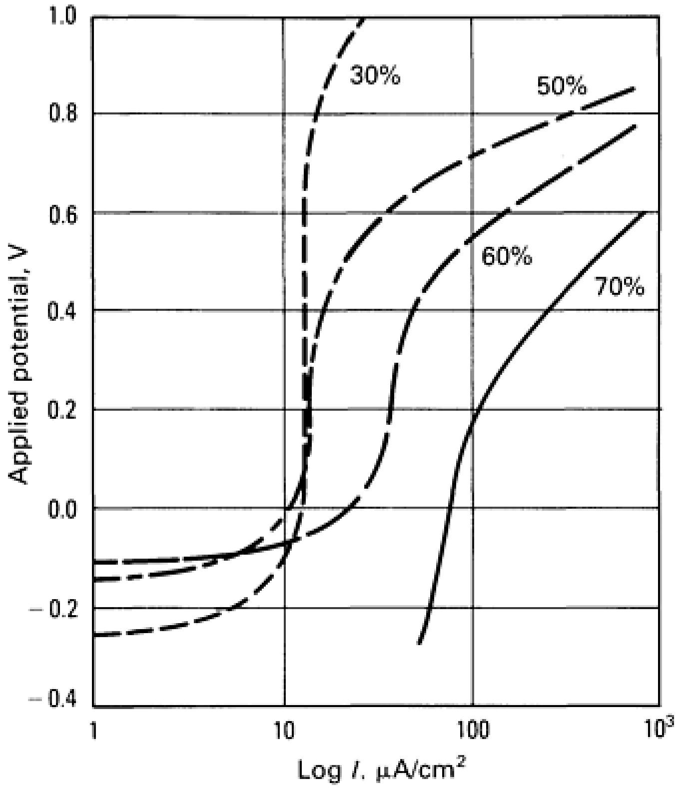

Fig. 14 Anodic polarization curves for zirconium in various concentrations of H_3PO_4. Applied potential is given in volts versus the saturated calomel electrode.

If H_3PO_4 contains more than a trace of F^- ion, attack on zirconium may occur. Because fluoride compounds are usually present in H_3PO_4, the use of zirconium has always been questioned. However, because P_2O_5 is an effective fluoride inhibitor for zirconium (Ref 36) and a large amount of P_2O_5 is often present in H_3PO_4 processes, tests should be performed to determine the suitability of zirconium in the actual H_3PO_4 medium.

Alkalies. Zirconium resists attack in almost all alkalies, either fused or in solution (Ref 37, 38, 39). This makes zirconium distinctly different from some other highly corrosion-resistant materials, such as tantalum, glass, graphite, and polytetrafluoroethylene (PTFE), which are attacked by strong alkalies. Moreover, steels and stainless alloys, which are resistant to alkalies, are subject to cracking at certain concentrations and temperatures.

Zirconium U-bend specimens were tested in boiling, concentrated sodium hydroxide (NaOH) (Ref 40). During the test period, the concentration changed from 50% to about 85%, and temperature increased from 150 to 300 °C (300 to 570 °F). The PTFE washers and tubes used to make the U-bend dissolved. However, the zirconium U-bends specimens remained ductile and did not show any cracks after 20 days.

Zirconium coupons were tested in a white liquor paper pulping solution, which contained NaOH and sodium sulfide (Na_2S), at 120, 175, and 225 °C (250, 345, and 435 °F) (Ref 40). All coupons had corrosion rates of less than 0.025 mm/yr (<1 mil/yr). In the same solution, graphite and glass both corroded rapidly at 100 °C (212 °F).

Salts. Zirconium is highly resistant to corrosion by most saline solutions. Corrosion rates are usually very low at all temperatures to the boiling point. Ferric chloride and $CuCl_2$ are examples of the few exceptions. Although zirconium has good corrosion resistance in sodium fluoride (NaF) and potassium fluorides (KF) at low temperatures, resistance decreases rapidly with increasing temperature. Consequently, zirconium is not recommended for handling any fluoride-containing solutions unless F^- ions are complexed.

Zirconium is considerably more resistant to chloride cracking than stainless steels are. No failure was observed in U-bend tests conducted in boiling 42% magnesium chloride ($MgCl_2$). The other attractive corrosion property of zirconium is its

high crevice corrosion resistance. Zirconium is not subject to crevice corrosion even in acidic chloride solutions at elevated temperatures.

Unlike many common metals, zirconium has very little affinity with sulfur. Zirconium-sulfur compounds were found to form only at temperatures above 500 °C (930 °F) (Ref 41). Furthermore, there is no instance of zirconium-sulfur bonds forming in aqueous systems (Ref 42). Consequently, the highly corrosive hydrogen sulfide (H_2S) will play a neutral role in the corrosion reactions of zirconium in sulfide-containing solutions. Zirconium coupons and U-bends were tested in numerous NaCl-H_2S solutions at temperatures to 205 °C (400 °F) (Ref 6, 43, 44). No pitting, crevice corrosion, or cracking was observed.

Zirconium is susceptible to pitting in acidic oxidizing chloride solutions. Cupric ions or more detrimental than Fe^{3+} ions in promoting the pitting and general corrosion of zirconium in acidic chloride solutions. The test results of zirconium in NaCl + $CuCl_2$ given in Tables 13 and 14 demonstrate the effects of pH surface condition, and heat treatment. The pitting and general corrosion of zirconium in NaCl + $CuCl_2$ can be controlled by adjusting the pH to 6 or higher (Table 13) or by heat treatments (Table 14). Also, resistance to pitting and general corrosion can be improved by surface conditioning. As usual, the weld metal is more susceptible to pitting than the base metal.

Table 13 Corrosion of zirconium in boiling NaCl solutions containing 500 ppm Cu^{2+}

Test consisted of seven 1-day runs.

(a) Pitting

Organic Media. Zirconium resists corrosion in a wide range of organic compounds, including acetic acid, acetic anhydride, formic acid, urea, ethylene dichloride, formaldehyde, citric acid, lactic acid, oxalic acid, tannic acid, and trichloroethylene.

Gases. Zirconium will react with oxygen in the air at temperatures above 540 °C (1000 °F), producing a white ZrO_2 film that is brittle and porous. At temperatures above 700 °C (1290 °F), zirconium will absorb oxygen and become embrittled after prolonged exposure.

The oxide film on zirconium provides an effective barrier to hydrogen absorption up to 760 °C (1400 °F). In an all-hydrogen atmosphere, hydrogen absorption will begin at 310 °C (590 °F), and the metal will ultimately become embrittled. Hydrogen can be removed from zirconium by prolonged vacuum annealing at temperatures above 750 °C (1380 °F). Zirconium is stable in NH_3 up to about 1000 °C (1830 °F), in most gases (CO, CO_2, SO_2, C_3H_8, and N_2) up to about 300 to 400 °C (570 to 750 °F), and in halogens up to about 200 °C (390 °F).

Molten Salts and Metals. Zirconium resists attack in some molten salts. It is very resistant to corrosion by molten NaOH to temperatures above 1000 °C (1830 °F). It is also fairly resistant to potassium hydroxide (KOH). The oxidation properties of zirconium in nitrate salts are similar to those in air.

Zirconium resists some types of molten metals, but the corrosion rate is affected by trace impurities, such as oxygen, hydrogen, or nitrogen, in the specific molten metal. Zirconium has a corrosion rate of less than 0.025 mm/yr (1 mil/yr) in liquid lead to 600 °C (1110 °F), lithium to 800 °C (1470 °F), mercury to 100 °C (212 °F), and sodium to 600 °C (1110 °F). The molten metals known to attack zirconium are zinc, bismuth, and magnesium.

Forms of Corrosion

Galvanic Corrosion. Because of the protective oxide film that forms on zirconium in air, zirconium assumes a noble potential similar to that of silver. When this protective film is damaged, zirconium can become activated and can therefore corrode when in contact with other more noble metals (Table 15).

Other less noble metals will corrode when in contact with zirconium when its oxide film is intact. For example, in seawater or acid solutions, corrosion of steels, aluminum, and zinc is accelerated in electrical contact with zirconium. Therefore, care should be taken to keep them electrically insulated.

Crevice Corrosion. Of all the corrosion-resistant structural metals, zirconium and tantalum are the most resistant to crevice corrosion. In low-pH chloride solutions or chlorine gas, for example, zirconium is not subject to crevice attack.

Pitting Corrosion. Zirconium is quite resistant to pitting corrosion in chloride, bromide, and iodide solutions. Electrochemical measurements, however, can reveal the pitting tendency of zirconium in these halide solutions. Zirconium does not pit in most halide environments, because the corrosion potential is lower than the pitting potential. The presence of oxidizing ions, such as Fe^{3+} or Cu^{2+}, in halide solutions increases the corrosion potential, and pitting will begin when the corrosion potential exceeds the pitting potential. Zirconium will also pit in perchlorate solutions if oxidizing impurities are present. Nitrate and sulfate ions (SO_4^{2-}) will inhibit the pitting of zirconium in certain concentrations.

Fretting corrosion takes place when vibrational contact is made at the interface of tight-fitting highly loaded surfaces, such as between the leaves of a spring or the parts of ball and roller bearings. Fretting of zirconium occurs when its protective oxide coating is damaged or removed. The best way to remove this type of corrosion (if it cannot be eliminated mechanically) is to apply a heavy oxide coating on the zirconium. This coating reduces friction drastically and prevents the removal of the passive protective oxide.

Stress Corrosion. Zirconium and its alloys resist SCC in many environments, such as NaCl, HCl, $MgCl_2$, NaOH, and H_2S, that would induce SCC in other alloys. Zirconium service failures due to SCC are few in chemical applications. The high SCC resistance of zirconium can probably be attributed to its high repassivation rate. Any break in the surface film will be quickly healed if sufficient oxygen is present. Even in dehydrated systems, sufficient oxygen is generally present for repassivation.

The environments known to cause SCC of zirconium alloys include $FeCl_3$ or $CuCl_2$ solutions, mixtures of methanol (CH_3OH) and HCl or methanol and iodine, concentrated HNO_3, and liquid mercury or cesium. Stress-corrosion cracking in zirconium alloys can be prevented by:

- Avoiding high sustained tensile stress
- Modifying the environment
- Achieving a crystallographic texture with the hexagonal basal planes perpendicular to the cracking path
- Maintaining a high-quality surface film, that is, one low in impurities, defects, and mechanical damage
- Using electrochemical protection techniques

Corrosion Protection of Zirconium

Oxide Film Formation. One of the unique properties of zirconium that makes it attractive for chemical use is the protective nature of its oxide film. This film gives excellent corrosion resistance in spite of the reactive nature of the metal. If it is mechanically destroyed, this impervious oxide barrier will regenerate itself in many environments. Aluminum and titanium exhibit similar characteristics, but the film on zirconium is considerably more corrosion resistant.

Several methods of oxide formation are possible, depending on the properties desired. Normal methods include anodizing, autoclaving in high-temperature water or steam, and formation in air.

Anodizing forms a very thin film, but may be useful in some applications. Because it is formed near room temperature, the film does not have the adhesion to the underlying metal of thermally produced coatings.

Autoclave film formation is a practice common to the nuclear reactor industry. In this process, the uniform film of high integrity that is formed is superior to the films, formed at lower temperatures. In addition to the slower corrosion rate, the rate of hydrogen absorption is drastically reduced. Films can be formed in 14 days in pressurized (19 MPa, or 2700 psi) deionized water at 360 °C (680 °F) or in 1 to 3 days at 400 °C (750 °F) and 10 MPa (1500 psi) in high-purity steam.

Film Formation in Air. The most common film used in the chemical industry is one formed in air. This film is often formed during the final stress relief of a component (30 min to 4 h at 550 °C, or 1020 °F). This film will range in color from a straw yellow to an iridescent blue or purple to a powdery tan or light grey. Such films need not be taken as a sign of metal contamination. This low-temperature stress relief does not cause significant penetration of oxygen into the metal, but it does form an oxide layer that is diffusion bonded to the base metal.

In addition to the corrosion resistance provided by the oxide film, a properly formed film serves as an excellent bearing surface against a variety of materials in several environments and over a broad temperature range (Ref 45). This treatment consists of cleaning the surface, followed by 4 to 6 h in air at 550 °C (1020 °F). The resultant oxide layer, approximately 5 μm (0.2 mil) thick, is equivalent to sapphire in hardness and is diffusion bonded to the base metal. The oxide layer can be damaged by a striking action, but it serves as an excellent bearing surface for sliding contacts. Oxidized zirconium pump shafts are an example of a common application.

Electrochemical Protection. Zirconium experiences a passive-to-transpassive transition with increasing potential in all mineral acids except HF (Ref 46). The commonly observed active nose in many metal-acid systems is not observed for

zirconium. Consequently, zirconium prefers a more reducing condition, which produces more stable passive films. In fact, zirconium is one of the best metals for handling reducing acids.

By impressing a potential that is arbitrarily 50 to 100 mV below its corrosion potential, zirconium can be used to handle oxidizing HCl solutions (Ref 26). Tables 16 and 17 demonstrate the benefits of electrochemical protection in greatly reducing pitting and SCC. The uniform corrosion rates of unprotected coupons are usually low. However, the penetration rates are much greater than the uniform corrosion rates and increase with immersion time. Electrochemical protection eliminates this local attack. Similarly, unprotected welded U-bends cracked in all but one case shortly after exposure, while protected U-bends resisted cracking for the 32-day test interval in all but one acid concentration. Thus, electrochemical protection offers a very definite improvement to the corrosion properties of zirconium in oxidizing acid chlorides.

Table 16 Corrosion of protected and unprotected Zr702 in HCl solutions containing 500 ppm Fe^{3+}

Test duration: 32 days

Medium	Acidity	Temperature		Corrosion rate			
				Unprotected		**Protected**[(a)]	
		°C	**°F**	**mm/yr**	**mils/yr**	**mm/yr**	**mils/yr**
10% HCl	3*N*	60	140	0.18	7.1	<0.0025	0.1

		77	170	0.1	20
37% HCl	12*N*	30	85	0.3	NF
		53	115	1	NF

(a) NF, no failure

This electrochemical protection technique can also be used to combat the SCC of zirconium in concentrated HNO_3 (Ref 35). In HNO_3, because of the difference between the corrosion potential and the critical potential that can cause SCC, it is desirable to control the potential of zirconium a few hundred millivolts below the corrosion potential, or at 500 mV versus SCE.

Applications

Nuclear Industry. The development of water-cooled nuclear power reactors brought about the use of zirconium for uranium fuel cladding and for structural components. As a result of these developments in the nuclear industry, the cost of zirconium and its alloys decreased considerably. Zirconium and its alloys have emerged as engineering materials rather than laboratory curiosities. Materials for fuel cladding and structural components in nuclear reactors are restricted because of the following crucial requirements:

- Low absorption cross section for thermal neutrons
- Adequate strength, creep resistance, and ductility after prolonged irradiation in reactor coolant
- Excellent corrosion and oxidation resistance
- Absence of interactions with the fuel material and fission products

Zirconium alloys, such as the Zircaloys and Zr-2.5Nb, have been developed to meet these requirements. In water-cooled reactors, zirconium alloys have found extensive use for fuel cladding and as pressure tubes. In systems in which the first requirement listed above is of overriding importance for reasons of neutron physics, the choice is virtually restricted to zirconium or one of its alloys.

Zirconium and its alloys also find application in other nuclear reactor systems, such as gas-cooled or organic coolant cooled reactors. More information on corrosion in nuclear power plants is available in the article "Corrosion in the Nuclear Power Industry" in this Volume.

Chemical-Processing Industry. The earliest application for zirconium was in the production of hydrogen peroxide (H_2O_2) using H_2SO_4. Zirconium shell and tube heat exchangers replaced graphite exchangers at one plant where they were

used to condense a 75% concentrated H_2SO_4 medium. The average maintenance-free life of the heat exchanger was 12 years. The tubes were thinned at the liquid/gas interface area because of bubble collapse, but no other corrosion occurred.

Because of this experience, the company replaced the graphite heat exchangers with zirconium shell and tube exchangers used in the manufacturing of acrylic films and fibers. In this application, the H_2SO_4 concentration was a high as 60% at 150 °C (300 °F).

Another major application in H_2SO_4 concerns the manufacture of methyl methacrylate. The system at one company includes pressure vessels, columns, heat exchangers, piping systems, pumps and valves made from zirconium

Zirconium is also widely used for column internals and reboilers in the manufacture of butyl alcohol. The operating conditions are 60 to 65% H_2SO_4 at temperatures to boiling and slightly above. Zirconium has corroded under upset conditions of elevated concentrations and when such impurities as $FeCl_3$ are present. Zirconium is also used in H_2SO_4 recovery and recycle systems in which fluorides are not present and the acid concentrations does not exceed 65%.

Zirconium has many applications in HCl, such as the production of concentrated HCl and polymers. Zirconium heat exchangers, pumps, and agitators have been used for over 15 years in an azo dye coupling reaction. In addition to being very corrosion resistant in this environment, zirconium does not plate out undesirable salts that would change the color and stability of the dyes. Other applications in HCl include the breaking down of cellulose in the food industry and the polymerization of ethylene chloride, which is carried out in HCl and chlorinated solvents.

Zirconium and its alloys were identified to offer the best prospects from a cost standpoint as materials for an HI decomposer in hydrogen production (Ref 47). Tantalum, molybdenum, Nb-1Zr, and zirconium alloys showed good corrosion resistance in HI_x media (as liquid or gas) from room temperature to 300 °C (570 °F), but most nickel- and iron-base alloys and some nonmetallic materials showed corrosion resistance only at low temperatures.

There is an increasing interest in the use of zirconium for HNO_3 service. For example, because of the high degree of concern over safety, zirconium is chosen as a major structural material for the critical equipment used to reprocess spent nuclear fuels. Another application is the production of HNO_3.

Zirconium columns and reboilers are being used at one company to produce 67% HNO_3 from 57% HNO_3. Previously, such materials as AISI type 304L stainless steel, titanium, and glasslined steel were used. Titanium and type 304L stainless steel had relatively short service lives, while glass-lined steel presented maintenance problems.

A 27-ton zirconium heat exchanger is being used by one company to produce 65% HNO_3 at 205 °C (400 °F). Before the use of zirconium, the company was faced with such problems as frequent replacement costs and downtime. In service since October, 1984, the zirconium heat exchanger has already outperformed the stainless steel predecessor.

With proper design, zirconium can be used to handle a highly concentrated HNO_3. For example, an Israeli chemical plant uses zirconium tubes in a U-tube cooler that processes bleached HNO_3 at concentrations between 98.5 and 99%. The unit cools the acid from 70 to 75 °C (160 to 170 °F) to 35 to 40 °C (95 to 100 °F). Previously, U-tube coolers were made from aluminum, which failed in 2 to 12 weeks. The zirconium has been in service for about 2 years, operating 24 h a day, six days a week.

Another very important application for zirconium is in process that cycle between HCl or H_2SO_4 and alkaline solutions. One company replaced a lead and brick lined carbon steel reactor vessel with zirconium because the reaction alternated between hot H_2SO_4 and caustic. The vessel has been in user for several years with no corrosion problems.

Zirconium reactor vessels and heat exchangers have been used in urea production for over 30 years. The use of zirconium equipment allows the reaction to take place at higher temperatures and pressures, permitting greater conversion of CO_2 to urea.

Zirconium is commonly used in the production of acetic acid and acetic anhydride. Its corrosion rate is less than 0.05 mm/yr (<2 mils/yr) in all concentrations and temperatures.

A zirconium distillation column proved to be safe and economical in a chlorinated hydrocarbon environment at more than 150 °C (300 °F). The column was built as a replacement for an old brick-lined column. Corrosion of the old column necessitated frequent renovations, with resultant high maintenance costs and plant downtime.

In the zirconium extraction process, several corrosive chemicals are used, including methyl isobutyl ketone, HCl, ammonium thiocyanate, H_2SO_4, and zirconyl chloride. Zirconium has been found to withstand the rigors of this manufacturing process, as in the following five examples.

First, the pumps used to transport the process chemicals are primary candidates for failure. Various materials, including stainless alloys, plastics, and high-silicon cast iron had been tried, but each had some limitation in this severe service. All wetted pump parts were converted to zirconium. The oldest one has been operating for more than 5 years and shows no sign of corrosion.

Second, for heat exchanger service in the same process chemicals, zirconium tubes replaced impervious graphite tubes that were prone to failure. The oldest zirconium heat exchanger has been in service more than 7 years and shows no signs of corrosion.

Third, steam stripper columns were converted from a furan resin to zirconium. At the 105 °C (220 °F) operating temperature of the columns, the plastic would embrittle and crack. Failure of these columns often resulted in expensive spills. By contrast, zirconium columns require no maintenance due to material failure.

Fourth, zirconium was selected for use in an electrostatic precipitator installed to scrub corrosive gases emitted from rotary kilns. The emitting electrodes and all fixtures exposed to the ammonium-sulfate and chloride-gas process stream were constructed from zirconium. The emitting electrodes are charged with 45,000 V.

Fifth, several parts of a crude chlorination scrubber were converted from plastic to zirconium. The plastic parts were replaced approximately every 6 months. The zirconium replacement is expected to last at least 25 years.

Zirconium is not toxic and has very low corrosion rates in many media. It is an excellent material for equipment used in food processing, the manufacture of electronic grade chemicals, and pharmaceutical preparations.

Potential applications also include heat exchangers exposed seawater, cladding for high-strength or lightweight alloys, parts subjected to thermal and mechanical stresses in a marine environment, and nuclear waste packages.

Finally, zirconium is an excellent material for laboratory equipment, such as crucible and autoclave. Preoxidized zirconium can be used as insulating washers and measuring devices exposed to high-temperature corrosives. More information on corrosion in the chemical industry is available in the article "Corrosion in the Chemical Processing Industry" in this Volume.

Corrosion Resistance of Hafnium

Hafnium occurs naturally in zirconium ores and is separated from zirconium for use in nuclear reactors. Hafnium shares many properties with zirconium, especially its high corrosion resistance to many media. Hafnium has a high thermal neutron absorption cross section in contrast to the very low absorption cross section of zirconium. This capability has made it a primary material for nuclear reactor control rods. The unique combination of high neutron absorption and excellent corrosion resistance to mineral acids also makes hafnium an excellent material for nuclear fuel reprocessing applications.

Hafnium is superior to zirconium and Zircaloy alloys in corrosion resistance in water and steam, molten alkali metals, and air. For example, weight gains in one of the standard corrosion tests (water at 360 °C, or 680 °F, and 18.5 MPa, or 2690 psi) for these nuclear grade metals are compared as follows:

Material	Weight gain, mg/dm^2	
	28 days	**56 days**
Zircaloy	20-22	25-28
Hafnium	3-6	5-7[a]

(a) Estimated range; test not run on routine basis.

However, at higher temperatures, hafnium begins to reach appreciably with oxygen, nitrogen, and hydrogen. Hafnium begins to react slowly with air or oxygen to form hafnium oxide at approximately 400 °C (750 °F); with nitrogen to form nitrides at approximately 900 °C (1650 °F); and rapidly with hydrogen at about 700 °C (1290 °F) to form hydrides. The oxides and nitrides formed at these elevated temperatures tend to remain at the surfaces; however, hydrogen diffuses rapidly and forms hydrides throughout the metal. Oxides, nitrides, and hydrides all lead to impaired ductility.

Like other reactive metals, hafnium resists attack at many chemicals because of the thin, tenacious layer of oxide that forms naturally on the surface of the metal. The corrosion properties are unaffected as long as this thin layer is not penetrated by reactants at increasing temperatures.

In aqueous solutions, hafnium is soluble in HF and concentrated H_2SO_4. It is resistant to dilute HCl and H_2SO_4 and is unaffected by HNO_3 in all concentrations. Aqua regia dissolves hafnium and, with the addition of small amounts of soluble fluoride salts, the reaction with other acids is appreciably increased. Hafnium is also very resistant to alkalies. The corrosion resistance of hafnium in various media is given in Table 18.

Table 18 Average corrosion rates of hafnium in various boiling solutions

Medium	Exposure time, days	Corrosion rate, mm/yr (mils/yr)
Seawater	10	nil
Saturated NaCl (pH 1)	21	<0.025 (<1)
70% $CaCl_2$	10	nil
40% HBr	10	0.025 (1.0)[a]
40% $Cu(NO_3)_2$	10	nil
40% $NaHSO_4$	10	1.1 (44)
10% NH_2SO_3H	10	nil

25% $Al_2(SO_4)$	10	nil
70% $ZnCl_2$	10	nil
20% HCl	8	0.005 (0.2)

(a) Pitting

Hafnium-Zirconium Alloys. The Hf-Zr system is one of the few metallic systems in which thermochemical properties are almost ideal. That is, hafnium and zirconium can form isomorphous alloys for all ratios of the components. Moreover, hafnium and zirconium exhibit similar excellent corrosion-resistant properties, although they differ greatly in neutron absorption. Therefore, hafnium-zirconium alloys offer a broad range of neutron absorption for special applications in which corrosion resistance and the neutron absorption are both important.

Hafnium alloys with 2.9, 17.3, 42.4, 59.5, and 81.4% Zr were evaluated for their corrosion resistance in various media. All of the alloys exhibited low corrosion rates (<0.0025 mm/yr, or 0.1 mil/yr) in the following boiling solutions: 30% HNO_3 with or without 1% NaCl, 50% HNO_3 with or without 1% NaCl, and 70% HNO_3, with or without 1% NaCl. Transverse-cut U-bend specimens of these alloys were tested in 90% HNO_3 at room temperature for 60 days. No cracking was observed.

The pitting resistance of these alloys was evaluated in boiling 20% HCl containing 200 ppm Fe^{3+} (as $FeCl_3$) and in chlorine gas saturated water. Test results are given in Tables 19 and 20. Although all alloys showed some pitting in these oxidizing chloride solutions, Hf-59.5Zr appeared to have the highest pitting resistance.

Table 19 Corrosion of hafnium-zirconium alloys in boiling 20% HCl + 200 ppm Fe^{3+}

Fe^{3+} added as $FeCl_3$

Alloy	Average corrosion rate				Pitting ranking[(a)]
	First test (2 days)		**Second test (4 days)**

Corrosion of Niobium and Niobium Alloys

T.L. Yau and R.T. Webster, Teledyne Wah Chang Albany

Introduction

NIOBIUM AND NIOBIUM ALLOYS are used in several corrosion-resistant applications, principally rocket and jet engines, nuclear reactors, sodium vapor highway lighting, and chemical-processing equipment. Niobium has many of the same properties of tantalum, its sister metal, but has one-half the density of tantalum (see the article "Corrosion of Tantalum" in this Volume). A common property niobium and tantalum is the interaction with the reactive elements hydrogen, oxygen, nitrogen, and carbon at temperatures above 300 °C (570 °F). These reactions will cause severe embrittlement. Consequently, at elevated temperatures, the metal must be protectively coated or used in vacuum or inert atmospheres. Niobium resists a wide variety of corrosive environments, including concentrated mineral acids, organic liquid metals (particularly sodium and lithium), metal vapors, and molten salts.

Mechanism of Corrosion Resistance

Niobium, like other reactive metals, derives its corrosion resistance from a readily formed, adherent, passive oxide film. The corrosion properties of niobium are similar to those of tantalum, but niobium is less resistant in aggressive media, such as hot concentrated mineral acids. Table 1 lists some typical corrosion data for niobium in aqueous media, Like tantalum, niobium is susceptible to hydrogen embrittlement if cathodically polarized by either galvanic coupling or by impressed potential. In addition to being very stable, the anodic niobium oxide film has a high dielectric constant and a high breakdown potential. These properties, coupled with its good electrical conductivity, have led to the use of niobium as a substrate for platinum-group metals in impressed-current cathodic protection anodes.

Table 1 Corrosion of niobium in aqueous media

Corrosion in Specific Media

Acid Solutions. Niobium is resistant to most organic acids and mineral acids, except hydrofluoric acid (HF), at all concentrations and temperatures below 100 °C (212 °F). This list of acids includes the halogen acids hydrochloric (HCl),hydroiodic (Hl), and hydrobromic (HBr); and nitric acid (HNO_3); sulfuric acid (H_2SO_4); and phosphoric acid (H_3PO_4). Niobium is especially resistant under oxidizing conditions--for example, in concentrated H_2SO_4 containing ferric (Fe^{3+})or cupric (Cu^{2+})ions. At room temperature, niobium is resistant to H_2SO_4 at all concentrations up to 95%. The corrosion rate increases rapidly with temperature and concentration. Figure 1 shows the corrosion rates for niobium and tantalum at elevated temperatures versus concentration in H_2SO_4.

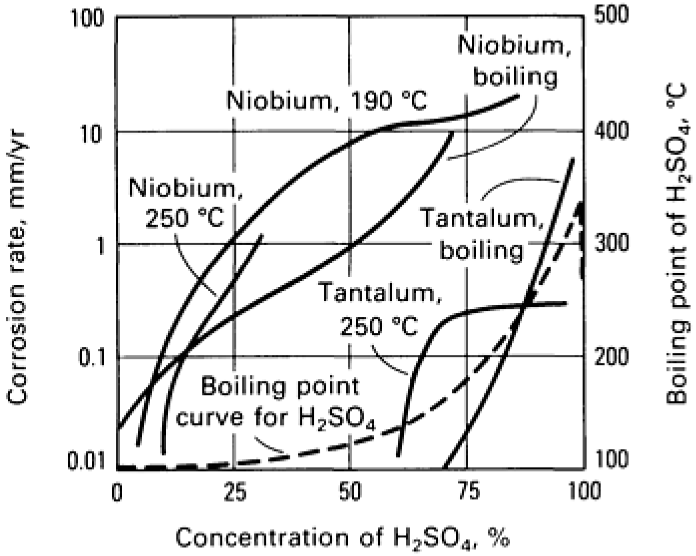

Fig. 1 Corrosion of niobium and tantalum in H_2SO_4 at various concentrations and temperatures. Source: Ref 1

Niobium is completely resistant in dilute sulfurous acid (H_2SO_3) at 100 °C (212 °F). In concentrated acid at the same temperature, it has a corrosion rate of 0.25 mm/yr (10 mils/yr). Niobium is completely resistant in HNO_3, having a corrosion rate of 0.025 mm/yr (1 mil/yr) in 70% HNO_3 at 250 °C (480 °F). In chromium plating solutions, niobium experiences only a slight weight change, and in the presence of small amounts of fluoride (F^-) catalyst, it exceeds the corrosion resistance of tantalum.

Niobium is inert in mixtures of $HNO_3$and HCl. It has aa corrosion rate of less than 0.025 mm/yr (1 mil/yr) in aqua regia at 55 °C (130 °F). In boiling 40 and 50% H_3PO_4 with small amounts of F^- impurity (5 ppm), niobium has a corrosion rate of 0.25 mm/yr(10 mils/yr). In mixtures of HNO_3 and H_2SO_4, niobium can dissolve readily.

Alkaline Solutions. In ambient aqueous alkaline solutions, niobium has corrosion rates of less than 0.025 mm/yr (1 mil/yr). At higher temperatures, even though the corrosion rate does not seem excessive, niobium is embrittled even at low concentrations (5%) of sodium hydroxide (NaOH) and potassium hydroxide (KOH). Like tantalum, niobium is

embrittled in salts that hydrolyze to form alkaline solutions. These salts include sodium and potassium carbonates and phosphates.

Salt Solutions. Niobium has excellent corrosion resistance in salt solutions, except those that hydrolyze to form alkalies. It is resistant to chloride solutions even in the presence of oxidizing agents. It does not corrode in 10% ferric chloride ($FeCl_3$)at room temperature, and it is resistant to attack in seawater. Niobium exhibits resistance similar to tantalum in salt solutions.

Gases. Niobium is easily oxidized. It will oxidize in air above 200 °C (390 °F). The reaction, however, does not become rapid until above red heat (about 500 °C, or 930 °F). At 980 °C (1795 °F), the oxidation rate is 430 mm/yr (17 in./yr). In pure oxygen, the attack is catastrophic at 390 °C (735 °F). Oxygen diffuses freely through the metal, and this causes embrittlement. Niobium reacts with nitrogen above 350 °C (660 °F), with water vapor above 300 °C (570 °F), with chlorine above 200 °C (390 °F), and with carbon dioxide, carbon monoxide, and hydrogen above 250 °C (480 °F). At temperature of 100 °C (212 °F), niobium is inert in most common gases, for example, bromine, chlorine, nitrogen, hydrogen, oxygen, carbon dioxide, argon monoxide, and sulfur dioxide (wet or dry).

Liquid Metals. Niobium resists attack in many liquid metals to relatively high temperatures. These include bismuth below 510 °C (950 °F), gallium below 400 °C (750 °F), lead below 850 °C (1560 °F), lithium below 1000 °C (1830 °F), mercury below 600 °C (1110 °F), sodium, potassium, and sodium-potassium alloys below 1000 °C (1830 °F), thorium-magnesium eutectic below 850 °C (1560 °F), uranium below 1400 °C (2550 °F), and zinc below 450 °C (840 °F). The presence of excessive amounts of nonmetallic impurities (for example, gases) may reduce the resistance of niobium to these liquid metals.

Because liquid metals are excellent heat transfer media, they can be used in very compact thermal systems, such as the fast breeder reactor, reactors for space vehicles, and fusion reactors. Niobium is a serious candidate as a material for high-efficiency reactors.

Niobium resists attack by sodium vapor at high temperatures and pressures. The Nb-lZr alloy is in use as the end caps in high-pressure sodium vapor lamps used for highways lighting.

Galvanic Effects. Niobium is susceptible to hydrogen embrittlement if it is polarized cathodically by galvanic coupling or by chemical attack. For this reason, niobium cannot be protected by cathodic protection. However, if niobium is polarized anodically, it forms a very stable passive film that protects the metal from corrosion. This property, combined with good electrical conductivity (13% that of copper) and good mechanical properties, has led to the use of niobium as a substrate metal for platinum in impressed-current cathodic protection anodes. Its anodic breakdown potential in chloride solution is about 115 V; titanium has a breakdown potential of about 10 V.

Niobium platinized anodes are used in high-resistivity waters and other environments that require high driving potential to obtain good current spread. In this application, niobium has an advantage over tantalum because it is less expensive. The cost can be further decreased by using a composite electrode with a copper core, which increases the conductivity of the anodes.

Localized Corrosion. Niobium is highly resistant to localized attacks, such as pitting, crevice corrosion, and stress-corrosion cracking (SCC). The presence of heavy-metal ions in reducing acids will improve the corrosion resistance of niobium (Table 2). Also, as shown in Table 2, niobium does not suffer pitting or crevice corrosion in simulated scrubber solutions (Ref 2).

Table 2 Corrosion of niobium in simulated scrubber solutions

Solution	Temperature		Test duration, days	Average corrosion rate		Pitting or crevice corrosion
	°C	°F		mm/yr	mils/yr	
7 vol% H_2SO_4 + 3 vol% HCl + 1% $FeCl_3$ + 1% $CuCl_2$	103	217	8	0.018	0.7	None
30 vol% H_2SO_4 + 3 vol% HCl + 1% $FeCl_3$ + 1% $CuCl_2$	110	230	8	0.12	4.8	None

In one study, niobium did not exhibit SCC in 90% HNO_3 at room temperature using the slow strain rate technique or in liquid bromine using the U-bend method (Ref 3). However, with particular types of surface contamination and preparation, niobium, like tantalum, was found to be sensitive to crevice corrosion at anodic potentials below those normally regarded as safe (Ref 4).

Corrosion in Waters. Niobium reacts with water to form niobium oxide. There is a direct transition from immunity to passivity without an intermediate region where corrosion occurs. Figure 2 shows the Pourbaix (potential-pH) diagram of niobium in water at 25 °C (75 °F).

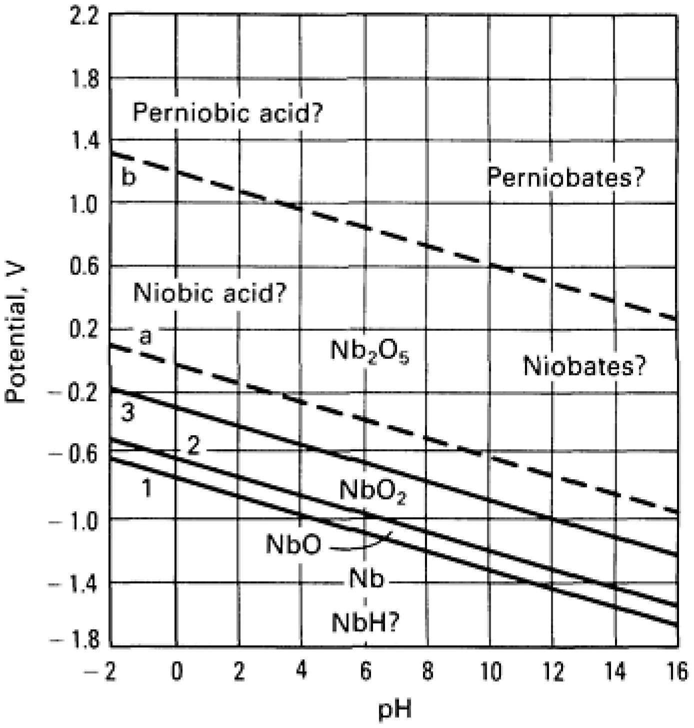

Fig. 2 Pourbaix (potential-pH) diagram for niobium in water at 25 °C (75 °F). See Ref 6 for details. Source: Ref 5 and 6

Applications

Chemical and Metal Processing. The high anodic breakdown potential of niobium (about 100 V in seawater), coupled with good electrical conductivity and mechanical properties, has led to its use as a substrate for platinum in impressed-current cathodic protection anodes. Niobium is an important metal in the chromium plating application. It is particularly attractive when fluoride ions are also present. It has the highest resistance to attack by fluoride ions among reactive and refractory metals.

Niobium retains excellent corrosion resistance in liquid bromine even when saturated with moisture. It can be used to make equipment designed to produce or transport liquid bromine.

Niobium would be well suited for handling hot, concentrated HNO_3. It can be considered for highly oxidizing solutions expected in chemical wastes, scrubber environments, and mining solutions.

The corrosion resistance and mechanical properties of niobium can now be more easily utilized because of advancements in cladding techniques. Thin layers (for example, 0.25 mm, or 0.01 in.) of niobium sheets can be cladded to common metals, such as steel, by using various cladding techniques. More information on corrosion in chemical- and metal-processing applications is available in the articles "Corrosion in the Chemical Processing Industry" and "Corrosion of Metal Processing Equipment" in this Volume.

Nuclear Applications. Niobium is used in certain fast breeder reactors because of its compatibility with uranium and liquid sodium/potassium.

Miscellaneous Applications. Niobium is finding use in components for high-pressure sodium lamps, in satellite launch vehicles and spacecraft, and in the production of superconducting devices. Niobium alloys are used for rocket nozzles on satellite launch vehicles and spacecraft. Because niobium is easily oxidized at elevated temperatures, it must be coated for this use. Aluminide and silicide coatings are used for this purpose. A major application is in superconducting devices. Niobium alloys also are used in aircraft fasteners.

Corrosion of Tantalum*

Mortimer Schussler (retired) and Charles Pokross, Fansteel Inc.

Introduction

TANTALUM is one of the most versatile corrosion-resistant metals known. It combines the inertness of glass with the strength and ductility of low-carbon steel and has a much higher heat transfer capability than glass. The relatively high cost of tantalum has been a limiting factor in its use, but where corrosion resistance is important, the economics are changing. Fabrication techniques, in which thin linings of tantalum are used in chemical-processing equipment, result in equipment that has the acid corrosion resistance provided by tantalum but at a much lower cost than an all-tantalum construction.

The long life and reliability of tantalum equipment in severe-corrosion applications often more than offsets its higher initial costs. Therefore, a new situation has been created for utilizing the benefits of tantalum products. When tantalum is properly applied in chemical applications--one of its primary uses--it can often be justified not only on a field replacement basis but also on initial installation. Table 1 lists numerous applications for tantalum in the chemical processing industry and in other industries.

Table 1 Applications for tantalum equipment

Product	Operation	Industry	Equipment	Remarks
Acetic acid, crude	Recovery from wood distillate	Chemical	Bayonet heaters, condensers	. . .
Aluminum chloride	Concentration	Chemical	Bayonet heaters, condensers	Condensers for HCl recovery
Amino acids	Digesting proteins in	Chemical, breweries,	Bayonet heaters, condensers,	See glutamic acid, monosodium

	HCl	distilleries, food	complete plants	glutamate
Ammonium chloride, crude	Concentration from gas house liquors	Gas and coke	Bayonet heaters, heat exchangers	. . .
Ammonium chloride, pure	Concentration before crystallizing	Chemical	Heat exchangers	High pressure
Ammonium nitrate	Concentration	Chemical	Heat exchangers	. . .
Aqua regia	Ore solution, stainless steel pickling	Chemical, steel	Bayonet heaters, heat exchangers, pickling tank coils	. . .
Aviation gasoline	Butane isomerization	Petroleum	Anhydrous HCl plants	. . .
Benzoic acid	Hydrolysis from benzyl chloride	Chemical, pharmaceutical	HCl absorbers	Recovery of by-product HCl

Mechanism of Corrosion Resistance

The outstanding corrosion resistance and inertness of tantalum are attributed to a very thin, impervious, protective oxide film that forms upon exposure of the metal to slightly anodic or oxidizing conditions (Ref 1). Although tantalum pentoxide (Ta_2O_5) is the usual oxide form, suboxides may also exist in transition between the base metal and the outer film (Ref 2). It is only when these oxide films react with or are penetrated by a chemical reagent that attack occurs on the underlying metal substrate. A visible, continuous oxide film can be formed on tantalum by electrolytic anodizing in an acid solution such as dilute phosphoric acid (H_3PO_4). This film has a high dielectric constant, which prevents the flow of direct current from tantalum to an electrolyte when the metal is made anodic. The high stability of the oxide film makes tantalum valuable for capacitor and rectifier applications.

Tantalum occupies a position toward the electropositive end of the electromotive force (emf) series and thus tends to become cathodic in the galvanic cell circuit formed by contact with almost all other metals. Because of this cathodic behavior, atomic hydrogen, which may be liberated, can be absorbed by the tantalum and result in hydrogen embrittlement. Stray voltages can also cause this undesired effect. Therefore, when used in chemical-processing equipment, tantalum must be protected from becoming cathodic so that the material will not become embrittled.

Hydrogen embrittlement and methods for minimizing its effect are discussed in the section "Hydrogen Embrittlement, Galvanic Effects, and Cathodic Protection of Tantalum" in this article.

Corrosion of Tantalum in Specific Media

Because of the wide ranges of type, concentration, and temperature of the media to which it exhibits excellent corrosion resistance, tantalum has found a primary application as a material of construction in the chemical-processing industry. This section will discuss the corrosion resistance of tantalum in many of the important media in which it is used (or could be used) commercially. Additional information is available in the article "Corrosion in the Chemical Processing Industry" in this Volume.

Water. Tantalum is not attacked by fresh water, mine waters (which are usually acidic), or seawater, either cold or hot. Tantalum shows no corrosion in deionized water at 40 °C (100 °F) (Ref 3).

For tantalum equipment exposed to boiler waters and condensates, the alkalinity must be controlled. The pH should be less than 9 and preferably no more than 8. No failures caused by exposure of tantalum to steam condensate have ever been recorded. Tantalum is used in many cases at saturated steam pressures above 1035 kPa (150 psi) at temperatures of 185 °C (365 °F) and is considered resistant to saturated steam below 250 °C (480 °F) at a pressure of 3.9 MPa (560 psi).

Acids. The chemical properties of tantalum are similar to those of glass. Like glass, tantalum is immune to attack by almost all acids except HF (see Table 2 for compatibility data on tantalum in numerous acids). Reactions conducted in the laboratory in glass equipment can be transferred to plan operations in tantalum equipment with complete assurance that the equipment will be free from corrosion, that the product will not become contaminated, and that undesired side reactions will not occur.

(a) E, no attack; V, variable depending on temperature and concentration: NR, not resistant

Tantalum is not attacked by such agents as sulfuric acid (H_2SO_4), nitric acid (HNO_3), hydrochloric acid (HCl), aqua regia, perchloric acid ($HClO_4$), chlorine, bromine, hydrobromic acid (HBr) or any of the bromides, phosphoric acid (H_3PO_4) when free of the F^- ion, nitric oxides, chlorine oxides, hypochlorous acid (HClO), organic acids, and hydrogen peroxide (H_2O_2) at ordinary temperatures. It is attacked, even at room temperature, by strong alkalies, HF, and free sulfur trioxide (SO_3) (as in fuming H_2SO_4). Table 3 compares the corrosion resistance of tantalum and other resistant metals in various acids.

Table 3 Corrosion resistance of tantalum and other metals to acids

(a) Became brittle.

(b) Tarnished.

(c) Uneven corrosion

Sulfuric Acid. Tantalum is highly resistant to corrosion by H_2SO_4 in all concentrations up to about 98%. It is inert to dilute acid even at boiling temperatures and is not attacked by concentrated acids at temperatures below 150 °C (300 °F). A slow, uniform attack by concentrated H_2SO_4 begins on tantalum at about 175 °C (345 °F). However, the corrosion by hot, concentrated H_2SO_4 is uniform, and at a temperature as high as 200 °C (390 °F), tantalum can be successfully used with 98% H_2SO_4 (Fig. 1).

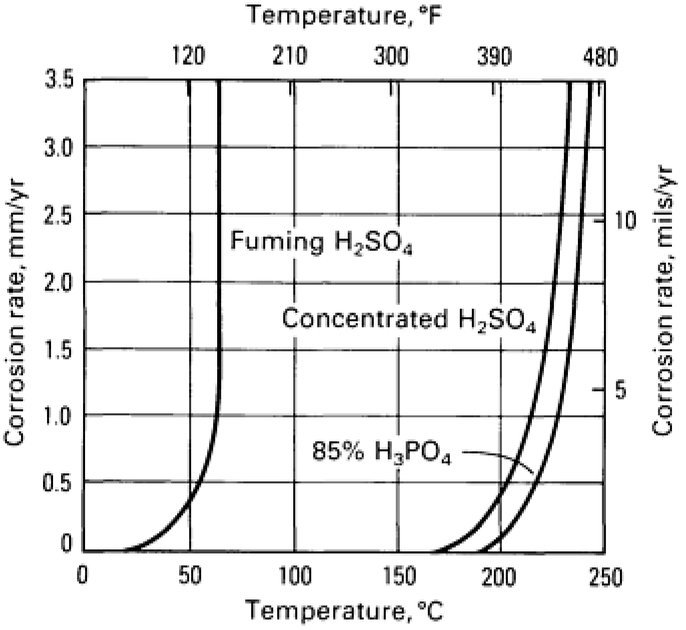

Fig. 1 Corrosion rates of tantalum in fuming H_2SO_4 (oleum) and concentrated H_2SO_4. Source: Ref 4

Fuming H_2SO_4 (oleum) attacks the metal much more rapidly than the concentrated acid does (Fig. 1), but the attack on tantalum by either concentrated H_2SO_4 or oleum is uniform over the surface. The presence of impurities does not increase the corrosion rate of tantalum in H_2SO_4. No failures due to hydrogen embrittlement have been reported for tantalum chemical-processing equipment used in H_2SO_4 service. However, under special laboratory test conditions, hydrogen embrittlement can be produced in tantalum (Ref 5). This behavior is discussed in the section "Hydrogen Embrittlement, Galvanic Effects, and Cathodic Protection of Tantalum" in this article.

Phosphoric Acid. Figure 2 shows the corrosion rate of tantalum exposed to various concentrations of reagent grade (chemically pure) H_3PO_4 at the boiling temperature and at 190 °C (375 °F). Figure 2 also shows the boiling point of H_3PO_4 as a function of concentration. Tantalum exhibits superior resistance to boiling H_3PO_4 at all concentrations. At temperature in excess of boiling, the superiority of tantalum is evident. However, if the H_3PO_4 contains more than a few parts per million of F^- ion, as is frequently the case with commercial acid, attack on the tantalum may occur.

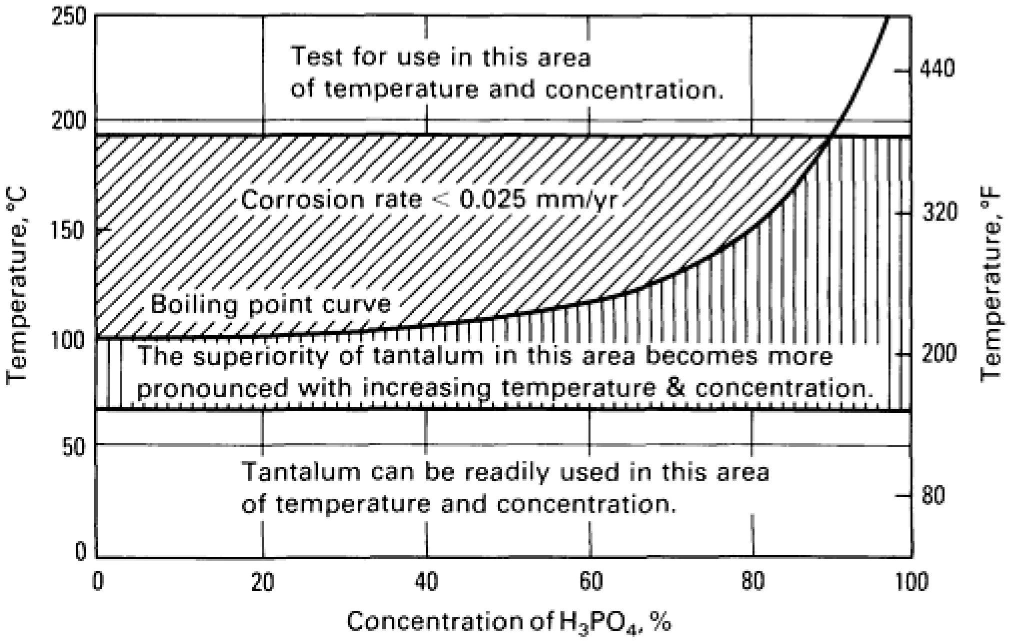

Fig. 2 Corrosion resistance of tantalum in H_3PO_4 at various concentrations and temperatures. Source: Ref 5, 6

In one study, the corrosion resistance of commercially pure tantalum to a mixture of H_3PO_4, potassium chloride (KCl), and water initially containing 60 to 260 ppm F^- was evaluated at 120 °C (250 °F) and at atmospheric pressure (Ref 7). Corrosion rates calculated from the test data were of the order of 0.0005 to 0.15 mm/yr (0.02 to 6 mils/yr), indicating good corrosion resistance.

Hydrochloric Acid. Specific corrosion tests and many industrial applications show that tantalum is completely inert to HCl in all concentrations under atmospheric pressure to at least 90 °C (195 °F). This has been demonstrated by long industrial experience. For example, bayonet heaters fabricated from tantalum with a wall thickness as thin as 0.33 mm (0.013 in.) have been in continuous industrial use in HCl distilling units for over 20 years without being attacked.

Figure 3 shows the corrosion rate of tantalum in HCl over the concentration range from 1 to 35%. Figure 4 shows a plot of the corrosion rate of tantalum in 20, 32, and 37% HCl as a function of temperature. Additions of HNO_3 and ferric or cupric chlorides ($FeCl_3$ or $CuCl_2$) to HCl tend to improve corrosion resistance.

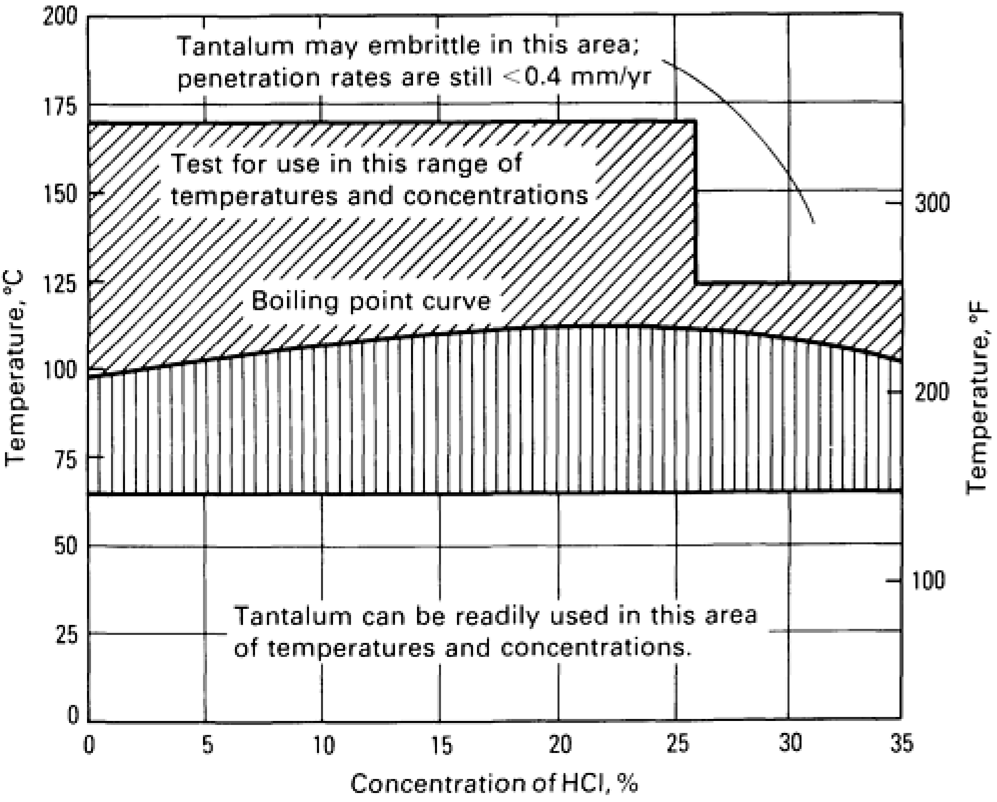

Fig. 3 Corrosion of tantalum in HCl at various concentrations and temperatures. Source: Ref 5, 6

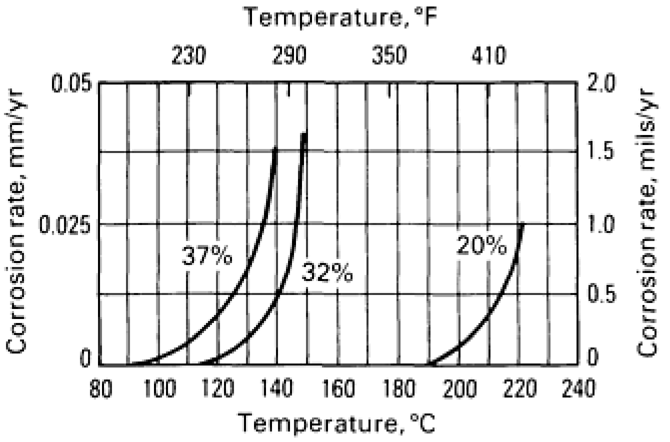

Fig. 4 Corrosion rates of tantalum in HCl of various concentrations

Tests indicate that tantalum resists HCl at all temperatures and concentrations to 190 °C (375 °F). At concentrations near 30% and at 190 °C (375 °F), some tendency toward hydrogen embrittlement has been noted. This possibility should be considered when handling concentrated solutions of acid above the boiling point. The tendency was not noted at or below the boiling point of HCl solutions.

Nitric Acid. Tantalum is inert to HNO_3 solutions in all concentrations and at all temperatures to boiling. The presence of Cl^- in HNO_3 does not reduce the corrosion resistance of the metal to this acid. Figure 5 shows the corrosion rate of tantalum in HNO_3 concentrations ranging from 1 to 70%.

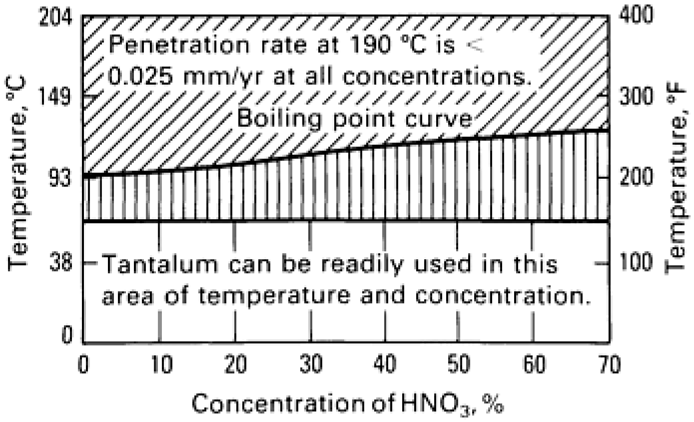

Fig. 5 Corrosion resistance of tantalum in HNO_3 at various concentrations and temperatures. Source: Ref 5, 6

The corrosion rate of tantalum to HNO_3 at sub-boiling temperature is less than 0.4 μm/yr (0.015 mils/yr) for most concentrations and temperatures. In general, the use of tantalum at these temperatures would not be economical, considering the resistance offered by stainless steels. At temperatures near and above the normal boiling point of HNO_3, the superior resistance of tantalum becomes pronounced. Corrosion testing of tantalum for equipment to be used at these temperatures is recommended. Tantalum has been successfully used for years to handle fuming HNO_3 at service conditions up to 5.5 MPa (800 psig) and 315 °C (600 °F) in chemical-processing equipment.

Hydrofluoric acid is the best solvent for tantalum. The rate of attack varies from slow for dilute acid to rapid for concentrated solutions. The rate of attack by HF can be greatly accelerated by the addition of HNO_3 and other oxidizing agents, such as H_2O_2. Embrittlement of the metal due to the absorption of atomic (nascent) hydrogen can occur when the metal is attacked by HF. However, when sufficient HNO_3 is present, hydrogen embrittlement does not occur, even after nearly all of the tantalum is dissolved--for example, by severe pickling. The rate of hydrogen absorption is greatly reduced in dilute HF if the tantalum is made positive by impressing 2 to 10 V on the material in an electrolytic cell. Embrittlement by hydrogen does not occur when tantalum is made positive. In solutions of HF, which prevent the formation of the protective oxide film, tantalum is less noble than zinc, manganese, aluminum, and zirconium (Ref 8).

Attack on tantalum apparently does not occur in chromium plating baths containing F^- (Ref 9). In one test, a corrosion rate of 0.0005 mm/yr (0.02 mils/yr) was observed on a sample placed in a chromium plating bath for $2\frac{1}{2}$ months. The solution contained 40% chromium trioxide (CrO_3) and 0.5% F^- ion at a temperature of 55 to 60 °C (130 to 140 °F). In another 4-day exposure, a corrosion rate of 0.005 mm/yr (0.2 mils/yr) occurred in a bath containing 250 g/L (33 oz/gal) CrO_3, 1.5 g/L (0.20 oz/gal) H_2SO_4, and 3 g/L (0.40 oz/gal) of F^- ion at 55 °C (130 °F). Complex ion formation between chromium and F^- ions is thought to explain the reduced activity of F^-.

Corrosion rates were determined on several construction materials, including tantalum, in HNO_3 plus HF mixtures (Ref 10). These studies were related to tests of various candidate materials for fuel element processing. Tantalum showed some promise but was not entirely satisfactory. Its possible use was considered restricted to low fluoride concentrations and temperatures below boiling.

Acid Mixtures. Tests were conducted to determine the suitability of tantalum to either hot or cool mixed solutions of HCl, H_2SO_4, and potassium hydrogen sulfate ($KHSO_4$). The initial temperature was the boiling point of the solution, 115 °C (235 °F). Because of a loss of fluid over a weekend, the boiling point elevated so that the temperature at the completion of the test was 120 °C (250 °F). The corrosion rate of the tantalum based on 4 days of exposure was 0.001 mm/yr (0.04 mils/yr). Examination of the sample after the test indicated no apparent discoloration. There were no visible signs of attack, and the sample remained ductile after the test. The very slight weight loss reported was believed to have been caused by physical scraping on the sample. Thus, tantalum exhibited excellent corrosion resistance to this mixture.

Corrosion rates were also determined on tantalum exposed to a mixture of concentrated H_2SO_4, HNO_3, and HCl at temperatures ranging from 200 to 270 °C (390 to 520 °F) (Ref 11). Corrosion rates were reduced by a factor of three

compared to the rate in H_2SO_4 alone. When only HCl or water was added, the corrosion rate was reduced only slightly. When HNO_3 was added alone, the corrosion rate was the same as when HCl and HNO_3 were both added. Thus, the oxidizing effect of HNO_3 reduced the tantalum corrosion rate.

Other Acids and Reagents. Over the temperature range commonly used in solution processes, tantalum is inert to sulfur and phosphorous chlorides, diphenyl and diphenyl oxide, and hydrogen sulfide (H_2S).

Hypochlorites do not affect tantalum unless they are strongly alkaline. The same is true of all chlorides, bromides, and iodides. Fluorides, however, will attack tantalum.

A detailed corrosion study was conducted in a chlorine dioxide (ClO_2) plant for pulp bleaching in an effort to secure useful information on the performance of various metals and alloys in this service (Ref 12). Tantalum was among the materials tested, and it showed no corrosion attack in any of the tests.

Salts. Tantalum is not attacked by dry salts or by salt solutions at any concentration or temperature unless HF is liberated when the salt dissolves or unless a strong alkali is present. Salts that form acidic solutions have no effect on tantalum. However, fused sodium hydrosulfate ($NaHSO_4$) or $KHSO_4$ dissolves tantalum (Ref 9). Table 4 gives compatibility data for tantalum in numerous salts.

Table 4 Effects of salts on tantalum

Salt	Concentration, %	Temperature, °C (°F)	Code[(a)]

(a) E, no attack; V, variable, depending on temperature and concentration; NR, not resistant

Alkalies. Sodium hydroxide (NaOH) and potassium hydroxide (KOH) solutions do not dissolve tantalum, but tend to destroy the metal by formation of successive layers of surface scale. The rate of the destruction increases with concentration and temperature. Damage to tantalum equipment has been experienced unexpectedly when strong alkaline solutions are used during cleaning and maintenance.

Tantalum is attacked, even at room temperature, by concentrated alkaline solutions and is dissolved by molten alkalies. However, tantalum is fairly resistant to dilute alkaline solutions. In one long-term exposure test in a paper mill, tantalum suffered no attack in a solution with a pH of 10.

A study using change in electrical resistivity to measure corrosion rates found that tantalum wire totally immersed in 10% NaOH solution at room temperature for 210 days corroded at the rate of 0.24 μm/yr. A similar rate occurred in 10% NaOH at 100 °C (212 °F). In the latter case, there was some local effect at the points where the wire left the solution and entered submerged rubber stoppers in the sides of the corrosion vessel; this accounted for most of the weight loss.

Tantalum has been used as anode baskets in a number of silver cyanide barrel platers for several years of service life, and although the solutions are quite alkaline with free KOH, the tantalum has remained bright and ductile, with no failures occurring. The tantalum anode basket is protected by the positive voltage of the cell itself.

Organic Compounds. In general, tantalum is completely resistant to organic compounds and is used in heat exchangers, spargers, and reaction vessels in several important organic reactions, particularly when corrosive inorganics are involved. These include solutions of phenol and of acetic, lactic, and oxalic acids. Table 5 lists the compatibility of tantalum in numerous corrosive environments, including many organic compounds.

(a) E, no attack; V, variable, depending on temperature and concentration; NR, not resistant

Most organic salts, gases, alcohols, ketones, alkaloids, and esters have no effect on tantalum. Specific exceptions, however, should be made for reagents that may hydrolyze to HF or contain free SO_3 or strong alkalies. One important exception was noted in Ref 13, which states that mixtures of anhydrous methanol with chlorine, bromine, or iodine cause pit-type corrosion on tantalum at 65 °C (150 °F). This is of particular interest because tantalum is not attacked individually by methanol, the halogens involved, or the product, methyl halide, even at somewhat higher temperatures. Also, pit-type corrosion on tantalum is rare.

Fine Chemicals, Foods, and Pharmaceuticals. The immunity of tantalum to corrosion also ensures freedom from product contamination and undesired side reactions in the processing of fine chemicals, foods, and pharmaceuticals.

Body Fluids and Tissues. Tantalum is completely inert to body fluids and tissues. Bone and tissue do not recede from tantalum, which makes it attractive as an implant material for the human body; however, the superior strength and rigidity of stainless steel and the castability of the high-cobalt alloys have led to their much greater use as prosthetic materials. Tantalum has been used for bone replacement and repair, suture wire, cranial repair plates, and wire gauze for abdominal-muscle support in hernia-repair surgery (Ref 14). More information on this subject is available in the article "Corrosion of Metallic Implants and Prosthetic Devices" in this Volume.

Carbon, Boron, and Silicon. Tantalum reacts at elevated temperatures (not stated) directly with carbon, boron, and silicon to form Ta_2C and TaC, TaB and TaB_2, and $TaSi_2$, respectively, although other binary compounds of these elements have been reported (Ref 9). These compounds are characterized by metallic appearance and properties, high melting point, and high hardness.

Phosphorus. Tantalum phosphides, TaP and TaP_2, are formed by heating tantalum filings in phosphorus vapor at 750 to 950 °C (1380 to 1740 °F) (Ref 9).

Sulfur. Tantalum reacts with sulfur or H_2S at red heat to form tantalum sulfide (Ta_2S_4). Tantalum sulfide is also formed when Ta_2O_5 is heated in H_2S or carbon disulfide (CS_2). Little or no data are available on the effect of solutions of sulfides, such as those of the alkali and alkaline earth metals, but the highly alkaline nature of these compounds indicates that they probably corrode tantalum to some degree.

Selenium and Tellurium. Tantalum is attacked by selenium and tellurium vapors at temperatures of 800 °C (1470 °F) and higher. In contrast, there is little or only slight attack on the metal by liquid selenides and tellurides of yttrium, the rare earths, and uranium at temperatures of 1300 to 2100 °C (2370 to 3810 °F), and tantalum is considered to be a satisfactory material in which to handle these intermetallic compounds.

Gases. The solubility of oxygen in tantalum, as determined by an x-ray technique, is shown by curve B in Fig. 6. There is some disagreement among investigators, but oxygen solubility may be accepted as being close to values based on electrical resistivity and hardness measurements (Ref 15).

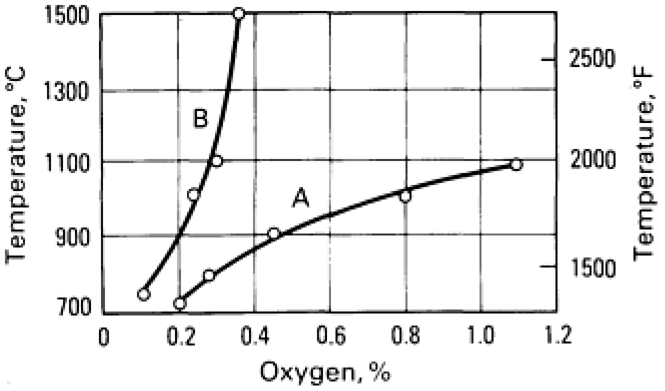

Fig. 6 Solubility of oxygen in niobium and tantalum. Curve A, niobium; Curve B, tantalum. Source: Ref 15

The conversion of tantalum into oxide was shown to occur by the nucleation and growth of small plates along the {100} planes of the bcc metal (Ref 16, 17). The kinetics of the oxidation of tantalum were studied at temperatures to 1400 °C (2550 °F) and at pressures ranging from less than 1 to over 40 atm (100 to 4050 kPa) (Ref 15). The reaction was found to be initially parabolic, with a transformation to a linear rate after a period of time.

Increasing the temperature not only increases the rate of oxidation of tantalum but also decreases the time before the reaction changes from parabolic to linear behavior. At a moderately high temperature (about 500 °C, or 930 °F), this transition occurs almost at once.

Under a pressure of 1 atm of oxygen, tantalum oxidizes rapidly and catastrophically at a temperature of 1300 °C (2370 °F). At slightly lower temperatures (1250 °C, or 2280 °F), the specimen oxidizes linearly at a high rate for a short period of time, then oxidizes catastrophically.

The effects of pressure on the oxygen-tantalum reaction have been established and can be summarized as follows: tantalum oxidizes linearly from 500 to 1000 °C (930 to 1830 °F) at all pressures between 1.3 and 4137 kPa (0.19 and 600 psi). From 600 to 800 °C (1200 to 1480 °F), the oxidation rate shows a pronounced increase in rate with oxygen pressures above 100 kPa (14.7 psi). Another investigator found that at a higher temperature (1000 °C, or 1830 °F), the rate tends to vary as the square root of pressure below 100 kPa (14.7 psi). At any one temperature between 500 and 800 °C (930 and 1480 °F), the rate of oxidation approaches a limiting rate as the pressure increases.

The presence of a few atomic percent of oxygen in tantalum increases electrical resistivity, hardness, tensile strength, and modulus of elasticity, but decreases elongation and reduction of area, magnetic susceptibility, and corrosion resistance to HF (Ref 18). When one realizes that 1 at.% O in tantalum equals 892 ppm, the effect of very small contents of oxygen on the properties is evident.

Nitrogen. The solubility of nitrogen in tantalum is shown by curve B in Fig. 7. It was found that tantalum dissolves 4 at.% N at 1000 °C (1830 °F) and that the solubility decreases rapidly with decreasing temperature. Other researchers indicated that the room-temperature solubility limit was 5.5 at.% for a stable solid solution and 7.7 at.% for a metastable solid solution (Ref 9, 15).

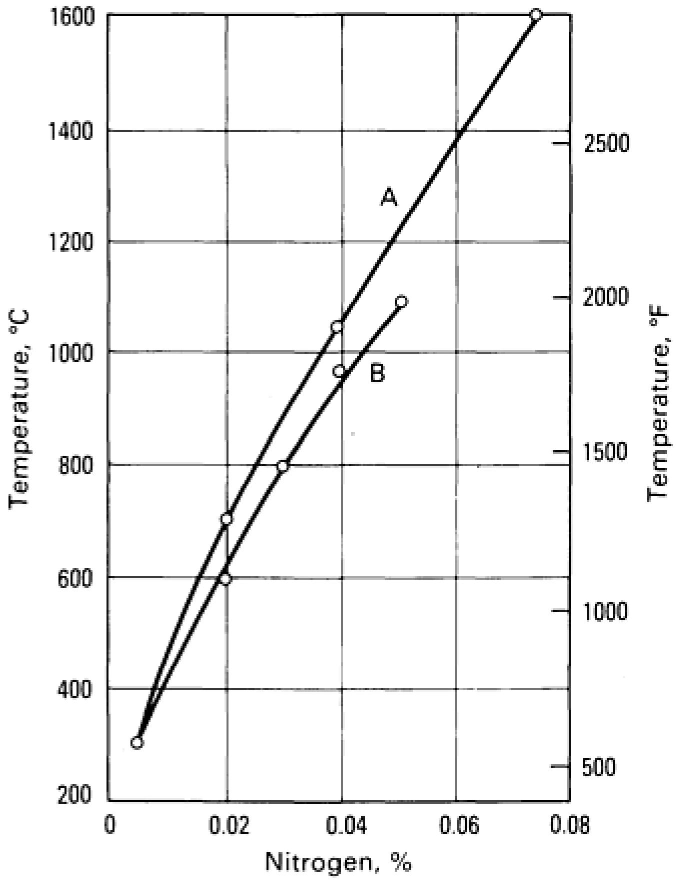

Fig. 7 Solubility of nitrogen in niobium and tantalum. Curve A, niobium; Curve B, tantalum. Source: Ref 15

Below 800 °C (1470 °F), the tantalum-nitrogen reaction was reported to be cubic by one investigator, or parabolic by another (Ref 15). In the latter case, the nonlinear behavior of the Arrhenius plot of parabolic rate constants below 600 °C (1200 °F) suggests that the reaction does not obey a parabolic rate law. In contrast, a plot of cubic rate constants, although showing a wide range of scatter, was stated to indicate linear behavior (Ref 18).

Above 800 °C (1470 °F), the reaction is parabolic, with rate constants increasing uniformly as temperature increases. Although both investigators agree on the rate law followed in this temperature region, neither their initial weight grain versus time data nor their rate constants are in agreement.

As in the case of oxygen in tantalum, the presence of nitrogen in only a few atomic percent concentration increases hardness, tensile strength, and electrical resistivity and decreases elongation and density. One atomic percent N_2 in tantalum equals 780 ppm N_2.

Air. The kinetics of the reaction of tantalum with air can be regarded as an extension of the reaction of tantalum with oxygen, because tantalum forms oxides preferentially over nitrides. The rate law governing the initial period of the reaction has not been established, but by analogy to the oxygen-tantalum reaction, it may be linear (with a rate constant differing from that of subsequent linear oxidation rates), parabolic, or logarithmic, depending on temperature and pressure conditions. Tantalum is quite stable in air at 250 °C (480 °F) and below; at 300 °C (570 °F), it shows a tarnish after 24 h of exposure. The rate of corrosion, as measured by weight gain, increases rapidly at higher temperatures (see Fig. 8). At 500 °C (930 °F), the white oxide. Ta_2O_5, begins to form. Figure 8 shows plot of weight gain versus temperature (Ref 9, 15).

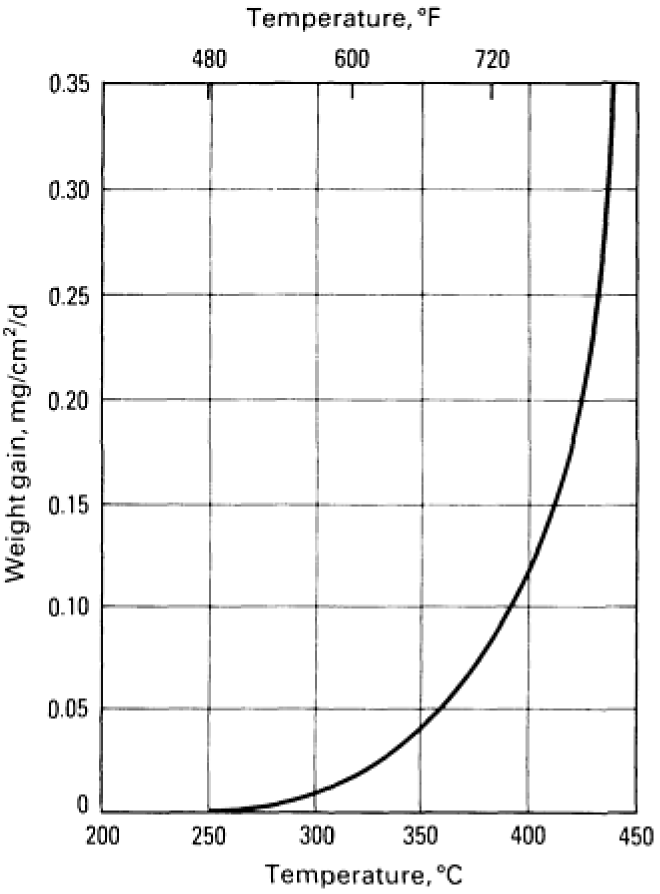

Fig. 8 Corrosion rate of tantalum in air as a function of temperature

After a certain amount of time, ranging from over 6 h at 400 °C (750 °F) to less than 2 min at 900 °C (1650 °F), the reaction was said to become linear (Ref 19). The possibility was expressed that, at high temperatures or after extended exposure at low temperature, the linear oxidation data may also fit one of the other rate laws.

Protection Against Oxidation. Although proposed environments for tantalum and tantalum alloy applications involve gases ranging from carbon dioxide (CO_2) to halides, most of the interest centers on applications that will expose the metals to either oxygen or air at an elevated temperature. A great deal of work has been done in an effort to understand the reactions involved and to develop methods to protect the metals against attack. Although nitrogen in air may in some cases be deleterious, oxygen attack is usually seen as the mechanism of failure under low loads at elevated temperatures. Consequently, most attempts to protect tantalum against elevated-temperature gas attack have focused on imparting resistance to the base metal.

If any degree of oxidation resistance is to be imparted to tantalum, two approaches are:

- Form a denser, more adherent oxide film by alloy additions to the tantalum that alter and modify the oxide phase
- Provide a protective coating to inhibit oxygen attack on the tantalum. Coatings include silicides, aluminides, and noble metals (Ref 20)

The use of coatings to protect tantalum substrates is also described in the article "Surface Engineering of Refractory Metals and Alloys" in *Surface Engineering*, Volume 5, *ASM Handbook.*

Other than by oxidation, tantalum structures may also fail in high-temperature service because of embrittlement by diffusion of an environmental gas into a subsurface layer of the base metal. Protection against this phenomenon, known as contamination, is achieved by the same techniques as used against surface oxidation, although the actual agents are often different. Because oxidation and contamination are both symptoms of the same basic problem, most work on contamination has been done as part of a larger effort on oxidation.

Hydrogen. Tantalum dissolves a considerable amount of hydrogen at comparatively low temperatures (Ref 9, 15). The maximum limit of solubility is 50 at.%.

Although tantalum generally does not react with molecular hydrogen below 250 °C (480 °F), it can absorb 740 times its own volume of hydrogen at red heat. However, it was reported that tantalum containing dissolved oxygen can absorb molecular hydrogen at room temperature when it is undergoing deformation. Tantalum containing more than 150 volumes of hydrogen loses its ductility (Ref 14).

Atomic hydrogen can be absorbed by tantalum, even at room temperature. Therefore, chemical equipment should be insulated from stray currents. In a few commercial cases, the metal is made electrolytically positive to prevent the liberation and absorption of atomic hydrogen on its surface.

Absorption of hydrogen is accompanied by an expansion of the bcc crystal lattice. When such material is heated to about 800 °C (1470 °F) or more in a high vacuum, it loses essentially all of its hydrogen. When permanent damage to the metal has not occurred, annealing or degassing at 800 °C (1470 °F) or higher temperature restores the metal to its original condition. In addition to decreasing the ductility, strength, and density of tantalum, the presence of hydrogen increases the hardness and the electrical resistivity.

Water Vapor. Although few published data have been found on the attack of steam on tantalum at high temperatures, it is known from industrial practice that tantalum is not affected adversely when heated with steam at pressures to 1380 kPa (200 psig), corresponding to a temperature of 200 °C (390 °F). It has been reported that at temperatures above 1125 °C (2240 °F), water is decomposed by tantalum with adsorption of oxygen by the metal and evolution of hydrogen. At 925 °C (1700 °F) and lower temperatures, the reaction is negligibly slow.

Halogens. Fluorine attacks tantalum at room temperature. Tantalum is totally inert to wet or dry chlorine, bromine, and iodine to 150 °C (300 °F), and these elements dissolved in solutions of salts or acids likewise have no effect. Chlorine begins to attack tantalum at about 250 °C (480 °F). The reaction is rapid at 450 °C (840 °F), and it occurs instantaneously at 500 °C (930 °F). The presence of water vapor sharply decreases corrosion by chlorine so that the maximum temperatures at which tantalum is sufficiently resistant to chlorine containing 1.5 to 30% H_2O for chemical equipment applications are 375 and 400 °C (705 and 750 °F), respectively. Bromine attacks tantalum at 300 °C (570 °F), and iodine begins to attack at about the same temperature (Ref 4, 9).

Carbon Dioxide and Carbon Monoxide. Tantalum is corroded by dry CO_2 at 810 kPa (8 atm) and 500 °C (930 °F). Tantalum reacts with CO_2 at 1100 °C (2010 °F) to form Ta_2O_5, and with carbon monoxide (CO) at the same temperature to form TaO. The latter reverts to Ta_2O_5 when exposed to oxygen (Ref 9, 15).

The oxidation rates of tantalum in various partial pressures of CO_2 in the temperature range of 700 to 950 °C (1290 to 1740 °F) were measured with a gravimetric balance (Ref 21). Oxidation involved a surface-controlled reaction associated with the formation of a nonprotective layer of Ta_2O_5. Below 720 °C (1330 °F), there was a change in the rate-determining mechanism, and above 830 °C (1525 °F), the linear rate was preceded by a complex region of nonlinear oxidation behavior. The linear oxidation at tantalum has been explained quantitatively in terms of CO_2 absorption, followed by a rate-controlling surface reaction. The initial absorption has been expressed both as an equilibrium process and as a steady-state reaction.

Nitrogen Monoxide and Nitrous Oxide. Below about 1125 °C (2050 °F), the reaction rate of nitrogen monoxide (NO) (as a 5% mixture in argon) with tantalum cannot be detected (Ref 9). As the temperature is increased, the reaction takes place with increasing rapidity, rising from 0.0065% area loss per second at 1195 °C (2180 °F) to 0.076% at 1457 °C (2670 °F) (Ref 22).

The oxidation by nitrous oxide (N_2O) on evaporated films of niobium, tantalum, and titanium was studied in the temperature range of 195 to 435 K (Ref 23). For tantalum, fast dissolution absorption of N_2O occurred at 195 K,

accompanied by N_2 evolution. Some incorporation of N_2O also occurred. The rate of N_2O absorption was found to depend on the pressure of the reacting gas.

Other Reactive Gases. Although little published data appear to exist on the subject, it is expected that tantalum would react at some elevated temperature with oxygen-containing gaseous compounds, such as sulfur dioxide (SO_2) and nitrogen dioxide (NO_2) (Ref 19). With such hydrocarbons as benzene or naphthalene, tantalum reacts at temperatures from 1700 to 2500 °C (3090 to 4530 °F) to form tantalum carbide. Tantalum is used as a getter in vacuum tubes at temperatures of 650 to 1000 °C (1200 to 1830 °F) to absorb gases and maintain a high vacuum.

Inert Gases. Pure helium and argon do not react with tantalum, even at its melting point. These gases are used as an inert atmosphere for arc melting or welding the metal.

Liquid Metals. Tantalum and some tantalum-base alloys exhibit good resistance to many liquid metals (Ref 5, 9, 24). Table 6 lists the effect of various liquid metals on tantalum. Such tantalum materials exhibit remarkable resistance to several liquid metals even to high temperatures (900 to 1100 °C, or 1650 to 2010 °F) in the absence of oxygen or nitrogen.

Table 6 Effects of molten metals on tantalum

Metal	Remarks	Temperature, °C (°F)	Code[(a)]
Aluminum	Forms		
	Al_3Ta	Molten	NR
Antimony	. . .	to 1000 (1830)	NR
Bismuth	. . .	to 900 (1650)	E
Cadmium	. . .	Molten	E
Gallium	. . .	to 450 (840)	E
Lead	. . .	to 1000 (1830)	E
Lithium	. . .	to 1000 (1830)	E
Magnesium	. . .	to 1150 (2100)	E
Mercury	. . .	to 600 (1110)	E
Potassium	. . .	to 900 (1650)	E
Sodium	. . .	to 900 (1650)	E
Sodium-potassium alloys	. . .	to 900 (1650)	E

Zinc	. . .	to 500 (930)	E/V
Tin	. . .	. . .	V
Uranium	. . .	. . .	V
Mg-37Th	In helium	to 800 (1470)	S
Bi-5 to 10U	In helium	to 1100 (2010)	S
Bi-5U-0.3Mn	In helium	to 1050 (1920)	S
Bi-10U-0.5Mn	In helium	to 1160 (2120)	S
Al-18Th-6U	Failed	to 1000 (1830)	NR
U-10Fe	Failed	to 900 (1650)	NR
U-Cr (eutectic)	Failed	to 900 (1650)	NR
YSb-intermetallic compound	. . .	1800-2000 (3270-3630)	S
YBi-intermetallic compound	. . .	1800-2000 (3270-3630)	S
ErSb-intermetallic compound	. . .	1800-2000 (3270-3630)	S
LaSb-intermetallic compound	. . .	1800-2000 (3270-3630)	S
Plutonium-cobalt-cerium	. . .	to 650 (1200)	V

(a) E, no attack; S, satisfactory; V, variable, depending on temperature and concentration; NR, not resistant

The severity of attack on tantalum by liquid metals may be markedly increased by increasing temperature. Because operating temperatures somewhat in excess of 700 °C (1290 °F) are desirable in many cases, refractory metals, including tantalum and niobium, seem to be particularly promising materials of construction for containing liquid metals.

Liquid aluminum reacts rapidly with tantalum to form the stable compound aluminum (Al_3Ta) (Ref 9).

Liquid bismuth has little action on tantalum at temperatures below 1000 °C (1830 °F) and exerts no detrimental effects on the stress rupture properties of tantalum at 815 °C (1500 °F); but it causes some intergranular attack at 1000 °C (1830 °F) (Ref 5, 25).

Calcium. Tantalum is only slightly attacked by calcium at 1200 °C (2190 °F). A crucible with a wall thickness of 0.15 mm (5.8 mils) was reduced to 0.13 mm (5.3 mils) after 12 days of exposure to calcium at 1200 °C (2190 °F) (Ref 9).

Cesium. Similar lack of corrosion resistance to cesium was found for tantalum as reported for niobium. Refluxing capsule tests indicated surface dissolution and severe attack after 720 h at 980 and 1370 °C (1800 and 2500 °F) (Ref 26).

Gallium. The resistance of tantalum to molten gallium is considered to be good at temperatures to 450 °C (840 °F), but poor at temperatures above 600 °C (1110 °F).

Lead. Tantalum is highly resistant to liquid lead at temperatures to 1000 °C (1830 °F), with a rate of attack of less than 0.025 mm/yr (1 mil/yr). It exhibits no detrimental effects when stress rupture tests are conducted in molten lead at 815 °C (1500 °F) (Ref 5).

Lithium. Tantalum possesses good resistance to molten lithium at temperatures to 1000 °C (1830 °F) (Ref 5, 24, 27, 28). Tantalum capability with lithium is similar to that of niobium in that corrosion resistance depends on oxygen concentration. Tantalum metal will exhibit good corrosion resistance to lithium as long as the oxygen concentration of the tantalum is maintained below 100 to 200 ppm.

Specimens of T-111 and T-222 (Ta-9.6W-2.4Hf-0.01C) alloys, oxygen contaminated to 500 ppm and welded in argon, were exposed to lithium at 750 and 1200 °C (1380 and 2190 °F) for 100 h. Evaluation indicated no attack in the weld areas; however, intergranular penetration was observed in the base metal of both alloys. Heat treatment at 1315 °C (2400 °F) eliminated the attack. In addition, a method of inhibiting the corrosion of tantalum by liquid lithium at temperatures above 1000 °C (1830 °F) by the addition of 0.15 to 1.5 at.% Si to the lithium is discussed in Ref 29.

Lithium and Uranium Mononitride Fuel. In one investigation, simulated nuclear-fuel element specimens, consisting of uranium mononitride (UN) fuel cylinders clad with tungsten-lined T-111 alloy were exposed in a pumped lithium loop operated at 1040 °C (1905 °F) (Ref 30) for up to 7500 h. The lithium flow velocity was 1.5 m/s (5 ft/s) in the specimen test section. A cladding crack was simulated in one specimen exposed for 50,000 h by an axial slot machined through both the cladding and the tungsten liner.

All of the fuel element specimens appeared to be in excellent condition after the tests. No evidence of any chemical compatibility problems between the specimens and the flowing lithium was found. Except for a slight reduction in the oxygen content of the T-111, very little change in chemistry was observed in the T-111 or the UN. No microstructural changes were observed in the UN, but bands of fine precipitates were seen in the T-111 after the lithium exposure. These precipitates were thought to be the result of thermal aging, not lithium exposure.

Direct exposure of the UN to the lithium through the simulated cladding crack resulted in some erosion of the UN and in some nitrogen contamination of the T-111 cladding in the area of the defect. The T-111 in the fuel element clad specimens was ductile after the long-term lithium exposure. Thermal aging at 1040 °C (1905 °F), however, resulted in the T-111 becoming sensitive to hydrogen embrittlement during post-test handling and testing.

Magnesium and Magnesium Alloys. Tantalum is unattacked by molten magnesium at 1150 °C (2100 °F) (Ref 9.)

Mercury. The limited amount of corrosion testing of refractory metals in mercury is summarized below. The results for tantalum are consistent with the solubility information (Ref 31).

In static tests, tantalum exhibited good resistance to mercury at temperatures to 600 °C (1110 °F). Refluxing capsule tests showed no attack of tantalum up to 760 °C (1400 °F). The corrosion resistance of tantalum to mercury was further documented in a two-phase natural-circulation loop test that ran for 19,975 h with a boiling temperature of 650 °C (1200 °F) and superheat temperature of 705 °C (1300 °F).

Post-test evaluation of the loop revealed no corrosion. As a result of the inertness of tantalum to mercury attack demonstrated in this long-term experiment, tantalum was evaluated as a replacement material for Croloy 9M steel in a mercury boiler (Ref 24). Results of other tests of tantalum in mercury are described in Ref 31 and 32.

Potassium. The compatibility of tantalum and potassium at 600, 800, and 1000 °C (1110, 1470, and 1830 °F) was studied in static capsule tests (Ref 33). As the oxygen concentration of potassium was increased, the amount of tantalum in the potassium was also found to increase. The results indicated the formation of an unidentified ternary oxide phase

that is either nonadherent or dissolved when the potassium is dissolved for chemical analysis. When the tantalum specimens contained oxygen above a certain threshold concentration, potassium penetrated the tantalum, and intergranular, as well as transgranular, attack was observed. The threshold levels for intergranular attack at the test temperatures were found to be 500, 700, and 1000 ppm O, respectively. The mechanism of attack was believed to be the formation of a ternary oxide phase.

Silver. Tantalum is only slightly attacked by silver at 1200 °C (2190 °F); a tantalum crucible tested in silver at this temperature for 35 days showed a loss in wall thickness of 0.02 mm (0.8 mil).

Liquid sodium, potassium, or alloys of these elements have little effect on tantalum at temperatures to 1000 °C (1830 °F), but oxygen contamination of sodium causes increases in corrosion. Sodium does not alloy with tantalum (Ref 5).

The presence of oxygen in liquid sodium leads to slight weight loss of tantalum in flowing systems. In addition, extensive intergranular and transgranular attack of tantalum by sodium was observed. This attack was attributed to the high (390 ppm) oxygen concentration of the tantalum before exposure to the sodium.

The compatibility of tantalum alloys T-111 and Ta-10W with static sodium was demonstrated in capsules tested at 1315 °C (2400 °F) for 6271 h and 300 h, respectively. No corrosion was found in either alloy.

Tellurium. Corrosion of candidate construction materials for stills to extract radioactive polonium-210 from bismuth by distillation at temperatures of 450 to 950 °C (840 to 1740 °F) was investigated (Ref 27, 34). Tellurium, which is chemically similar to polonium, was used as a nonradioactive substitute for polonium. Of the materials investigated, tantalum appeared to be the most satisfactory from the standpoint of fabricability and long-term corrosion resistance. Tantalum was corroded at rates up to 0.5 μm/h (0.02 mils/h) during the initial 100 to 200 h of exposure; the rate decreased to less than 0.05 μm/h (0.002 mils/h) after 400 h for concentrations of tellurium of less than 30% in bismuth.

Thorium-Magnesium. In static tests, the thorium-magnesium eutectic had no appreciable effect on tantalum at 1000 °C (1830 °F). No measurable corrosion of tantalum by the thorium-magnesium eutectic was noted in dynamic tests for 28 days with a temperature range of 700 to 840 °C (1290 to 1545 °F) (Ref 5). Extensive tests on components for molten-metal fuel reactors revealed that tantalum is a satisfactory material for several thousand hours of service in high-temperature circulating loops containing a molten magnesium-thorium alloy having a composition in the range of the magnesium-rich eutectic (Ref 9).

Uranium and Plutonium Alloys. Short-term tests indicated that the practical upper limit for tantalum as a container material for uranium is about 1450 °C (2640 °F). However, attack below this temperature is also significant because a tantalum crucible with a wall thickness of 1.5 mm (0.06 in.) was completely corroded within a test period of 50 h at 1275 °C (2325 °F) (Ref 5). Other investigations showed that tantalum is not attacked by uranium-magnesium and plutonium-magnesium alloys at 1150 °C (2100 °F) (Ref 9). Extensive tests on components for molten-metal fuel reactors revealed that tantalum is a satisfactory material for several thousand hours of service in several liquid-metal environments (Ref 9).

Zinc is reported to wet and attack tantalum, the surface of which is abraded in zinc at 440 °C (825 °F); also, molten zinc attacks tantalum at significant rates at temperatures above 450 °C (840 °F) (Ref 9). Tantalum showed appreciable attack from molten zinc at 750 °C (1380 °F) (Ref 15). However, one industrial zinc producer observed excellent corrosion resistance at 500 °C (930 °F) (Ref 9). The maintenance of the oxide film on the tantalum may account for the latter result.

Other Molten Metals. The intermetallic compounds YSb, ErSb, LaSb, and YBi have little effect on tantalum at 1800 to 2000 °C (3270 to 3630 °F), but antimony vapor severely attacks tantalum at temperatures of 1000 °C (1830 °F) and higher (Ref 9).

Hydrogen Embrittlement, Galvanic Effects, and Cathodic Protection of Tantalum

The hydrogen embrittlement experienced in corrosion tests on tantalum exposed to HCl in sealed capsules (Ref 5) was mentioned in the section "Corrosion of Tantalum in Specific Media" in this article. Also, hydrogen embrittlement of tantalum was observed when it was exposed to concentrated H_2SO_4 at 250 °C (480 °F) or to concentrated HCl at 150 °C (300 °F) (Ref 35).

Failures due to hydrogen embrittlement have occurred in some severe aqueous acid media in chemical industry applications where tantalum was, or became, electrically coupled to a less noble material, such as low-carbon steel. Under these conditions, tantalum became the cathode in the galvanic cell thus created.

Because of the presence of stray currents, tantalum may become a cathode in the system and consequently may absorb and become embrittled by atomic hydrogen in the electrolytic cell (galvanic cell). The presence of stray current can result from induction from adjacent lines, leakages, variable ground voltages, and other sources. Although stray voltages may be transient, absorbed hydrogen is cumulative in its effect on producing hydrogen embrittlement of tantalum.

For applications of pure tantalum in aggressive acids at high temperatures, hydrogen embrittlement rather than uniform corrosion attack is the crucial concern (Ref 5, 35). References cited in Ref 35 propose a specific mechanism for hydrogen embrittlement of tantalum based on stress-induced hydride precipitation.

Several methods have been used or proposed to reduce hydrogen embrittlement of tantalum (Ref 5, 36, 37, 38):

- Complete electrical insulation of tantalum from all metals in system. For additional protection, the insulated tantalum may be connected to the positive pole of a DC source (about 15 V), while the negative pole is connected to some other metallic part, which is exposed to the solution in the vessel or to ground
- Addition of a selected oxidizing agent to the solution
- Coupling the tantalum surface to a noble metal
- Anodizing the tantalum

Galvanic Effects. If tantalum is the cathode in a galvanic couple, hydrogen embrittlement can prove disastrous (Ref 5). If tantalum is the anode in such a cell, anodization occurs so readily that no damage occurs and galvanic current quickly drops to a very low value. In couples of tantalum with platinum, silver, copper, bismuth, antimony, molybdenum, nickel, lead, tin, zinc, and aluminum, tantalum was initially the more electronegative member of the couple (except for zinc and aluminum). However, galvanic current rapidly decayed as the tantalum spontaneously anodized. In HF, tantalum was again more noble than zinc and aluminum and was more active than platinum, silver, copper, antimony, nickel, and lead. The latter six couples result in high steady-state currents, because tantalum dissolves rather than anodizes in fluoride solution. The anomalous behavior of tantalum when coupled with bismuth or iron in HF is apparently attributable to the formation of insoluble fluorides on the surfaces of the bismuth or iron electrodes.

Time is an important factor in determining whether tantalum will be damaged by galvanic effects (Ref 39). In practice, it is dangerous to depend on laboratory tests to provide information on whether tantalum is anodic in a given galvanic couple. In results reported in Ref 39, tantalum was cathodic to aluminum in dilute NaCl, HCl, and NaCl after times of 0.5 and 60 min. When tantalum was coupled to certain of the other metals--notably Hastelloy B, nickel, and lead--the polarity of the tantalum reversed with time in some electrolytes from anodic to cathodic. When tantalum is cathodic, or becomes cathodic, hydrogen embrittlement can occur. In probably all of the couples, tantalum would become cathodic if given sufficient time (Ref 39). The conclusion is drawn that it is highly desirable to prevent galvanic cell formation by providing adequate electrical insulation.

Cathodic Protection. Applying low-overvoltage elements, such as platinum and other noble metals, to tantalum and other metals has received further attention in efforts to develop improved anodes for cathodic protection (Ref 40). The first of the precious metals containing anodes to become commercial was platinum or platinum alloy on a titanium substrate. The uniqueness of this concept was not that of platinum, which has been used as an electrode material for many years, but the nature of titanium (or tantalum) itself. Titanium and tantalum have a very adherent, nonporous inert oxide film that will not transfer current unless the electrode-to-electrode potential reaches a certain value. With proper treatment, this oxide film can be removed, and a very thin layer of platinum can be applied to the titanium (or tantalum) surface. Any unplatinized surface will reoxidize, leaving a surface that will pass current from the platinized areas but not from the oxidized areas.

The commonly used precious metal and anode materials are lead-platinum bielectrodes, platinized titanium, platinized niobium, and platinized tantalum. The latter two substrates allow greater applied voltage to the anode system. Like platinized titanium anodes, the mechanism for successful operation of the platinized niobium or platinized tantalum anodes is the valve-like nature of the oxide film on the niobium or tantalum substrates. Niobium in such anodes operates

to a breakdown voltage of 40 to 50 V, but tantalum will operate up to 200 V. For both materials, the resistivity of the alloy used is approximately one-third that of titanium, which is said to give better anode characteristics (Ref 40). More information on this subject is available in the article "Cathodic Protection" in this Volume.

Corrosion Resistance of Tantalum-Base Alloys

Most of the preceding discussion has concerned the corrosion resistance of unalloyed tantalum. Limited corrosion data have been obtained on tantalum-base alloys. Some of the data on the more promising tantalum alloys are cited in this section, especially on Tantaloy 63 (Ta-2.5W-0.15Nb). In addition, the outstanding corrosion resistance found for certain low substitutional alloy content tantalum-base alloys, notably tantalum-molybdenum, is described (Ref 35). Data found in the literature on the corrosion resistance of other tantalum-base alloys are also summarized.

Tantalum-Tungsten Alloys. Samples of 0.18-to 0.75-mm (0.007-to 0.03-in.) thick strip or sheet of the following materials were exposed for selected times in concentrated (95.5 to 98%) H_2SO_4 at chosen temperatures ranging from 175 to 200 °C (345 to 390 °F):

- Tantalum, electron beam melted
- Tantalum, powder metallurgy
- Tantaloy 63 (Ta-2.5W-0.15Nb)
- Fansteel 65 metal (Ta-5W)
- Fansteel 60 metal (Ta-10W)

Some tests on electron beam melted tantalum and Tantaloy 63 were conducted on materials in the as-rolled, stress-relieved, and fully recrystallized conditions. The average corrosion rates observed in these tests are listed in Table 7. Corrosion rate as a function of tungsten content is plotted in Fig. 9 for additional tests on electron beam melted tantalum, Tantaloy 63 (Ta-2.5W-0.15Nb), Ta-5W, and Ta-10W exposed to concentrated H_2SO_4 at 180 and 210 °C (360 and 405 °F).

Table 7 Corrosion rates for tantalum materials exposed to concentrated H_2SO_4 at 175 to 200 °C (345 to 392 °F)

Material	Metallurgical condition	Temperature		Exposure, days	Corrosion rate	
		°C	**°F**		**mm/yr**	**mils/yr**
Ta, electron beam melted	Recrystallized	175	345	60	0.005	0.189
Ta, P/M	Recrystallized	175	345	60	0.0055	0.217
Tantaloy 63	Recrystallized	175	345	60	0.0058	0.229
Tantaloy 63	As-rolled	181	360	7	0.0026	0.104
Tantaloy 63	Stress-relieved	181	360	7	0.0022	0.087
Tantaloy 63	Recrystallized	181	360	7	0.0022	0.087
Ta, electron beam melted	As-rolled	199	390	3	0.018	0.72

Ta, electron beam melted	Recrystallized	199	390	3	0.024	0.96
Tantaloy 63	As-rolled	199	390	3	0.0048	0.19
Tantaloy 63	Stress-relieved	199	390	3	0.0043	0.17
Tantaloy 63	Recrystallized	199	390	3	0.0045	0.18
Ta, electron beam melted	Recrystallized	200	392	32	0.057	2.24

Ta-10W	Recrystallized	200	392	13	0.05	1.98

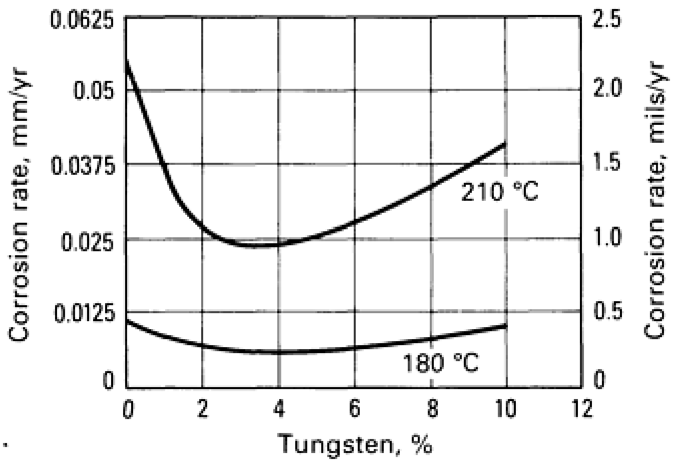

Fig. 9 Corrosion rate versus tungsten content for tantalum-tungsten alloys exposed to concentrated H_2SO_4 at 180 °C (360 °F) and 210 °C (405 °F)

The corrosion behavior of substitutional tantalum-molybdenum, tantalum-tungsten, tantalum-niobium, tantalum-hafnium, tantalum-zirconium, tantalum-rhenium, tantalum-nickel, tantalum-vanadium, tantalum-tungsten-molybdenum, tantalum-tungsten-niobium, tantalum-tungsten-hafnium, and tantalum-tungsten-rhenium alloys was studied in various corrosive mediums, including concentrated H_2SO_4 at 200 and 250 °C (390 and 480 °F) (Ref 35). Figure 10 gives corrosion data in 95% H_2SO_4 for several binary tantalum alloys. Tantalum became embrittled in concentrated H_2SO_4 at 250 °C (480 °F). Additions of tungsten reduced the corrosion rate and hydrogen absorption, but additions of molybdenum and rhenium were more effective in reducing both effects. Additions of niobium and vanadium had only a slight influence on the corrosion rate of tantalum; lower-valence elements, such as hafnium, increased the corrosion rate (Ref 35).

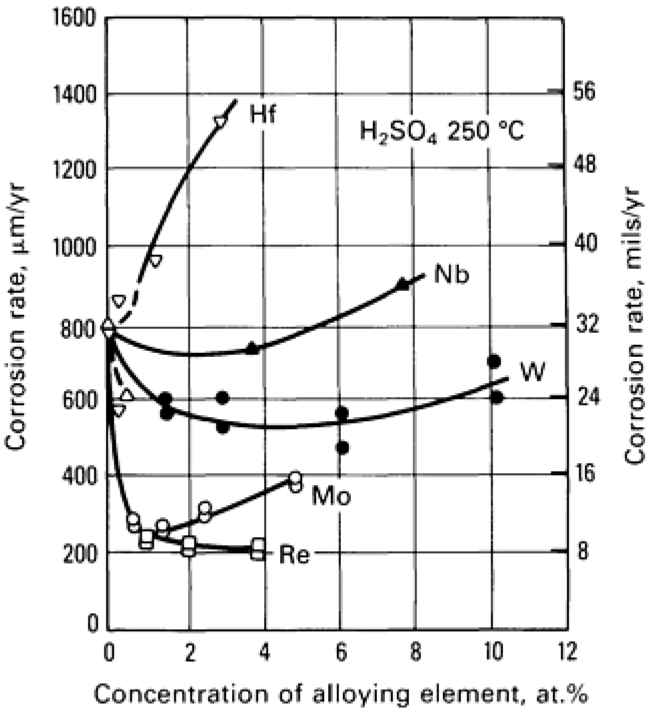

Fig. 10 Influence of alloying elements on the corrosion rate of binary tantalum alloys exposed 3 days to 95% H_2SO_4 at 250 °C (480 °F). Source: Ref 35

Hydrochloric Acid. Samples of recrystallized sheet of electron beam melted tantalum and Tantaloy 63 were exposed in the same test in a tantalum autoclave to concentrated (37 to 38%) HCl at 100 °C (212 °F) for 24 h. The corrosion rates of these materials were:

Alloy	Corrosion rate	
	mm/yr	**mils/yr**
Tantalum	0.04	1.6
Tantaloy 63	0.023	0.9

Corrosion rates for Tantaloy 63 in three metallurgical conditions exposed to concentrated HCl at 100 °C (212 °F) for 24 h in another autoclave test were about tenfold lower:

Condition	Corrosion rate	
	μm/yr	**mils/yr**
As-rolled	0.8	0.032
Stress relieved	1.0	0.039
Fully recrystallized	1.0	0.039

Researchers in other tests also found that tantalum and substitutional tantalum-base alloys became hydrogen embrittled in concentrated HCl at 150 °C (300 °F) (Ref 35).

Nitric Acid. Samples of unalloyed, electron beam melted tantalum and Tantaloy 63 were exposed to concentrated (70%) HNO_3 for 3 days at about 200 °C (390 °F). Following this test, neither material showed any measurable weight loss. Additional tests on Tantaloy 63 tested in 70% HNO_3 at about 200 °C (390 °F) for 72 h in an autoclave reactor gave the following corrosion rates for material in three metallurgical conditions:

Condition	Corrosion rate	
	μm/yr	**mils/yr**
As-rolled	0.1	0.0038
Stress-relieved	0.04	0.0016
Fully recrystallized	0.038	0.0015

Other Aqueous Media. The Ta-10W binary solid-solution alloy, also known as Fansteel 60 Metal, has been used in some applications, such as pump and valve parts, for which a material appreciably harder and stronger than the pure metal is desired. For example, Ta-10W alloy is used as an insert in the plug of a tantalum-lined split-body valve to give a hard plug to soft seat combination when used with a tantalum seat.

A search of the literature indicated that very little corrosion data were available on the Ta-10W alloy (Ref 41). This alloy is of interest as a repair metal for glass-lined steel equipment because it is of much higher strength than unalloyed tantalum. Consequently, corrosion tests were conducted on the Ta-10W alloy in various environments (Ref 41).

Figure 11 shows the corrosion rate as a function of H_2SO_4 concentration for tests at 205 and 230 °C (400 and 450 °F). These data indicate that either unalloyed tantalum or Ta-10W alloy can be used at 230 °C (450 °F) to handle H_2SO_4 in concentrations below 90%. Although the corrosion rates at 205 °C (450 °F) are similar for the two materials, on the basis of this graph, the corrosion weight loss of the Ta-10W alloy is about twice that of unalloyed tantalum at 230 °C (450 °F) in H_2SO_4 over the concentration range of 70 to 90%.

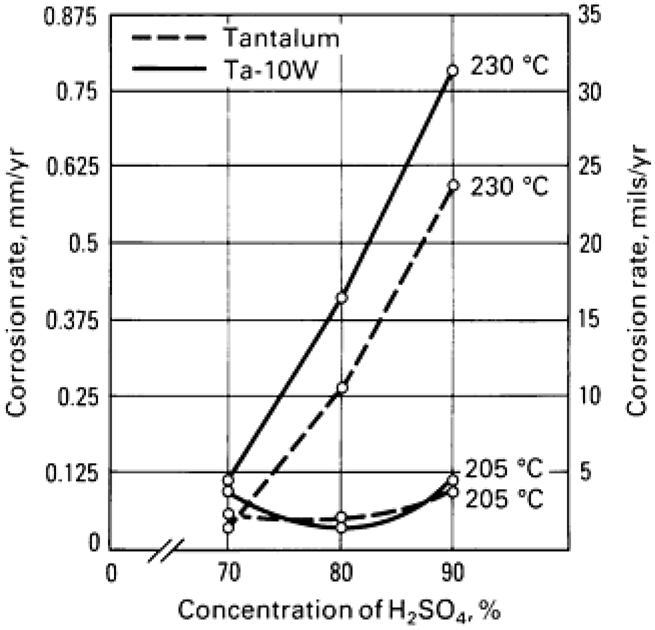

Fig. 11 Corrosion rate versus concentration for tantalum and Ta-10W alloy exposed to H_2SO_4 at various temperatures. Source: Ref 41

Little or no weight loss occurred below 175 °C (350 °F) in HCl, even at 30% concentration. At 190 °C (375 °F), a small amount of attack was detected, with that for the Ta-10W alloy being more severe.

In the HNO_3 corrosion tests, even up to 175 °C (350 °F) in concentrations to 60%, it was concluded that neither the tantalum nor the Ta-10W alloy showed any perceptible loss in weight (Ref 48). No comments were made regarding the small weight gains observed in most cases.

Tests were also conducted in 5% NaOH solution at 100 °C (212 °F). Considerable weight losses occurred on both the unalloyed tantalum and the alloy under caustic conditions. The difference, if any, in the corrosion rates of the two materials appears small.

The NaOH corrosion test was conducted because tantalum is known to be susceptible to caustic embrittlement; therefore, it was desired to determine whether the Ta-10W alloy suffered embrittlement also. Unalloyed tantalum showed approximately a 25% increase in yield strength and a 10% increase was attributed to a pickup of interstitial elements (oxygen, nitrogen, and hydrogen), although chemical analyses of the materials before and after exposure were not conducted. With the Ta-10W alloy, the exposure to 5% NaOH at 100 °C (212 °F) produced embrittlement as evidenced by the premature fracture in the tensile test. Reportedly, such embrittlement was not evident on the sample of the Ta-10W alloy to which a platinum spot had been welded before the test. The corrosion resistance of tantalum-tungsten alloys was also studied in 50% KOH at 30 and 80 °C (85 and 175 °F), 20% HF at 20 °C (70 °F), and $KOH:3K_3Fe(CN)_6$ mixture (concentration not given) (Ref 9).

In the hydroxide solutions, a maximum corrosion rate was obtained at about 60 at.% tantalum. Although the alloy system reportedly represents a continuous series of solid solutions, a maximum electrical resistance also was found at the same composition. In 20% HF solution, the tantalum-tungsten alloy system essentially exhibits the relatively low corrosion rates associated with tungsten, except when the tantalum concentration exceeds 80 at.%, at which concentration the corrosion increases markedly. Alloys containing more than 18% W show no corrosion in 20% HF, thus offering an advantage over pure tantalum. Other tests have been conducted on tantalum and tantalum-tungsten alloys having tungsten contents ranging from 8.7 to 20.4% in 20% HF. This work showed that tantalum and tantalum-tungsten alloys containing less than about 20% W were more susceptible to attack by 20% HF than was previously reported. Tantalum-tungsten alloys showed little improvement over tantalum when tested in the $KOH:3Fe(CN)_6$ mixture.

Combined Reagents. In a proposed dehydrator application, the exposure was to be to an environment containing 61.5% HNO_3 plus 7% magnesium nitrate ($Mg(NO_3)_2$) at 115 °C (238 °F). Although no significant corrosion on tantalum would be expected upon exposure to the separate reagents, tests were conducted on the mixture to determine corrosion rates. Base metal and weldment specimens of tantalum and Tantaloy 63 were used. Within the precision of the weight measurements, no specimen of either tantalum or Tantaloy 63 showed any weight loss in these corrosion tests.

Phosphoric Acid Plus Residual Hydrofluoric Acid. The use of tantalum in H_3PO_4, other than the high-purity Food Grade acid, has always been questioned because fluoride compounds are usually present. The observation has been made in several publications and bulletins that the presence of a small amount of HF (<5 ppm) in commercial H_3PO_4 causes severe corrosion of tantalum (Ref 42). Therefore, tantalum has not been considered resistant to H_3PO_4 containing more than a trace of F^- ion.

In one test, a sample of Tantaloy 63 was exposed to a wet-process H_3PO_4 at an average temperature of 155 °C (310 °F) for a total of 283.5 h. Following the corrosion exposure, the sample (0.64 mm, or 0.025 in., thick) was fully ductile and withstood bending flat on itself with no evidence of cracking. There was no indication of corrosion on the surface of the specimen, and metallographic examination of a cross section of the specimen showed no evidence of corrosion attack. The weight loss data for the exposure equated to a corrosion penetration rate of 0.004 mm/yr (0.15 mils/yr). These data suggested that the tantalum alloy showed good corrosion resistance to the hot-wet process H_3PO_4.

Tantalum-Molybdenum Alloys. Corrosion resistance was studied on tantalum-molybdenum alloys that form a continuous series of solid solutions (Ref 5). The entire alloy system is extremely corrosion resistant, and the corrosion resistance of tantalum is generally retained when the alloy contains more than about 50% Ta. Table 8 gives weight loss data for tantalum-molybdenum alloys in concentrated H_2SO_4 and concentrated HCl at 150 °C (300 °F).

Table 8 Corrosion rates of tantalum-molybdenum alloys in concentrated H_2SO_4 at 150 °C (300 °F)

Solutions were saturated with oxygen.

71.5	0.000	. . .

82.8	0.000	0.000
91.4	0.000	0.000
100.0	0.000	0.000

Tantalum-Niobium Alloys. Corrosion tests were conducted in hot and cold concentrated HCl and H_2SO_4 on alloys having various proportions of tantalum and niobium (Ref 43). The corrosion rates increased roughly in proportion to the niobium content in the alloy. Even though the 95Ta-5Nb alloy showed excellent resistance in all exposures, the attack was three times that obtained on pure tantalum. Additional corrosion data on binary tantalum-niobium alloys are given in Ref 44 and 45.

Other data were reported on corrosion tests of binary tantalum-niobium alloys and ternary alloys based on the Ta-Nb system (Ref 46). Tests on the materials were carried out in 75% H_2SO_4 at 185 °C (360 °F), in 70% H_2SO_4 at 165 °C (330 °F), in 75% H_2SO_4 at room temperature, and in 20% HCl at room temperature. The tantalum-niobium alloys containing approximately 60% or more tantalum appeared promising for boiling 70% H_2SO_4. Ternary alloys containing elements of groups IVA, VA, and VIA with tantalum and niobium did not offer any advantages in fabricability, and addition of zirconium, hafnium, chromium, and vanadium lowered the corrosion resistance.

One manufacturer developed an alloy designated WC-640 for corrosion-resistant applications (Ref 47). Analysis of a sheet sample showed that the chemical composition actually corresponded to a ternary tantalum-niobium-tungsten alloy, nominally Ta-40Nb-0.5W. Tensile properties of WC-640 were found to be similar to those of Tantaloy 63. The alloy exhibited excellent resistance to all test environments except concentrated H_2SO_4 at 200 °C (390 °F) and 40% NaOH at 100 °C (212 °F).

Tantalum-Titanium Alloys. Considerable data have been accumulated on the corrosion resistance of tantalum-titanium alloys (Ref 5). Dilution of tantalum with titanium shows considerable promise for the possibility of providing a lower-cost alloy with corrosion resistance almost comparable to that of tantalum in some selected environments. In addition to dilution with a lower-cost material, the resulting marked reduction in density is particularly advantageous because corrosion applications generally require materials on a volume rather than a weight basis. Corrosion tests in 10 to 70% HNO_3 at the boiling point and at 190 °C (375 °F) (in sealed glass tubes) were conducted on tantalum-titanium alloys ranging from pure tantalum to Ta-90Ti. All of these materials showed excellent behavior, with corrosion rates less than 0.025 mm/yr (1 mil/yr) and no indication of embrittlement.

Hydrogen embrittlement may occur when this alloy system is exposed to reducing corrosive conditions in tests conducted in sealed capsules. The tendency for hydrogen damage is markedly decreased as the tantalum concentration is increased (Ref 9).

Ternary Alloys. The corrosion behavior of alloys in the Ti-Ta-Nb system in 5% HCl at 100 °C (212 °F) was investigated (Ref 48). The corrosion rate dropped by a factor of 1.5 to 2 times less than that of titanium with a total of 15 to 20% Nb or Ta in the alloy. At 20 to 30% additions of these elements, the corrosion rate dropped by a factor of 10 to 70 times less than that of titanium. Tantalum increased the corrosion resistance of the alloys more effectively than niobium did.

The role of the structural factor in increasing the corrosion resistance of the titanium-tantalum-chromium and titanium-chromium alloys in a 5% HCl solution at 100 °C (212 °F) was demonstrated (Ref 49). The corrosion rate of quenched alloys was 2 to 10 times or more lower than that of annealed alloys. As the tantalum content increases, the corrosion rate decreases for both quenched and annealed alloys. The ternary alloys with a tantalum to chromium ratio of 3:1 and binary titanium-tantalum alloys with 20% more tantalum were found to have good corrosion resistance.

Other Tantalum Alloys. It has been observed that the presence of a small amount of iron or nickel, for example, in a tantalum weld makes that site subject to about the same acid attack as would be experienced by iron or nickel alone (Ref 9). Galvanic action, as well as simple chemical attack, is undoubtedly involved.

Corrosion of Magnesium and Magnesium Alloys

Allan Froats, Chromasco/Timminco, Ltd.; Terje Kr. Aune, Norsk Hydro; David Hawke, Amax Magnesium; William Unsworth, Magnesium Elektron, Ltd.; and James Hillis, Dow Chemical Company

Introduction

THE CORROSION RESISTANCE of a magnesium or a magnesium alloy part depends on many of the same factors that are critical to other metals. However, because of the electrochemical activity of magnesium (Table 1), the relative importance of some factors is greatly amplified. This article will discuss the effects of heavy-metal impurities, the type of environment (rural atmosphere, marine atmosphere, elevated temperatures, and so on), the surface condition of the part (such as as-cast, treated, and painted), and the assembly practice. In some environments, a magnesium part can be severely damaged unless galvanic couples are avoided by proper design or surface protection. Therefore, this aspect will be discussed in detail in the section "Galvanic Corrosion" in this article.

Table 1 Standard reduction potentials

Electrode	Reaction	Potential, V
Li, Li^{+}	$Li^{+} + e^{-} \longrightarrow Li$	-3.02
K, K^{+}	$K^{+} + e^{-} \longrightarrow K$	-2.92
Na, Na^{+}	$Na^{+} + e^{-} \longrightarrow Na$	-2.71
Mg, Mg^{2+}	$Mg^{2+} + e^{-} \longrightarrow Mg$	-2.37
Al, Al^{3+}	$Al^{3+} + e^{-} \longrightarrow Al$	-1.71
Zn, Zn^{2+}	$Zn^{2+} + e^{-} \longrightarrow Zn$	-0.76
Fe, Fe^{2+}	$Fe^{2+} + e^{-} \longrightarrow Fe$	-0.44
Cd, Cd^{2+}	$Cd^{2+} + e^{-} \longrightarrow Cd$	-0.40
Ni, Ni^{2+}	$Ni^{2+} + e^{-} \longrightarrow Ni$	-0.24
Sn, Sn^{2+}	$Sn^{2+} + e^{-} \longrightarrow Sn$	-0.14
Cu, Cu^{2+}	$Cu^{2+} + e^{-} \longrightarrow Cu$	0.34

Ag, Ag^+	$Ag^+ + e^- \rightarrow Ag$	0.80

Unalloyed magnesium is not extensively used for structural purposes. Consequently, the corrosion resistance of magnesium alloys is of primary concern. Two major magnesium alloy systems are available to the designer. The first includes alloys containing 2 to 10% Al, combined with minor additions of zinc and manganese. These alloys are widely available at moderate cost, and their mechanical properties are good to 95 to 120 °C (200 to 250 °F). Beyond this, the properties deteriorate rapidly with increasing temperature. The second group consists of magnesium alloyed with various elements (rare earths, zinc, thorium, silver, and so on) except aluminum, all containing a small but effective zirconium content that imparts a fine grain structure (and thus improved mechanical properties). These alloys generally possess much better elevated-temperature properties, but their more costly elemental additions, combined with the specialized manufacturing technology required, result in significantly higher costs. Table 2 lists the compositions commonly available in both systems.

Table 2 Typical magnesium alloy systems and nominal compositions

Alloy	Element, %[(a)]							Product form[(b)]
	Al	**Zn**	**Mn**	**Ag**	**Zr**	**Th**	**Re**

If a magnesium part is to perform satisfactorily in a particular application, it must not only be designed to meet the mechanical requirements but environmental factors, finishing, and assembly methods must also be properly assessed. This article will describe in detail the causes of past corrosion failures and the measures available to prevent such failures in future applications.

Metallurgical Factors

Chemical Composition. Figure 1 shows the effects of 14 elements on the saltwater corrosion performance of magnesium in binary alloys with increasing levels of the individual elements. Six of the elements included in Fig. 1 (aluminum, manganese, sodium, silicon, tin, and lead) plus thorium, zirconium, beryllium, cerium, praseo-dymium, and yttrium are known to have little if any deleterious effect on the basic saltwater corrosion performance of pure magnesium when present at levels exceeding their solid solubility or up to a maximum of 5% (Ref 2). Four elements in Fig. 1 (cadmium, zinc, calcium, and silver) have mild-to-moderate accelerating effects on corrosion rates, whereas four others (iron, nickel, copper, and cobalt) have extremely deleterious effects because of their low solid-solubility limits and their ability to serve as active cathodic sites for the reduction of water at the sacrifice of elemental magnesium. Although cobalt is seldom encountered at detrimental levels and cannot be introduced even through the long immersion of cobalt steels in magnesium melts, iron, nickel, and copper are common contaminants that can be readily introduced through poor molten-metal handling practices. These elements must be held to levels under their individual solubility limits (or their activity moderated through the use of alloying elements such as manganese or zinc) to obtain good corrosion resistance.

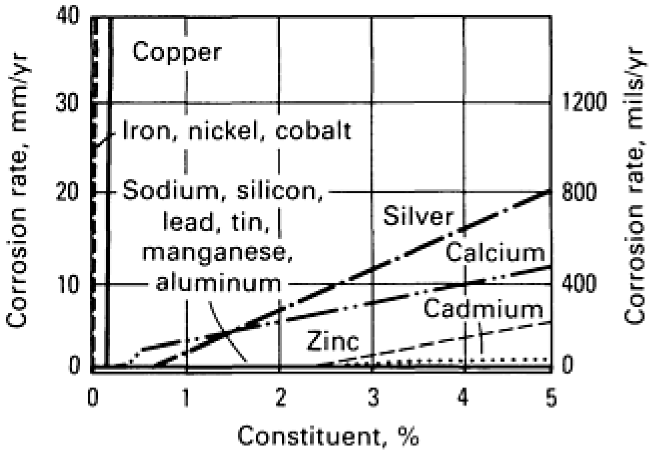

Fig. 1 Effect of alloying and contaminant metals on the corrosion rate of magnesium as determined by alternate immersion in 3% NaCl solution. Source: Ref 1

Figure 2 illustrates the effect of increasing iron, nickel, and copper contamination on the standard ASTM salt spray performance of die-cast AZ91 test specimens as compared to the range of performance observed for cold-rolled steel and die-cast aluminum alloy 380 samples. Such results have led to the definition of the critical contaminant limits for two magnesium-aluminum alloys in both low- and high-pressure cast form and the introduction of improved high-purity versions of the alloys. Table 3 lists some of the critical contaminant limits defined to date. The iron tolerance for the magnesium-aluminum alloys depends on the manganese present, a fact suggested many years ago but only recently proved. For AZ91 with a manganese content of 0.15%, this means that the iron tolerance would be 0.0048% (0.032 × 0.15%) (Ref 7).

Table 3 Known contaminant tolerance limits in high- and low-pressure cast forms

Alloy/form	Grain size, μm	Critical contaminant limit, %			Ref
		Fe	**Ni**	**Cu**	
Unalloyed magnesium	. . .	0.015	0.0005	0.1	1
AZ91/high pressure	5-10	0.032 Mn[(a)]	0.0050	0.040	4
AZ91/low pressure	100-200	0.032 Mn[(a)]	0.0010	0.040	4
AM60/high pressure	5-10	0.021 Mn[(b)]	0.0030	0.010	3
AM60/low pressure	100-200	0.021 Mn[(b)]	0.0010	0.010	5
AZ63/low pressure	. . .	0.003[(c)]	0.0040	>0.45	1
K1A/low pressure	. . .	>0.003	0.003	. . .	6

(a) Iron tolerance equals manganese content of alloy times 0.032.

(b) Iron tolerance equals manganese content of alloy times 0.021.

(c) Magnesium content of AZ63 reported as 0.2%

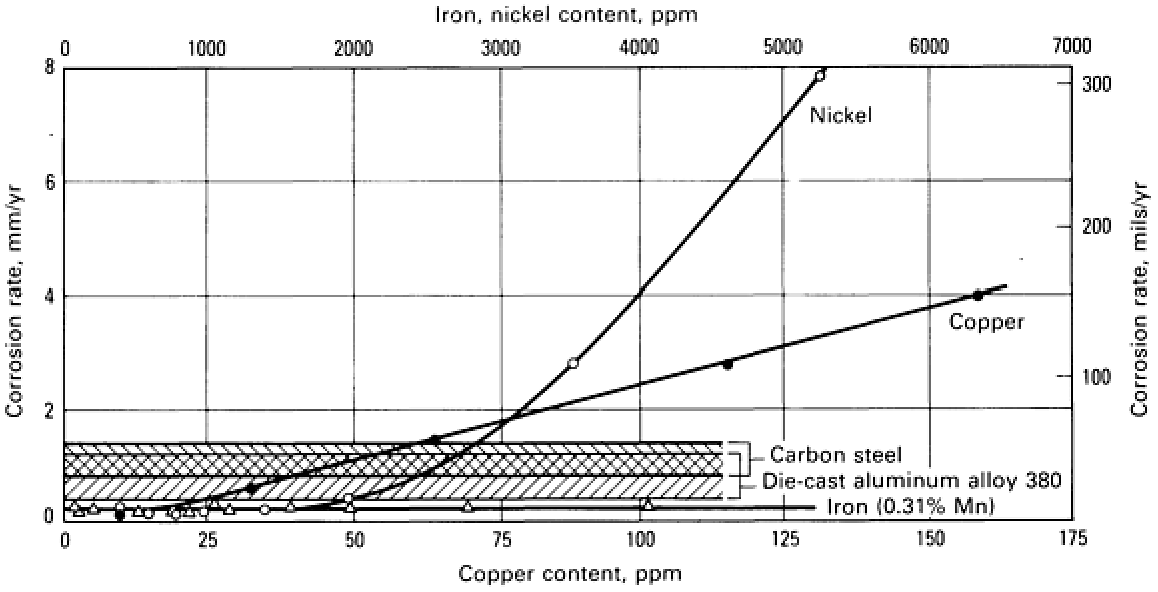

Fig. 2 Effect of nickel and copper contamination on the salt spray corrosion performance of die-cast AZ91 alloy. Source: Ref 3

It should also be noted that the nickel tolerance depends strongly on the cast form, which influences grain size, with the low-pressure cast alloys showing just a 10-ppm tolerance for nickel in the as-cast (F) temper. Therefore, alloys intended for low-pressure cast applications should be of the lowest possible nickel level (Ref 4). The low tolerance limits for the contaminants in AM60 alloy when compared to AZ91 alloy can be related to the absence of zinc. Zinc is thought to improve the tolerance of magnesium-aluminum alloys for all three contaminants, but it is limited to 1 to 3% because of its detrimental effects on microshrinkage porosity and its accelerating effect on corrosion.

For the rare-earth, thorium, and zinc alloys containing zirconium, the normal saltwater corrosion resistance is only moderately reduced when compared to high-purity magnesium-aluminum alloys--0.5 to 0.76 mm/yr (20 to 30 mils/yr) as opposed to less than 0.25 mm/yr (10 mils/yr) in 5% salt spray--but contaminants must again be controlled. This zirconium alloying element is effective in this case because it serves as a strong grain refiner for magnesium alloys and it precipitates the iron contaminant from the alloys before casting. However, if alloys containing more than 0.5 to 0.7% Ag or more than 2.7 to 3% Zn are used, a sacrifice in corrosion resistance should beexpected (Fig. 1). Nevertheless, when properly finished, these alloys provide excellent service in harsh environments.

Heat-Treating, Grain Size, and Cold-Work Effects. Using controlled-purity AZ91 alloy cast in both high- and low-pressure forms, the contaminant tolerance limits have been defined as summarized in Table 4 for the as-cast (F), the solution-treated (T4, held 16 h at 410 °C, or 775 °F and quenched), and the solution-treated and aged (T6, held 16 h at 410 °C, or 775 °F, quenched, and aged 4 h at 215 °C, or 420 °F) (Ref 4, 5).

Table 4 Contaminant tolerance limits versus temper and cast form for AZ91 alloy

High-pressure die cast, 5-10 μm average grain size; low-pressure cast, 100-200 μm average grain size

Contaminant, %	Critical contaminant limit[(a)]			
	High pressure F	**Low pressure**		
		F	**T4**	**T6**
Iron	0.032 Mn	0.032 Mn	0.035 Mn	0.046 Mn
Nickel	0.0050	0.0010	0.001	0.001
Copper	0.040	0.040	<0.010	0.040

(a) Tolerance limits expressed in wt% except for iron, which is expressed as the fraction of the manganese content (for example, the iron tolerance of 0.2% Mn alloy = 0.0064% Fe in F temper)

Table 5 compares the average 5% salt spray corrosion performance of sand-cast samples produced in a standard AZ91C and a high-purity AZ91E composition. The alloys were cast with and without standard grain-refining practices used to evaluate physical and compositional effects. The cast samples were then tested in the F, T4, T6, and T5 (aged 4 h at 215 °C, or 420 °F) tempers. In the case of the high-iron-containing AZ91C, none of the variations tested significantly affected the poor corrosion performance resulting from an iron level 2 to 3 times the alloy tolerance. In the case of the high-purity alloy, however, the T5 and T6 tempers consistently gave salt spray corrosion rates under 0.25 mm/yr (10 mils/yr), whereas the as-cast and solution-treated samples exhibited an inverse response to grain size and/or the grain-refining agents (Ref 4, 5). Welds on aluminum-zinc alloys should be aged or should be solution treated and aged to obtain good corrosion resistance in harsh environments and to reduce the risk of failure due to stress-corrosion cracking (SCC).

Table 5 Typical corrosion rates versus temper and grain size for two magnesium alloys

ASTM B 117 salt spray test

Alloy	Grain size, μm	Mn, %	Fe[(a)]	Temper corrosion rate							
				F		**T4**		**T6**		**T5**	
				mm/yr	**mils/yr**	**mm/yr**	**mils/yr**	**mm/yr**	**mils/yr**	**mm/yr**	**mils/yr**
AZ91C (untreated)	187	0.18	0.087	18	700	15	600	15	600	. . .	. . .
AZ91C (degassed and grain refined)	66	0.16	0.099	17	690	18	700	15	600	. . .	. . .
AZ91E[(b)] (untreated)	146	0.23	0.008	0.64	25	4	160	0.15	6	0.12	5

(a) Iron is expressed as a fraction of analyzed manganese content.

(b) AZ91E alloy pending ASTM approval.

Cold working of magnesium alloys, such as stretching or bending, has no appreciable effect on corrosion rate. Shot- or grit-blasted surfaces often exhibit poor corrosion performance--not from induced cold work but from embedded contaminants. Acid pickling to a depth of 0.01 to 0.05 mm (0.0004 to 0.002 in.) can be used to remove reactive contaminants, but unless the process is carefully controlled, reprecipitation of the contaminant is possible, particularly with steel shot residues. Therefore, fluoride anodizing is often used when complete removal of the contaminant is essential (Ref 8).

Causes of corrosion failures typically include heavy-metal contamination, blast residues, flux inclusions, and galvanic attack. The characteristics of each will be discussed.

Heavy-metal contamination often results in general pitting attack that is unassociated with fasteners or dissimilar-metal attachments. The rate of attack on unpainted surfaces will be essentially unaltered by surface condition, that is, freshly sanded or machined, acid pickled, or chrome treated. The iron, nickel, or copper content will analyze in excess of the tolerance limit for one or more of the elements. Figure 3 illustrates the effect of heavy-metal contamination on the ASTM salt spray corrosion performance of low-pressure cast AZ91.

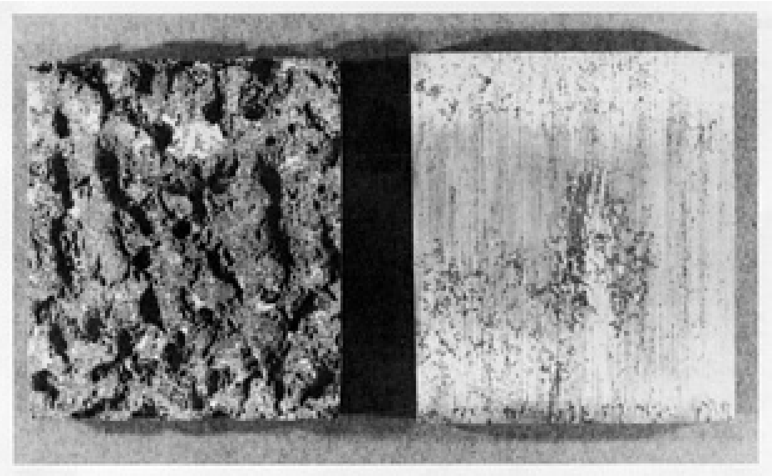

Fig. 3 Effect of heavy-metal contamination on the salt spray (ASTM B 117) performance of sand-cast AZ91 samples in the T6 temper. The samples, containing less than 10 ppm Ni and less than 100 ppm Cu, were simultaneously exposed for 240 h. The sample at left contained 160 ppm Fe and had a corrosion rate of 15 mm/yr (591 mils/yr). The sample at right contained 19 ppm Fe, and the corrosion rate was 0.15 mm/yr (5.9 mils/yr).

Blast residues can cause general pitting attack in saline environments. Attack is normally limited to unmachined surfaces of sand castings. Sanded or acid-etched (2% sulfuric acid (H_2SO_4) for 15 to 30 s) samples will show vastly improved performance in saltwater immersion or salt spray tests because of removal of the contaminant. Scanning electron microscopy and energy-dispersive x-ray analysis samples cleaned in chromic acid (H_2CrO_4) can be used to confirm and identify the presence of the contaminant, which is usually iron (from steel shot blasting) or silica (from sand blasting). Preventive measures are discussed in the section "Protective Coating Systems" in this article.

Flux inclusions result in localized attack that is clustered or distributed randomly on machined surfaces of castings. Freshly machined surfaces exposed to 70 to 90% relative humidity will develop active corrosion sites overnight. Scanning electron microscopy/energy-dispersive x-ray analysis of a freshly machined surface (free of fingerprints or other sources of contamination) will reveal pockets of magnesium and potassium chloride, as well as possible traces of calcium, barium, and sulfur. In zirconium-bearing alloys, elemental zirconium and zirconium-iron compounds may also be associated with the deposits. Chromic acid pickling followed by chemical treatment and surface sealing can alleviate the problem of inclusions in finished castings. With the use of sulfur hexafluoride (SF_6) rapidly replacing fluxes for the protection of melts during casting, this problem should be eliminated in the future.

Galvanic attack is usually observed as heavy localized attack on the magnesium, normally within 3.2 to 4.8 mm ($\frac{1}{8}$ to $\frac{3}{16}$ in.) of fasteners or an interface with other parts of dissimilar metal. Proper design and assembly methods can minimize galvanic attack, as detailed in subsequent sections in this article.

Environmental Factors

The information in this section is based on the behavior of unprotected metal. Improved resistance is obtained by using proper protection systems. The alloy composition as summarized above does affect corrosion behavior. Table 6 indicates the suitability of magnesium for exposure to a wide range of substances. This information is intended as an indication; further testing is recommended before final conclusions are drawn concerning specific alloys and exposure conditions.

Table 6 Magnesium suitability for testing in various substances

Follow precautions in text.

Chemical	Concentration, %	Service test warranted
Acetaldehyde	Any	No
Acetic acid	Any	No
Acetone	Any	Yes
Acetylene	100	Yes
Alcohol, butyl	100	Yes
Alcohol, ethyl	100	Yes
Alcohol, isopropyl	100	Yes

Water, boiling	100	No
Water, distilled	100	Yes
Water, rain	100	Yes
Waxes (acid-free)	100	Yes
Xylol	100	Yes

Atmospheres. A clean, unprotected magnesium alloy surface exposed to indoor or outdoor atmospheres free from salt spray will develop a gray film that protects the metal from corrosion while causing only negligible losses in mechanical properties. Chlorides, sulfates, and foreign materials that hold moisture on the surface can promote corrosion and pitting of some alloys unless the metal is protected by properly applied coatings.

The surface film that ordinarily forms on magnesium alloys exposed to the atmosphere gives limited protection from further attack. Unprotected magnesium and magnesium alloy parts are resistant to rural atmospheres and moderately resistant to industrial and mild marine atmospheres, provided they do not contain joints or recesses that entrap water in association with an active galvanic couple.

Compositions of the corrosion products that form on magnesium vary from one location to another and from indoor to outdoor exposure. X-ray diffraction analysis of corrosion products scraped from magnesium ingots after 18 months of exposure in a rural atmosphere have shown the presence of various hydrated carbonates of magnesium, including $MgCO_3 \cdot H_2O$, $MgCO_3 \cdot 5H_2O$, and $3MgCO_3 \cdot Mg(OH)_2 \cdot 3H_2O$. In an industrial atmosphere, hydrated and basic carbonates were found, together with magnesium sulfite ($MgSO_3 \cdot 6H_2O$) and magnesium sulfate ($MgSO_4 \cdot 7H_2O$).

These analyses, in addition to similar analyses after shorter periods of exposure, indicate that the primary reaction in corrosion of magnesium is the formation of magnesium hydroxide ($Mg(OH)_2$), followed by a secondary reaction with carbonic acid to convert the hydroxide to a hydrated carbonate. In atmospheres contaminated with sulfur compounds, sulfites or sulfates may also be present in the corrosion product. The sulfates may be formed by the reaction of acidic sulfur-bearing gases with $Mg(OH)_2$ or $MgCO_3$.

Corrosion of magnesium alloys increases with relative humidity. At 9.5% humidity, neither pure magnesium nor any of its alloys exhibit evidence of surface corrosion after 18 months. At 30% humidity, only minor corrosion may occur. At 80% humidity, the surface may exhibit considerable corrosion. In marine atmospheres heavily loaded with salt spray, magnesium alloys require protection for prolonged survival.

Fresh Water. In stagnant distilled water at room temperature, magnesium alloys rapidly form a protective film that prevents further corrosion. Small amounts of dissolved salts in water, particularly chlorides or heavy-metal salts, will break down the protective film locally, which usually results in pitting.

Dissolved oxygen plays no major role in the corrosion of magnesium in either freshwater or saline solutions. However, agitation or any other means of destroying or preventing the formation of a protective film leads to corrosion. When magnesium is immersed in a small volume of stagnant water, its corrosion rate is negligible. When the water is constantly replenished so that the solubility limit of $Mg(OH)_2$ is never reached, the corrosion rate may increase.

The corrosion of magnesium alloys by pure water increases substantially with temperature. At 100 °C (212 °F), the AZ alloys corrode typically at 0.25 to 0.50 mm/yr (10 to 20 mils/yr). Pure magnesium and alloy ZK60A corrode excessively at 100 °C (212 °F) with rates up to 25 mm/yr (1000 mils/yr). At 150 °C (302 °F), all alloys corrode excessively (Ref 9).

Salt Solutions. Severe corrosion may occur in neutral solutions of salts of heavy metals, such as copper, iron, and nickel. Such corrosion occurs when the heavy metal, the heavy-metal basic salts, or both plate out to form active cathodes on the anodic magnesium surface.

Chloride solutions are corrosive because chlorides, even in small amounts, usually break down the protective film on magnesium. Fluorides form insoluble magnesium fluoride and consequently are not appreciably corrosive. Oxidizing salts, especially those containing chlorine or sulfur atoms, are more corrosive than nonoxidizing salts, but chromates, vanadates, phosphates, and many others are film forming and thus retard corrosion, except at elevated temperatures.

Acids and Alkalis. Magnesium is rapidly attacked by all mineral acids except hydrofluoric acid (HF) and H_2CrO_4. Hydrofluoric acid does not attack magnesium to an appreciable extent, because it forms an insoluble, protective magnesium fluoride film on the magnesium; however, pitting develops at low acid concentrations. With increasing temperature, the rate of attack increases at the liquid line, but to a negligible extent elsewhere.

Pure H_2CrO_4 attacks magnesium and its alloys at a very low rate. However, traces of chloride ion in the acid will markedly increase this rate. A boiling solution of 20% H_2CrO_4 in water is widely used to remove corrosion products from magnesium alloys without attacking the base metal. Magnesium resists dilute alkalis, and 10% caustic solution is commonly used for cleaning at temperatures up to the boiling point.

Organic Compounds. Aliphatic and aromatic hydrocarbons, ketones, ethers, glycols, and higher alcohols are not corrosive to magnesium and its alloys. Ethanol causes slight attack, but anhydrous methanol causes severe attack. The rate of attack in the latter is reduced by the presence of water. Gasoline-methanol fuel blends in which the water content equals or exceeds about 0.25 wt% of the methanol content do not attack magnesium (Ref 10).

Pure halogenated organic compounds do not attack magnesium at ambient temperatures. At elevated temperatures or if water is present, such compounds may cause severe corrosion, particularly those compounds having acidic final products.

Dry fluorinated hydrocarbons, such as the freon refrigerants, usually do not attack magnesium alloys at room temperature, but when water is present, they may stimulate significant attack. At elevated temperatures, fluorinated hydrocarbons may react violently with magnesium alloys.

In acidic foodstuffs, such as fruit juices and carbonated beverages, attack of magnesium is slow but measurable. Milk causes attack particularly when souring.

At room temperature, ethylene glycol solutions produce negligible corrosion of magnesium that is used alone or galvanically connected to steel; at elevated temperatures, such as 115 °C (240 °F), the rate increases, and corrosion occurs unless proper inhibitors are added. Measures should be taken to control the galvanic corrosion.

Gases. Dry chlorine, iodine, bromine, and fluorine cause little or no corrosion of magnesium at room or slightly elevated temperature. Even when it contains 0.02% H_2O, dry bromine causes no more attack at its boiling temperature (58 °C, or 136 °F) than at room temperature. The presence of a small amount of water causes pronounced attack by chlorine, some attack by iodine and bromine, and negligible attack by fluorine. Wet chlorine, iodine, or bromine below the dew point of any aqueous phase causes severe attack of magnesium. Dry, gaseous sulfur dioxide causes no attack at ordinary temperatures. If water vapor is present, some corrosion may occur. Wet (below dew point) sulfur dioxide gas is severely corrosive to magnesium due to the formation of sulfurous and sulfuric acids. Ammonia, wet or dry, causes no attack at ordinary temperatures. Dry, gaseous sulfur dioxide (SO_2) or ammonia causes no attack at ordinary temperatures; some corrosion may occur if water vapor is present.

Water vapor in air or in oxygen sharply increases the rates of oxidation of magnesium and its alloys above 100 °C (212 °F), but boron trifluoride (BF_3), SO_2, and SF_6 are effective in reducing oxidation rates. The presence of BF_3 or SF_6 in the ambient atmosphere is particularly effective in suppressing high-temperature oxidation up to and including the temperature at which the alloy normally ignites.

The oxidation rate of magnesium in oxygen increases with temperature. At elevated temperature (approaching melting), the oxidation rate is a linear function of time. Cerium, lanthanum, calcium, and beryllium in the metal reduce the oxidation rate below that of pure magnesium. Beryllium additions have the most striking effects, protecting some alloys at temperatures up to the melting point over extended periods of time. Structural applications of magnesium alloys at elevated temperature are usually limited by creep strength rather than by oxidation.

Soils. Except when used as galvanic anodes, magnesium alloys have good corrosion resistance in clay or nonsaline sandy soils, but have poor resistance in saline sandy soils.

Corrosion in Real and Simulated Environments

Structural applications of magnesium alloys usually involve environmental conditions ranging from indoor atmospheres (computer disk drive components) to intermittent salt splash (automotive clutch housings). Allowable corrosion in these applications may range from zero for disk drive parts or critical military and aerospace components to substantial for some automotive castings, provided there is no interference with function for a specified period. Magnesium alloys of controlled high purity have demonstrated the capability of withstanding these environments in properly designed assemblies. Designers, however, must have advance information about the type and magnitude of corrosion that can occur under particular service conditions.

The best sources of such information would be previous service experience or long-term data from tests in the actual environment. When these are lacking, accelerated corrosion tests, such as alternate (intermittent) immersion in salt water or salt spray, are often used to compare the corrosion resistance of magnesium alloys to each other and to other metals. In addition, such tests are used to examine the relative merits of protective chemical treatments and coatings and the galvanic compatibilities of dissimilar metals with magnesium. The ASTM B 117 salt spray test (Ref 11) in particular is widely used and is firmly established as an acceptance test in many specifications. Magnesium is also subjected to various saltwater-based accelerated corrosion tests developed for special purposes. An important example is the proving ground cycle tests used by automobile manufacturers. Correlation has been established between proving ground cycle performance and vehicle corrosion in long-term service.

Specific Effects of Chloride Environments. Salt-based accelerated tests can provide useful information on the performance of magnesium alloys and assemblies, both bare and coated, in saline environments. The results of such tests must be interpreted with care, however, and no attempt should be made to relate them to the behavior of magnesium in rural, urban, or industrial atmospheres in which chloride is not the controlling constituent of the environment.

The corrosion of magnesium alloys in saline solutions is governed by the concentration and distribution of the critical impurities nickel, iron, and copper, whose presence in precipitated alloy phases creates active cathodic sites of low hydrogen overvoltage. The chloride ion further stimulates corrosion through its interference with protective-film formation and through the high solubility and acidic nature of magnesium chloride which accumulates at local anodic sites. The high conductivity of the chloride electrolyte also promotes the flow of corrosion current. If an adverse galvanic couple is introduced, for example, by attaching a steel bolt to the magnesium, and if the junction is bridged by salt water, corrosion of magnesium is greatly accelerated, and alloy purity provides no defense. In a salt spray test, galvanic corrosion of magnesium in such an assembly would be excessive compared to that which would occur in a marine atmosphere or even under roadsalt splash conditions.

Rural, Urban, and Industrial Atmospheres. In contrast to wet chloride exposure, a rural atmosphere would probably cause negligible corrosion damage to the magnesium assembly referred to above. Some corrosion, still minor compared to that caused by salt water, would be expected in urban or industrial atmospheres containing significant acidic gas pollution, principally SO_2. These gases convert the insoluble hydroxide-carbonate films that form naturally on magnesium alloys into soluble bicarbonates, sulfites, and sulfates that can be washed away by rain. This increases the rate of weathering and can provide conductive electrolytic paths, allowing some galvanic corrosion to occur.

To simulate atmospheric exposure where chloride does not exert a controlling influence, various humidity tests have been used or proposed. Water fog and water immersion tests are also used, primarily to evaluate the adhesion and blister resistance of organic coatings. Table 7 lists some simulated environmental tests and their intended purposes.

Table 7 Accelerated or simulated environmental corrosion tests for magnesium alloys

Test condition	Used to evaluate
Humidity tests	
95% relative humidity, 38 °C (100 °F)	Flux inclusions, indoor tarnishing, filiform corrosion
100% relative humidity, 38 °C (100 °F), condensing (ASTM D 2247)	Paint adhesion and blistering, corrosion in rural (uncontaminated) atmospheres
Polluted atmosphere (DIN-50018-1960), 100% relative humidity, 40 °C (105 °F), Air + SO_2 + CO_2 for 8 h, then 16 h in air at room temperature	Corrosion and coating performance in industrial atmospheres
Water tests	
Water fog (ASTM D 1735), deionized water, 38 °C (100 °F)	Paint adhesion and blistering (roughly equivalent to condensing humidity)
Water immersion (ASTM D 870), deionized water, 38 °C (100 °F)	Paint adhesion and blistering (severe test)
Salt tests	

Salt spray (ASTM B 117), 5% NaCl, pH 6.5-7.2	Corrosion of magnesium alloys, impurity effects, surface treatments and coatings on the same substrate alloy, galvanic compatibilities of other materials with magnesium. Valid for chloride environments, with careful interpretation. A severe accelerated test
Salt immersion, 5% NaCl, 25 °C (75 °F), pH 10.5, intermittent or continuous immersion with mild air agitation	Same as salt spray
Copper-accelerated acetic acid salt spray (ASTM B 368), 5% NaCl, 1 g $CuCl_2{\cdot}2H_2O$ per 3.8 L of solution, 49 °C (120 °F), pH 3.1-3.3	Plated coatings on magnesium
Salt spray-SO_2, 5% NaCl + SO_2, 35 °C (95 °F), pH 2.5-3.2, naval air development center	Naval aircraft materials (simulates sea spray plus ship stack gases)
Automotive proving ground test, repeated cycles of salt-mud splash, partial drying, and high-humidity storage	Magnesium alloys, bare or coated, for exposed automobile and truck parts. Galvanic compatibilities. Simulates severe road deicing salts exposure

Tests for Stress-Corrosion Cracking. Magnesium alloys containing more than about 1.5% Al are susceptible to stress-corrosion cracking, and the tendency increases with aluminum content. Alloys in wrought form appear to be more susceptible than castings. The stress sources likely to promote cracking are weldments and inserts. Welded structures of these alloys require stress-relief annealing. While there is little documented record of SCC failures of castings in service, magnesium castings have been shown to fail in laboratory tests under tensile loads as low as 50% of yield strength in environments causing negligible general corrosion. The apparent low incidence of SCC service failures of castings is attributable to low stresses actually applied or to stress relaxation by yielding or creep when a fixed deflection is imposed.

Although laboratory tests of the type described are useful in encouraging conservative design of magnesium alloy structures, principal reliance has been placed on long-term atmospheric tests of tensile-loaded specimens. Short-term accelerated tests, such as the sodium chloride/potassium chromate ($NaCl/K_2CrO_4$) tests, do not indicate SCC behavior reliably in practice.

Corrosion Fatigue. Substantial reductions in fatigue strength of magnesium alloys are shown in laboratory tests using NaCl spray or drops. Such tests are useful for comparing alloys, heat treatments, and protective coatings. Effective coatings, by excluding the corrosive environment, provide the primary defense against corrosion fatigue.

Corrosion Rates in Salt Spray, Salt Immersion, and Natural Marine Environments. Figures 2 and 4 show the effects of nickel, iron, and copper content on the corrosion of controlled-purity AZ91 die-casting alloy in a 10-day salt spray (5% NaCl, ASTM B 117) test and in a 2-year atmospheric exposure on the Texas Gulf Coast. Although the salt spray corrosion scale is 200 times larger than the marine atmospheric corrosion scale, some parallels can be drawn:

- The breakpoints relative to nickel and copper contamination are the same in both exposures (50 and 500 ppm, respectively)
- AZ91 corrosion remains low in both exposures over the iron contamination range studied (0.31% Mn alloy), confirming that the critical iron/manganese ratio (0.032 for this alloy) was not significantly exceeded
- High-purity AZ91 alloy is shown in both exposures to have lower overall corrosion rates than carbon steel or die-cast aluminum 380

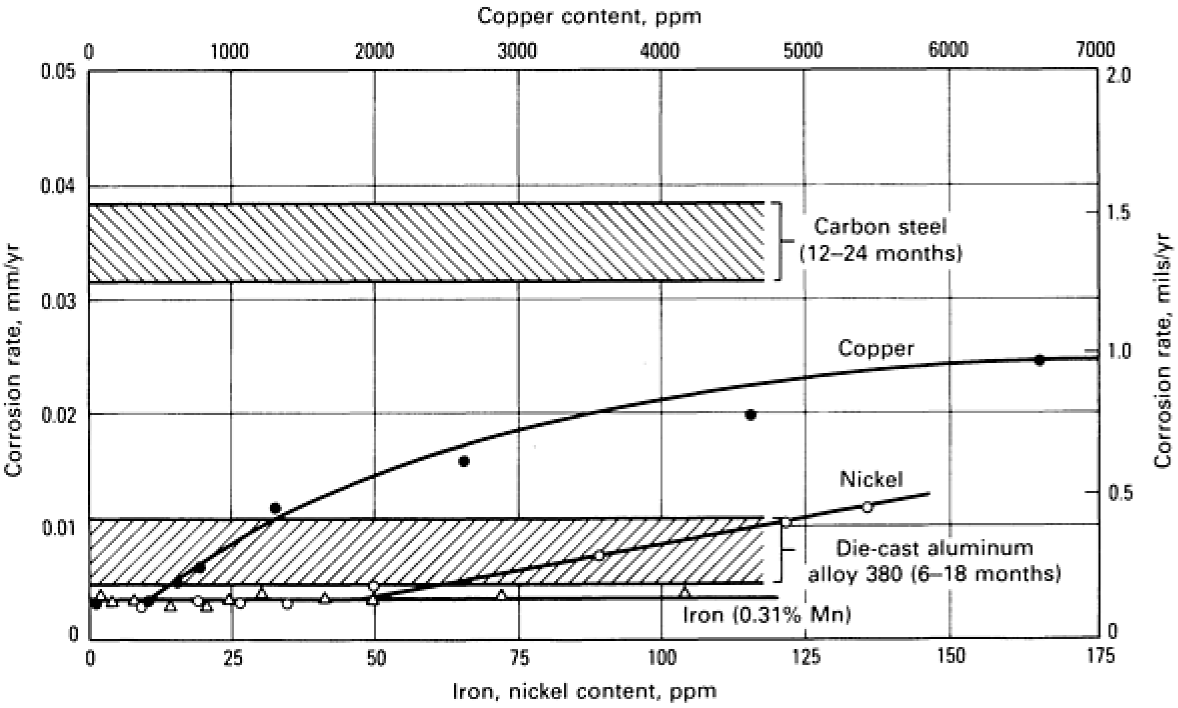

Fig. 4 Effect of copper and nickel contamination on the atmospheric corrosion of die-cast AZ91 alloy exposed for 2 years on the Texas Gulf Coast

Figure 5 shows average corrosion rates found for three unprotected magnesium alloys in salt spray (20% NaCl), tidal-immersion, and marine atmospheres. The principal alloy and impurity constituents of the specimens tested were as follows:

Element	AZ31B-H24 sheet	AZ63-F sand cast	AZ91C-F sand cast
Aluminum	2.6	5.8	8.8
Zinc	1.0	2.9	0.68
Manganese	0.51	0.25	0.22
Silicon	0.0017	<0.05	<0.05
Nickel	0.0005	<0.001	<0.01
Iron	0.0007	0.005	0.006

Copper	0.0019	0.015	0.013
Fe/Mn	0.0014	0.020	0.027

The marine atmosphere and tidal-immersion exposures were conducted at the Naval Air Station, Norfolk, VA. The atmospheric panels were suspended directly over the water, 3 m (10 ft) above mean tide level, at an angle of 45° from the horizontal and facing east-southeast. The tidal-immersion panels were mounted vertically so that they were totally immersed in the water at high tide and totally exposed to atmosphere at low tide.

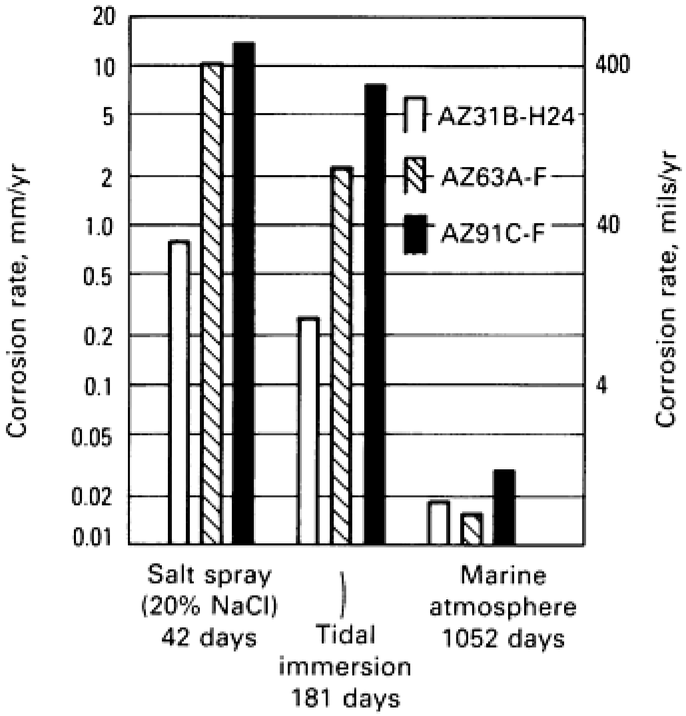

Fig. 5 Relative performance of magnesium alloys in saltwater exposures

The salt spray and tidal-immersion results are in good agreement in rating the three alloys in order of actual corrosion rates. The atmospheric panels, even though directly above the water, sustained only a small fraction of the corrosion damage seen in the salt spray and tidal tests.

No fundamental differences exist between spray and immersion tests that would lead to serious misjudgments about the relative corrosion resistance of magnesium alloys or the relative value of protective coating systems. (Caution should be exercised, however, when comparing the relative performance of magnesium alloys of different families, for example, QE22 and ZE41, or when comparing magnesium with other metals.) Figure 6 shows average corrosion rates over various exposure times for two die-cast alloys in salt spray and in 5% NaCl continuous immersion.

Influence of Galvanic Couples in Salt Spray and Marine Atmospheres. The combination of salt spray and dissimilar metals coupled to magnesium represents an extreme in accelerated corrosion testing. The gap between such a test and a marine atmosphere exposure is illustrated in Fig. 7 and in Table 8. Figure 7 shows magnesium die-cast plates that were assembled with steel cap screws and nuts and exposed to salt spray (5% NaCl) for 10 days. Table 8 lists losses of tensile strength of AZ31B-H24 sheet with an original thickness of 4.8 mm (0.188 in.), coupled with various dissimilar-metal cleats and exposed for 1.1 years at Kure Beach, NC, at 24.4 m (80 ft) from the mean tide point. Comparative data

are shown for rural and an urban-industrial test site. Marine exposure of steel magnesium couples will produce nearly complete perforation failure of 4.8 mm (0.188 in.) magnesium panels in 10 days. However, it should be noted that the steel panels retained 88% of their tensile strength after 13 months.

Atmospheric Corrosion Rates in Rural, Industrial, and Marine Environments. Table 9 lists the average corrosion rates reported for a number of alloys after 2.5 to 3 years of exposure at three different atmospheric test sites: a rural site (Midland, MI) an industrial site (Madison, IL), and a severe marine site (the Kure Beach, NC, site mentioned earlier). These data reveal that the alloy with the best corrosion resistance in all three environments is AZ91-T6 (10 ppm Fe). The alloys with the worst performance are ZE10A-0, EZ33A-T5/ZH62A-T5, and ZH62A-T5 in the rural, industrial, and marine exposures, respectively. Based on the average site corrosion rates for all alloys, the relative severity of the exposures is 1:2.1:1.7. Therefore, the industrial, SO_2-rich atmosphere is the more severe of the three sites.

Effect of SO_2 Pollution on Atmospheric Corrosion. Figure 8, prepared from data of the National Research Council of Canada, shows the effects of SO_2 pollution on the corrosion of ZK61A, AZ80A, and low-carbon steel. These effects may cause industrial atmospheres to corrode magnesium at average rates that are somewhat higher than those found in marine atmospheres (Table 9). The marine atmosphere poses a greater threat, however, for two reasons:

- The greater sensitivity of the marine corrosion rate to critical impurity content
- Greatly increased susceptibility to galvanic-corrosion damage by incompatible coupling metals in a wet chloride environment

These principles demonstrated in Tables 10 and 11. Table 10 lists the corrosion rates of high- and low-iron samplings of AZ31 sheet and AZ91C-T6 castings at the three test sites represented in Table 9 plus a 20% NaCl salt spray test for the

AZ91 castings. Table 11 assesses the relative galvanic damage to AZ31B-H24 caused by various cleat metals in rural, industrial, and marine exposures.

Indoor Atmospheres. Before the computer age, reaction of magnesium alloys with indoor atmospheres was of concern primarily from the standpoint of appearance, not function. The wide-spread introduction of magnesium die castings into the computer disk drive environment has imposed strict new standards of surface stability on the metal because of the need to maintain a clean particle-free atmosphere at the disk/head interface. The corrosion of magnesium alloys in indoor atmospheres increases with relative humidity. At relative humidities to about 90%, corrosion is very

minor, resulting in the formation of a nearly invisible film of amorphous $Mg(OH)_2$. As humidity increases beyond this level, heavier tarnish films develop, the principal corrosion product now being crystalline$Mg(OH)_2$. In die castings, small traces of chloride residues from cover or refining fluxes may serve as nuclei for corrosion spots in humid air.

The strict requirements of these applications are being met by a combination of the following factors:

- Constant efforts by alloy producers and die casters to provide metal that is extremely low in nonmetallic inclusions
- Use of selected conversion coatings and proprietary protective coatings for supplementary surface stabilization

Accelerated tests involving cyclic humidity and temperature variation provide useful information for these applications, both on coating performance and by detection of any flux inclusions that might be present.

Galvanic Corrosion

Insufficient attention to galvanic corrosion has been one of the major obstacles to the growth of structural applications of magnesium alloys. Serious galvanic problems occur mainly in wet saline environments for the reasons described earlier.

Outstanding improvements in general saltwater corrosion resistance of magnesium alloys have been achieved by reducing the internal corrosion currents through strict limitations on the critical impurities nickel, iron, and copper, as well as on the iron-to-manganese ratio. These improvements have no significant effect on galvanic corrosion, because the electromotive force (emf) for corrosion now comes from an external source, the dissimilar metal coupled to magnesium. Prevention of galvanic damage thus requires consideration of a combination of measures involving:

- Design to prevent access and entrapment of salt water at the dissimilar-metal junction
- Selection of the most compatible dissimilar metals
- Introduction of high resistance into the metallic portion of the circuit through insulators or into the electrolytic portion of the circuit by increasing the length of the path the electrolytic current must follow
- Protective coating of the full assembly

Details of these measures are treated in the section "Protection of Assemblies" in this article. It is useful, however, to review the basic principles governing the galvanic corrosion of magnesium and the relative compatibility of dissimilar metals with magnesium.

Relative Compatibility of Metals. All structural metals are cathodic to (more noble than) magnesium. The degree to which the corrosion of magnesium is accelerated under a given set of exposure conditions depends partly on the relative positions of the two metals in the emf series, but more importantly on how rapidly the effective potential of the couple is reduced by polarization as galvanic current flows. The principal polarization mechanism in a magnesium couple in salt water is the resistance to the formation and liberation of hydrogen gas at the cathode. Therefore, metals of low hydrogen overvoltage, such as nickel, iron, and copper, constitute efficient cathodes for magnesium and cause severe galvanic corrosion. Metals that combine active potentials with higher hydrogen overvoltages, such as aluminum, zinc, cadmium, and tin, are much less damaging, although not fully compatible with magnesium.

Data were compiled in tests at Kure Beach, NC, in which sheets of dissimilar metals were fastened to panels of AZ31B and AZ61A. The dissimilar metals were divided into five groups based on observed gradations of galvanic damage to magnesium. These ratings are summarized in Table 12.

Table 12 Relative effects of various metals on galvanic corrosion of magnesium alloys AZ31B and AZ61A exposed at the 24.4- and 244-m (80- and 800-ft) stations, Kure Beach, NC

Group 1 (least effect)	Group 2	Group 3	Group 4	Group 5 (greatest effect)
Aluminum alloy 5052	Aluminum alloy 6063	AlClad alloy 2024	Zinc-plated steel	Low-carbon steel
Aluminum alloy 5056	AlClad alloy 7075	Aluminum alloy 2017	Cadmium-plated steel	Stainless steel
Aluminum alloy 6061	Aluminum alloy 3003	Aluminum alloy 2024		Monel
	Aluminum alloy 7075	Zinc		Titanium
				Lead
				Copper
				Brass

Effects of Anode and Cathode Areas. The relative areas of the magnesium anode and the dissimilar-metal cathode have an important effect on the corrosion damage that occurs. A large cathode coupled with a small area of magnesium results in rapid penetration of the magnesium, because the galvanic current density at the small magnesium anode is very high, and anodic polarization in chloride solutions is very limited. This explains why painted magnesium should not be coupled with an active cathodic metal if the couple will be exposed to saline environments. A small break in the coating at the junction results in a high concentration of galvanic current at that point unmitigated by any polarization. Unfavorable area effects can also be seen in the behavior of some proprietary coatings using aluminum or zinc powder. When used as a coating on a steel bolt attached to magnesium, the metallic pigment can present a very large effective surface area, which may be more detrimental than bare steel. Galvanic action is further accelerated if the metallic pigment contains such impurities as iron.

Effects of Minor Constituents on Compatibility of Aluminum With Magnesium. Aluminum alloys containing small percentages of copper (7000 and 2000 series and 380 die-casting alloy) may cause serious galvanic corrosion of magnesium in saline environments. Very pure aluminum is quite compatible, acting as a polarizable cathode; but when iron content exceeds 200 ppm, cathodic activity becomes significant (apparently because of the depolarizing effect of the intermetallic compound $FeAl_3$), and galvanic attack of magnesium increases rapidly with increasing iron content. The effect of iron is diminished by the presence of magnesium in the alloy (Fig. 9). This agrees with the relatively compatible behavior of aluminum alloys 5052, 5056, and 6061 shown in Table 11.

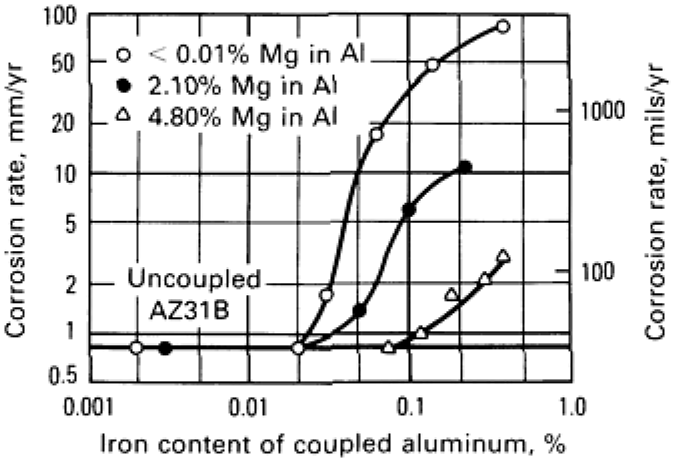

Fig. 9 Corrosion rates in 3% NaCl solution of magnesium alloy AZ31B coupled with aluminum containing varying amounts of iron and magnesium. The corrosion rate of uncoupled AZ31B is shown for comparison.

Cathodic Corrosion of Aluminum. Judgments of compatibility of aluminum alloys with magnesium alloys are complicated by the fact that aluminum can be attacked by the strong alkali generated at the cathode when magnesium corrodes sacrificially in static NaCl solutions. Such attack destroys compatibility in alloys containing significant iron

contamination, apparently by exposing fresh, active sites with low overvoltage. The aluminum alloys having substantial magnesium content (5052 and 5056) are more resistant, to this effect, but not completely so. The essential requirement for a fully compatible aluminum alloy, as indicated in Fig. 9, would be met by a 5052 alloy with a maximum of 200 ppm Fe or a 5056 alloy with a maximum of 1000 ppm Fe. Commercially produced 5052 alloy is permitted by specification to have a maximum (iron + silicon) content of 0.45% and may typically contain 0.3% Fe. In a severe exposure such as 5% NaCl immersion, this iron content, combined with the cathodic corrosion caused by the current from the magnesium, can render the 5052 alloy incompatible with magnesium. In most real situations, however, this extreme condition would not exist, and a 5052 washer under the head of a plated steel bolt in a magnesium assembly would reduce galvanic attack of the magnesium. For maximum effect of the washer, the linear distance along the aluminum from the bolt should be about 4.8 mm ($\frac{3}{16}$ in.)

Cathodic corrosion of aluminum is much less severe in seawater than in NaCl solution, because the buffering effect of magnesium ions reduces the equilibrium pH from 10.5 to about 8.8 (Ref 15). The compatibility of aluminum with magnesium is accordingly better in seawater and is less sensitive to iron content.

Cathodic Damage to Coatings. Hydrogen evolution and strong alkalinity generated at the cathode can damage or destroy organic coatings applied to fasteners or other accessories coupled to magnesium. Alkali-resistant resins are necessary, but under severe conditions such as salt spray or salt immersion, the coatings may be simply blown off by hydrogen, starting at small voids or pores. Because of its severity, the salt spray test can lead to rejection of some fastener coatings that may provide useful benefits in real service environments. Salt spray should not be relied upon exclusively to evaluate these coatings.

Compatibility of Plated Steel. Zinc, cadmium, or tin plating on steel all reduce galvanic attack of magnesium substantially compared to bare steel. This agrees with the more compatible potentials and/or the higher hydrogen overvoltages of the plated deposits. The relative merit of the three electroplates is generally considered to be (in decreasing order) tin, cadmium, zinc. The salt spray test is biased against zinc because zinc is rapidly removed from the steel substrate in this test medium due to general corrosion as well as cathodic attack when coupled with magnesium. This does not occur in many natural environments, and the failure of the salt spray test to rate zinc and cadmium plating properly in marine atmospheres is well known (Fig. 10).

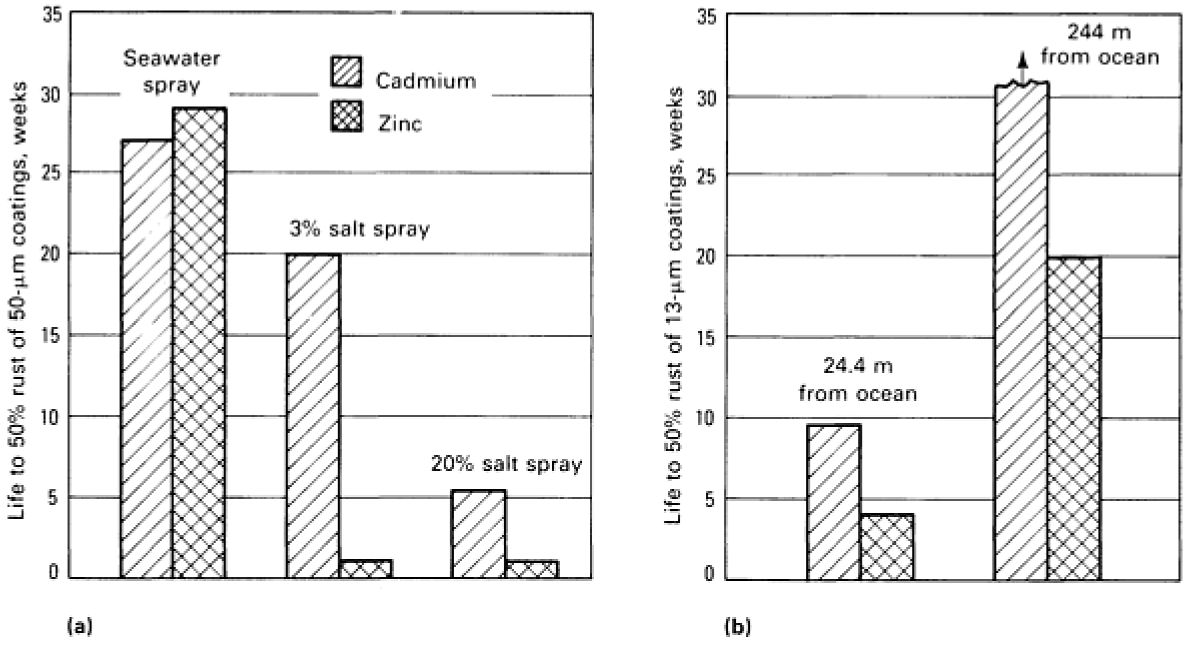

Fig. 10 Comparison of cadmium and zinc plate on steel in salt spray tests and in marine atmospheres. (a) 200-μm coating. (b) 50-μm coating. Source: Ref 16

Protection of Assemblies

A dissimilar metal in contact with magnesium will not by itself result in galvanic corrosion. For corrosion to occur, both surfaces must also be wetted by a common electrolyte. The degree to which precautions against galvanic corrosion are taken will depend on many factors, of which the operating environment is of primary importance.

For indoor use, where condensation is not likely, no protection is necessary. Even in some sheltered outdoor environments, magnesium components can give good service lives without special precautions against galvanic attack provided other mitigating factors are present. These might include design elimination of water traps, good ventilation, component warmth, or the presence of an oil film.

For continuous outdoor use, during which magnesium assemblies may be wetted or subjected to salt splash or spray, precautions against galvanic attack must be taken. Although corrosive attack from any source can jeopardize the satisfactory performance of magnesium components, attack resulting from galvanic corrosion is probably the most detrimental. Under corrosive conditions, use of high-purity magnesium alloys will have no significant influence in reducing the effects of galvanic corrosion.

Magnesium-to-Magnesium Assemblies. For all practical purposes, galvanic corrosion between magnesium alloys is negligible. However, because joining two magnesium components almost invariably involves use of dissimilar-metal fasteners and the formation of a crevice at the joint, good assembly practice dictates that in corrosive conditions some precautions should be taken (Fig. 11). Magnesium faying or mating surfaces should be assembled using wet assembly techniques. Chromate-inhibited primers or sealing compounds are placed between the surfaces at the time of assembly. Sealing/jointing compounds of the polymerizing or nonpolymerizing type are preferred because they remain flexible and resist cracking. Polymerizing-type compounds are also used for caulking operations. In bolted assemblies, the retorquing of bolts shortly after assembly will help eliminate any joint relaxation problems. For additional protection, mating surfaces should be primed before assembly and painted after assembly.

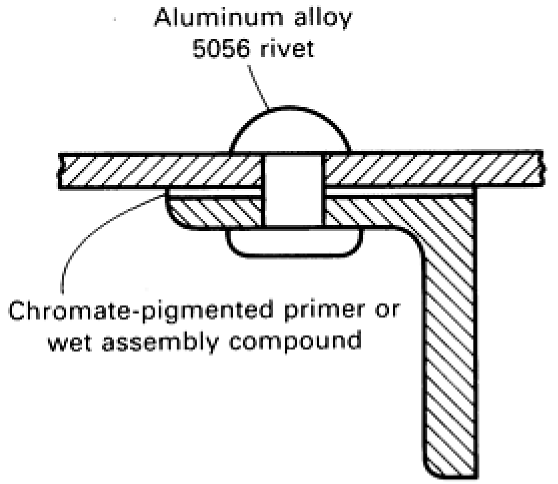

Fig. 11 Schematic of the proper method of protecting faying surfaces in magnesium-to-magnesium assemblies

Magnesium-to-Nonmetallic Assemblies. Although the joining of most nonmetallic materials, such as plastics and ceramics, to magnesium will not result in any potential corrosion hazard, there are some notable exceptions. Magnesium-to-wood assemblies present an unusual problem because of the water absorbency of wood and the tendency of the assemblies to leach out natural acids. To protect magnesium from attack, the wood should first be sealed with paint or varnish, and the faying surface of the magnesium treated as described above for magnesium-to-magnesium assemblies. The joining of magnesium to carbon fiber reinforced plastics is another exception that, in the presence of a common electrolyte, could result in corrosion of the magnesium unless similar assembly precautions are observed.

Magnesium-to-Dissimilar-Metal Assemblies. Several techniques can be implemented to minimize or eliminate galvanic corrosion or, if breakdown occurs, to reduce its effect in magnesium-to-dissimilar-metal couples. These include:

- Elimination of the common electrolyte
- Reduction of the relative area of dissimilar metal present
- Minimization of the potential difference of the dissimilar metal
- Protection of the dissimilar metal and the magnesium from the common electrolyte

Good design can play a vital role in reducing the threat of galvanic corrosion (Fig. 12). Elimination of a common electrolyte may be possible by the provision of a simple drain hole or shield to prevent liquid entrapment at the dissimilar-metal junction. Alternatively, the location of screws or bolts on raised bosses may also help avoid common electrolyte contact, as would use of nylon washers, spacers, or similar moisture-impermeable gaskets. The use of studs in place of bolts will reduce the area of dissimilar metal exposed by up to 50% provided the captive ends of the studs are located in blind holes.

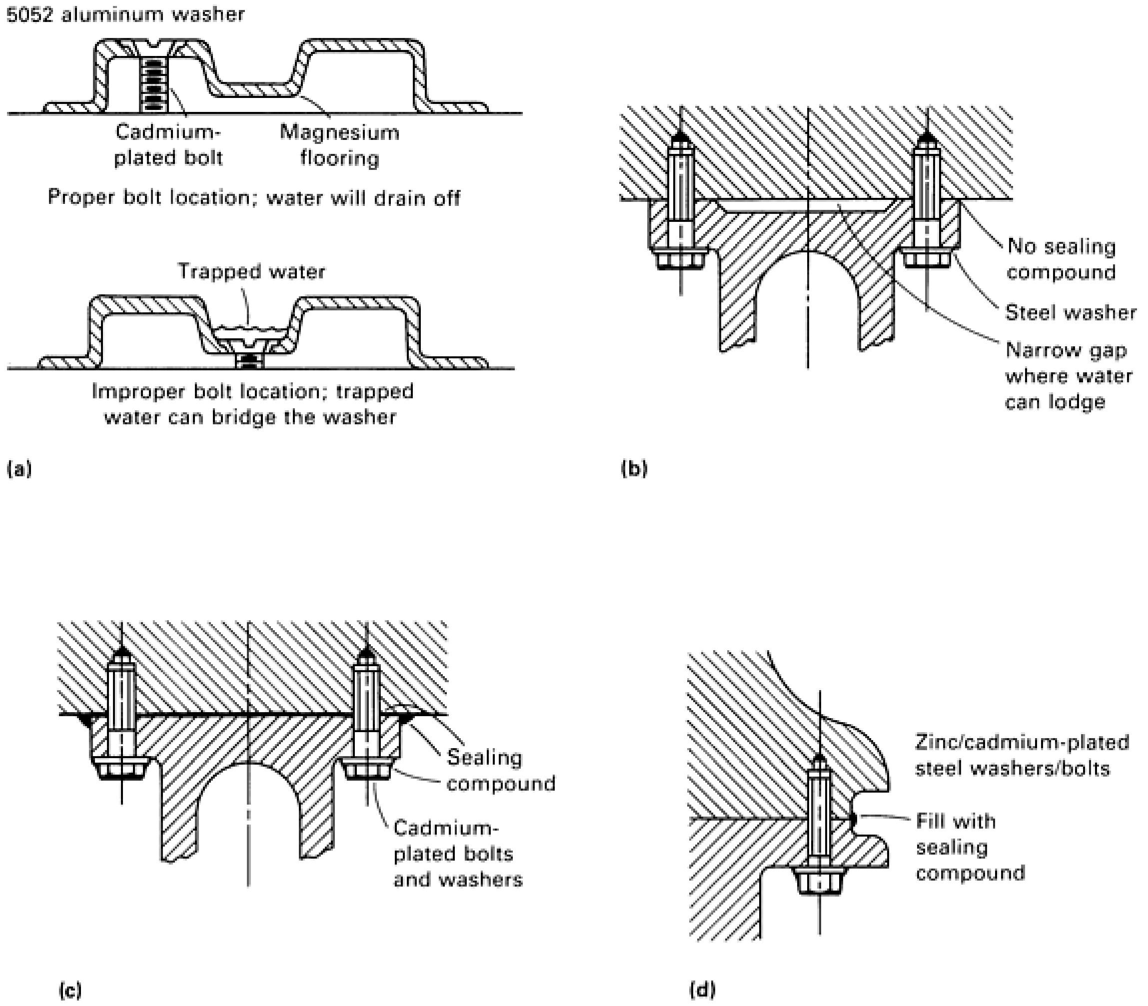

Fig. 12 Design considerations for reducing galvanic corrosion. (a) Proper bolt location. (b) Poor practice. (c) Good with no gap. (d) For use when direct metal-to-metal contact is required for electrical reasons

The degree of attack resulting from galvanic corrosion is, among other things, proportional to the potential difference between the metals involved. Consequently, this should be reduced to a minimum by careful material selection or the use of selected plating or coating of metals brought into contact with magnesium.

Dissimilar metals that are relatively compatible with magnesium are the aluminum-magnesium (5000 series) or aluminum-magnesium-silicon (6000 series) aluminum alloys, which should be used for washers, shims, fasteners (rivets

and special bolts), and structural members, where possible. Other aluminum alloys, steels, titanium, copper, brass, monel, and so on, will corrode magnesium when coupled with it under corrosive conditions, and protection is therefore required.

Aluminum, zinc, cadmium, and tin are used to coat steel or brass components to reduce the galvanic couple with magnesium. Reducing the potential difference or plating using materials with high hydrogen overvoltages will help reduce galvanic corrosion under mildly corrosive environments, but will have minimal effect in severe environments; additional precautions are required for corrosion protection.

Use of wet assembly techniques, as discussed previously, will eliminate galvanic corrosion in crevices. Caulking the metal junctions will increase the electrical resistance of the galvanic couple by lengthening the electrolytic path and thus reduce the degree of attack should it occur (Fig. 13). Vinyl tapes have also been used to separate magnesium from dissimilar metals or a common electrolyte and thus prevent galvanic attack (Fig. 14). Finally, painting the magnesium and, more important, the dissimilar metal after assembly will effectively insulate the two materials externally from any common electrolyte.

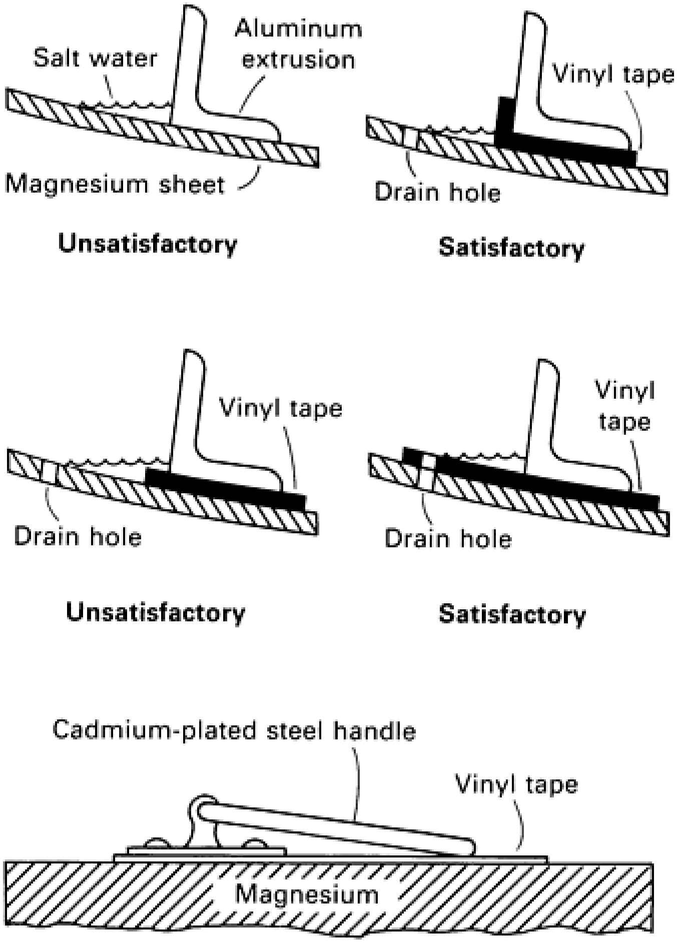

Fig. 14 Use of insulating tapes to avoid galvanic corrosion

Protective Coating Systems

Inorganic Surface Treatments. A full range of chemical and electrochemical cleaning and surface pretreatments before application of paint finishes is available for magnesium. Whichever pretreatment is selected, it must be applied to a clean metal surface. In the case of magnesium, this implies the removal of oil, dirt, or grease, and more important, a surface free of other contaminants. Heavy-metal contamination arising from blasting, brushing, tumbling, lapping, and other abrasive operations is particularly detrimental, as is contamination from graphite-containing die-forming lubricants. The use of abrasive materials compatible with magnesium--for example, high-purity alumina, silicon carbide, and glass--will help ensure that heavy metal pickup is kept to a minimum.

Oil, dirt, and grease are removed by conventional solvent immersion or vapor-degreasing techniques using chlorinated solvents. Alkali cleaning in high-pH cleaners is also suitable. Oxides, die-forming compounds, and other surface contaminants are removed by a range of acid-pickling solutions. Details are given in Table 13. In addition, an electrochemical process known as fluoride anodizing will more effectively remove sand or heavy-metal contamination. This process is also applicable to finished work when dimensional losses cannot be tolerated.

Table 13 Some chemical cleaning treatments for magnesium alloys

Type	Composition[a]	Operating conditions			Typical metal removal		Comments
		Time, min	Temperature				
			°C	°F	mm/surface	in./surface	
Nitric acid	50-100 mL 70% HNO_3, to 1 mL H_2O	$\frac{1}{2}$-1$\frac{1}{2}$	21-27	70-80	0.01-0.05	0.0004-0.002	General cleaning of rough castings, forgings, etc.
Acetic-nitrate	200 mL glacial acetic acid, 50 g $NaNO_3$ (sodium nitrate), to 1 L H_2O	$\frac{1}{2}$-1	21-27	70-80	0.012-0.025	0.0005-0.0009	Removal of mill scale and other surface contamination from wrought products
Chromic-nitrate	180 g CrO_3, 30 g $NaNO_3$, to 1 L H_2O	2-20	21-32	70-90	0.012-0.025	0.0005-0.0009	Removal of mill scale and graphite lubricants from wrought or founded products
Hydrofluoric-sulfuric	250 mL 60% HF, 31 mL 96% H_2SO_4, to 1 L H_2O	2-5	21-32	70-90	0.003	0.0001	Brightens die castings. Improves response to chemical pretreatment
Chromic-nitric-hydrofluoric	280 g CrO_3, 8 mL 60% HF, 25 mL 70% HNO_3, to 1 L H_2O	$\frac{1}{2}$-2	21-32	70-90	0.012-0.025	0.0005-0.0009	Removal of surface segregation from die castings to leave a smut-free surface. Improves response to chemical treatment
Chromic acid	100-200 g CrO_3, to 1 L H_2O	1-15	90-100	195-212	Negligible		Removal of oxides, corrosion product, and conversion coatings. Negligible metal removal providing bath uncontaminated by chlorides, sulfates, etc. Use silver chromate addition to control chloride contamination.
Chromic-sulfuric	100 g CrO_3, 10 mL 96% H_2SO_4, to 1 L H_2O	Swab until clean	21-32	70-90	Negligible		Local removal of superficial corrosion product
Nitric-sulfuric	80 mL 70% HNO_3, 20 mL 96% H_2SO_4, to 1 L H_2O	10-15 s	21-32	70-90	0.05	0.002	Preliminary treatment for sand castings to remove surface-contaminating effects of blast cleaning
Nitric acid/hydrofluoric acid treatment	(1) 50-100 mL 70% HNO_3, to 1 L H_2O (2) 100 mL 60%	Up to 2 min in (1), rinse, then 15 min in	21-27	70-80	0.05	0.002	Removal of heavy metal contamination from surface of rough castings. Second-stage immersion removes reprecipitated contaminants

	HF, to 1 L H_2O	(2)				remaining after first- stage cleaning.
Fluoride, anodizing	150-250 g $NH_4F \cdot HF$ (ammonium bifluoride), to 1 L H_2O	AC anodize at 200 A/m^2 (0.13 A/in.^{2}) up to 120 V	30	85 max	Negligible	Super cleaning of heavy metal contaminated surfaces. Fluoride film formed requires removal in H_2CrO_4 before chemical pretreatment.

(a) Whenever water is specified, use deionized water.

The primary function of dip or anodic coatings on magnesium is to provide a suitable surface to promote the adhesion of subsequent organic coatings. Conversion coatings should not be regarded as protective treatments in their own right unless they are to be exposed only to noncorrosive environments. Under these conditions, they will delay the onset of natural surface oxidation and may provide a more visually attractive surface appearance.

Table 14 lists some of the treatments used worldwide, together with brief application details and uses. Some treatments are quick and inexpensive to use, but may not provide as good a paint base as others. Consequently, their use should be restricted to mildly corrosive environments.

Table 14 Some chemical conversion coating treatments for magnesium alloys

Name	Bath composition[(a)]	Procedure	Appearance	Typical metal removal	Comments
Chrome pickle (acid chromate)	180 g $Na_2Cr_2O_7 \cdot 2H_2O$ (sodium dichromate), 187 mL 70% HNO_3, to 1 L H_2O	$\frac{1}{2}$ - to 2-min immersion at room temperature; allow to drain for 5-30 s; rinse in cold water, then hot water to aid drying	Golden yellow, often with iridescence	Up to 0.015 mm (0.0006 in.)	Applicable to all alloys and forms; mainly applied to wrought and die castings; good paint base
Modified chrome pickle	15 g $NaHF_2$ (sodium acid fluoride), 180 g $Na_2Cr_2O_7 \cdot 2H_2O$, 10 g $Al_2(SO_4)_3 \cdot 14H_2O$ (aluminum sulfate), 125 mL 70% HNO_3, to 1 L H_2O	$\frac{1}{2}$ - to 2-min immersion at room temperature; allow to drain for 5 s; rinse in cold water, then hot water to aid drying	Yellow-red iridescence to gold	Up to 0.012 mm (0.0005 in.)	Particularly suited to treatment of die castings; prepickle in $HF \cdot H_2SO_4$ mixture or hot alkaline clean; good paint base
Galvanic dichromate	(1) 50 g $NH_4F \cdot HF$ (ammonium bifluoride) (or sodium or potassium bifluoride), to 1 L H_2O	Immerse in activator for 5 min and rinse	Dark brown to black	Negligible	Applicable to all alloys and forms; matte black film useful for optical applications; good paint base
	(2) 30 g $(NH_4)_2SO_4$ (ammonium sulfate), 30 g $Na_2Cr_2O_7 \cdot 2H_2O$, 2.6 mL 0.880 NH_4OH, to 1 L H_2O	10- to 30-min immersion at 50-60 °C (120-140 °F) with parts coupled to low-carbon steel cathode; bath pH 5.6-6.2			
Dichromate	(1) 50 g $NH_4F \cdot HF$, or 187 mL 60% HF, to 1 L	5-min immersion in activator at room	Brassy to dark	Negligible	Applicable to most alloys and all forms; as-cast die-

	H_2O	temperature, except for AZ31 alloy, which should only be immersed for $\frac{1}{2}$-1 min if HF activator is used; rinse thoroughly	brown		cast surfaces should be prepickled to remove skin segregation; excellent paint base
	(2) 180 g $Na_2Cr_2O_7 \cdot 2H_2O$, 2.5 g CaF_2 or MgF_2 (calcium or magnesium fluoride), to 1 L H_2O	Immersion for 30 min in boiling solution (95 °C, or 205 °F, min); maintain pH 4.0-5.5; rinse and dry			
Chrome-manganese	100 g $Na_2Cr_2O_7 \cdot 2H_2O$, 50 g $MnSO_4 \cdot 5H_2O$ (manganese sulfate), 50 g $MgSO_4 \cdot 7H_2O$ (magnesium sulfate), to 1 L H_2O	Up to 2-h immersion at room temperature, proportionately less at higher temperatures, e.g. 10 min at boiling; maintain pH 4.0-6.0; rinse and dry	Dark brown to black	Negligible	Applicable to most alloys and all forms; as-cast die-cast surfaces should be prepickled to remove skin segregation; excellent paint base
Dilute chromic acid	10 g CrO_3, 7.5 g $CaSO_4 \cdot 2H_2O$ (calcium sulfate), to 1 L H_2O	Immerse or swab for 1-2 min; rinse and hot air dry	Brassy to brown	Negligible	For touch-up use or as complete treatment; moderate paint base; solution should be stirred or shaken vigorously before use
Iridite mag-coat	37.5 g proprietary Iridite 15 chromate compound, 58.5 mL 37% HCl, 0.26 mL proprietary wetting agent, to 1 L H_2O	Immerse or swab for 15-30 s at 21-32 °C (70-90 °F); maintain pH 0.2-0.6; rinse thoroughly in cold water and hot air dry	Brown to dark brown	Slight, up to 0.003 mm (0.0001 in.)	For touch-up use or as complete treatment; as-cast surfaces should be prepickled in $H_2CrO_4 \cdot HNO_3 \cdot HF$ to remove skin segregation; good paint base
Parker phosphate	(1) Proprietary Parco Coater 2557 (2) Proprietary Parcolene "Dilute"	3- to 5-min immersion at 55-70 °C (130-160 °F) followed by hot water rinse, then immerse for 15-45 s in hot supplementary treatment and hot air dry	Gray to matte silver	Negligible	Paint base for mild environments only when applied to high-purity alloys; not recommended for corrosive environments; nonchromate-containing treatment
Amchem phosphate	(1) Proprietary, Prep-n-Cote 978 (2) Deoxylite 41 (optional)	1- to 5-min immersion or spray at 38 °C (100 °F); water rinse; final rinse at 60 °C (140 °F) with Deoxylite	Light gray to beige	Negligible	Paint base for mild environments when applied to high-purity alloys; provides option of a chromium-free treatment
Dilute chromate; NH35	2.5 g $NaHF_2$, 2.5 g $Na_2Cr_2O_7 \cdot 2H_2O$, 3 g $MgSO_4 \cdot 7H_2O$, 32 mL 65% HNO_3, to 2 L H_2O	Clean (alkaline bath/or solvent); water rinse; NH35 treat 20-30 s; water rinse and dry	Yellow to yellow-brown low-pressure castings; yellow-brown to matte gray on high-pressure die	0.002 mm (0.00008 in.)	A dilute chromate treatment developed primarily for high-pressure die-cast alloys; is near equivalent of standard chromates in both shelf life and paint base

	castings	performance

(a) Whenever water is specified, use deionized water.

Several hard-anodizing treatments are available for magnesium, but the most commonly used are the No. 17 and HAE treatments (Table 15). Both may be applied as thin (0.005 mm, or 0.0002 in.) or thick (0.038 mm, or 0.0015 in.) coatings, with the thicker treatments imparting wear and abrasion resistance. These coatings are porous and provide excellent bases for subsequent painting. However, particularly for the thicker films, conventional painting may not completely seal the anodic pores. To prevent the risk of subsurface lateral corrosion spread from a point of damage, resin impregnation is used for maximum serviceability in aggressive corrosive environments. Inorganic chemical post-treatments are sometimes used to impregnate the anodic film with corrosion inhibitors, but these treatments can be detrimental to subsequently applied organic coatings and are not as effective as resin impregnation.

Table 15 Details of two hard-anodizing treatments for magnesium alloys

Name	Bath composition[a]	Anodizing conditions			Coating appearance	Coating buildup		Comments
		Time, min	**Temperature**					
			°C	**°F**		**mm**	**in.**	
HAE	135-165 g KOH, 34 g $Al(OH)_3$ (aluminum hydroxide), 34 g KF (potassium fluoride), 34 g Na_3PO_4 (trisodium phosphate), 20 g K_2MnO_4 (potassium manganate), to 1 L H_2O	8 min at 200 A/m^2 (0.13 $A/in.^2$) for thin coating (70 V)	15-30 max (cooling required)	60-85	Light tan (thin)	0.005	0.0002	Applicable to all alloys and forms. Thin coating provides excellent paint base. Thick coating provides excellent wear resistance, and if sealed with organic resins, provides superior corrosion protection as well. Process has good throwing power.
		60 min at 250 A/m^2 (0.16 $A/in.^2$) for thick coating (90 V) (AC anodize)			Dark brown (thick)	0.040	0.0016	
No. 17	240 g $NH_4F{\cdot}HF$, 100 g $Na_2Cr_2O_7{\cdot}2H_2O$, 90 mL 85% H_3PO_4, to 1 L H_2O	5 min at 200 A/m^2 (0.13 $A/in.^2$) for thin coating (70 V)	70-80	160-175	Light green (thin)	0.006	0.0002	Applicable to all alloys and forms. Thin coating provides excellent paint base. Thick coating gives good wear resistance and, if sealed with organic resins, provides superior corrosion protection. Process has excellent throwing power.
		25 min at 200 A/m^2 (0.13 $A/in.^2$) for thick coating (90 V) (AC anodize)			Dark green (thick)	0.030	0.0012	

(a) Whenever water is specified, use deionized water.

Organic Coatings. Adhesion and subsequent corrosion protection to cleaned and pretreated magnesium surfaces are enhanced by the use of alkali-resistant paint systems. Paints based on epoxy, epoxy ester, phenolic, polyurethane, vinyl, acrylic, polyester, silicone, and epoxy silicone systems are generally suitable. Those based on linseed, soya or other oils, alkyds, or nitrocellulose are best avoided unless applied for decorative purposes only.

Inhibiting pigments, such as strontium or zinc chromates, are often incorporated into primer systems for magnesium. These slightly soluble compounds will release chromate ions to retard subsequent corrosion should the paint film be damaged. Chromate inhibitors are, however, not as effective on magnesium as on aluminum alloys, particularly under corrosive conditions. Primers containing metallic zinc, lead, or any other metallic pigmentation should not be used on magnesium.

The full range of application techniques can be used. These include brushing, dipping, solvent or electrostatic powder spray, and electrophoretic techniques. Multilayer compatible coatings of primer, filler, and top coat systems will provide optimum protection in corrosive environments. Use of high-temperature stoving (baking) systems is also beneficial in developing maximum resistance to moisture permeability.

General Recommendations. Selection of a suitable protective scheme depends on many factors, especially the expected operational environment, design life, inspection and maintenance costs, the component cost, and of course the cost of original surface protection. For new applications, it is advisable to err on the side of over-protection until enough experience is gained to enable a more valued judgment to be made.

For indoor and similar noncorrosive environments, surface protection requirements are minimal and may range from none to simple chromate or phosphate conversion coatings with primer only or a decorative paint finish. Even under apparently more corrosive conditions, other mitigating factors, such as the use of high-purity alloys, good ventilation, component warmth, good design, and oil films, will enable magnesium components to be used with little or no protection.

For mildly or moderately corrosive environments, a chromate pretreatment followed by one coat of suitable primer and one or more coats of compatible finish should be applied. Under these conditions, the effect of galvanic couples, if present, should be considered, and some precautions taken, as previously outlined. It is expected that most commercial applications would be covered by this and the preceding general recommendation. (See the section "Proven Protection Systems" in this article.)

For moderately to severely corrosive environments, good-quality chromate conversion coatings or thin anodic pretreatments should be used. Chromate-inhibited epoxy primer systems, careful wet assembly procedures, and painting after assembly with primer and top coat are recommended. Use of low temperature baking paints is beneficial for improving humidity resistance (Fig. 15a).

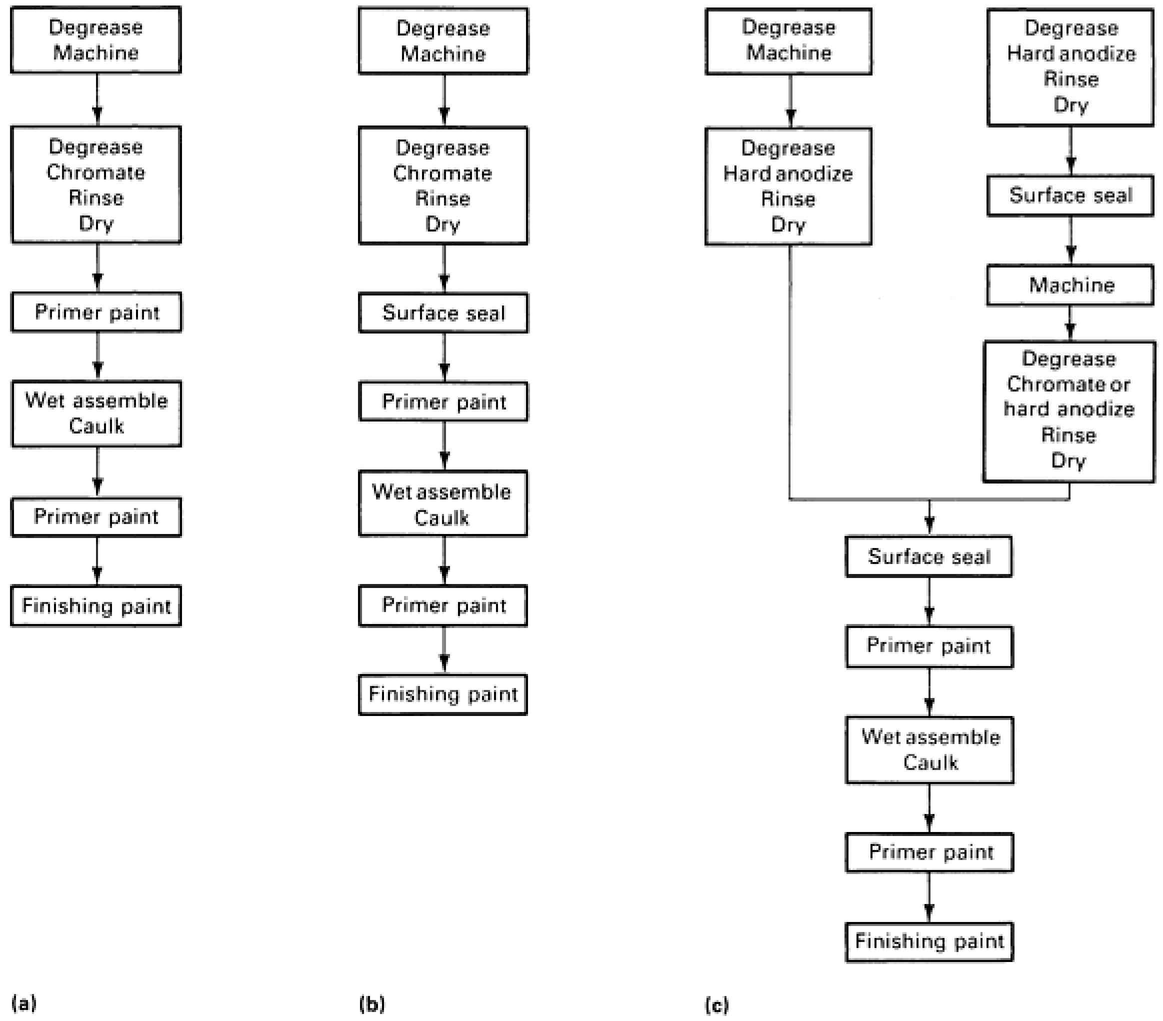

Fig. 15 Diagram of protection schemes for critical applications in corrosive environments. (a) For moderately corrosive environments. (b) For severely corrosive environments. (c) For severely corrosive environments with risk of abrasion or damage

For severely corrosive environments, for which maximum chemical, salt spray, and humidity resistance are required (Fig. 15b), specialized paints and coating techniques are used. Good-quality chromate or anodic pretreatments are required. Use of thick anodic coatings will also impart a measure of abrasion and damage resistance (Fig. 15c). Pretreatments should then be sealed with high temperature baking organic resins. This is achieved by a process known as Surface Sealing (MIL-M-3171 Section 3.9.3, MIL-M-46080), in which three coats of thinned resin are applied to a preheated component by spraying or, preferably, by dipping. Epoxy resin systems are preferred (MIL-C-46079), although the technique would be beneficial for other high temperature baking resins, such as phenolics and epoxy silicones.

After this foundation treatment, full wet assembly procedures, including caulking of joints, should be performed before application of a cold or low temperature curing chromate-inhibited primer and a compatible top coat system. For additional protection, a high temperature baking paint system should be maintained throughout. The above recommendations are necessarily very general in scope, but represent the various protection schemes in worldwide use on magnesium.

Proven Protection Systems

Aerospace Applications. Even within this specialized area, many surface protection schemes that reflect the differing operational environments encountered are in use.

For military and helicopter applications, comprehensive protection schemes are required to achieve extended component life and to reduce maintenance costs. Such schemes, as recommended for severely corrosive environments in the previous section, are required, and indeed, are mandatory in certain countries. Full wet assembly procedure and the coating of all exposed surfaces are essential. These schemes have given total protection for thousands of hours in various accelerated testing programs and will minimize corrosion spread.

For civil and other less aggressive aerospace applications, the protection schemes outlined for moderately corrosive environments are applicable. Good-quality aerospace paint systems should be used with wet assembly techniques.

Automotive Applications. The most notable automotive use of magnesium has undoubtedly been for the engine and transmission casings on the Volkswagen Beetle. For this application, no protective treatment was required to obtain long and reliable service life because of the mitigating environmental factors previously outlined. More modern automotive applications include air cleaner covers, engine compartment grills, retractable headlight assemblies, clutch and brake pedal supports, and clutch and transmission housings. For some applications, no protection is required. For others, where aesthetic appearance or corrosion protection is needed, the protective schemes outlined for mildly corrosive environments are suitable.

Cathodic electrophoretic epoxy primers applied to chromic acid pickled or dichromate pretreatments have proved effective, particularly in conjunction with high-purity AZ91D die castings. Electrostatic powder spray is used for top coating. Specially designed fasteners incorporating nylon or plastic washers, sleeves, shims, and so on, help reduce the risk of galvanic corrosion on exposed parts.

Some evaluations (Ref 17, 18), however, demonstrated that for structural underbody and road wheel applications, in which frequent exposure to water splash, stone impact damage, and the absence of mitigating environmental factors are problems, more comprehensive protection schemes may be required, together with protection against galvanic corrosion. Where applicable, use of underbody wax-type coatings can provide additional protection. It is expected that use of high-purity alloys will enable designers to specify many more magnesium automotive applications in the future.

Electronic and Computer Applications. Die-cast, investment-cast, and wrought magnesium components are used by computer and computer peripheral manufacturers for several applications where lightweight, low inertia, rigidity, and heat sink requirements preclude the use of other metals or plastics. The noncorrosive operational environment within the computer eliminates the need for galvanic-corrosion precautions.

For exterior housings, decorative surface treatments consisting of chromate pretreatment followed by textured epoxy powder coatings have proved satisfactory. Within disk drive units, where minute dust or other particles could cause disk or head failure, very thin (0.003 mm, or 0.0001 in.) specialized conformal coatings are applied to protect against atmospheric oxidation. Other similar commercial applications include housing or support frames in portable video equipment and a range of optical and medical electronic equipment.

Other Applications. Some magnesium applications may require surface protection against wear and corrosion. The use of resin-sealed hard-anodizing treatments, particularly thick HAE treatments, will provide excellent abrasion and corrosion resistance, but in some applications--for example, pulley wheels--will themselves cause excessive wear on other components. Under these conditions, dry-lubricant coatings are required. Nylon coatings applied by electrostatic powder or fluidized bed techniques onto a chromated and suitably primed magnesium surfaces have proved effective for use in aircraft pulley control systems. Thick nylon coatings also offer good damage and erosion resistance. Other systems, based on fluorocarbon (Teflon) impregnation of anodic pretreatments or resin-bonded solvent-base fluoropolymer coatings, are also effective in providing combined corrosion resistance and lubricity.

For high-temperature (above 200 °C, or 390 °F) applications, silicone-, epoxy-silicone-, and polyimide-based paints will provide effective corrosion-resistant coatings on magnesium. In environments where lubricants may be present, polyimide coatings are preferred, particularly when applied onto No. 17 anodic pretreatment.

There are a few applications in which magnesium components may be subjected to prolonged immersion or contact with corrosive electrolyte. In some systems, it may be possible to add corrosion-inhibiting agents to the electrolyte. Maintaining electrolyte pH above 10.5 or adding soluble chromates or neutral fluorides is effective in reducing magnesium-base metal corrosion. In other applications, comprehensive surface protection schemes and good maintenance are essential to achieve satisfactory service life. One such example is an atmospheric pressure deep-sea diving suit, the body and helmet of which are in magnesium alloy (Fig. 16). Surface protection consists of a thick HAE anodic film that is

surface sealed with high temperature stoving epoxy resin, full wet assembly procedures, and final painting with primer and top coat. Coupled with good maintenance, this protection scheme has given satisfactory service between major overhaul intervals of 4 years.

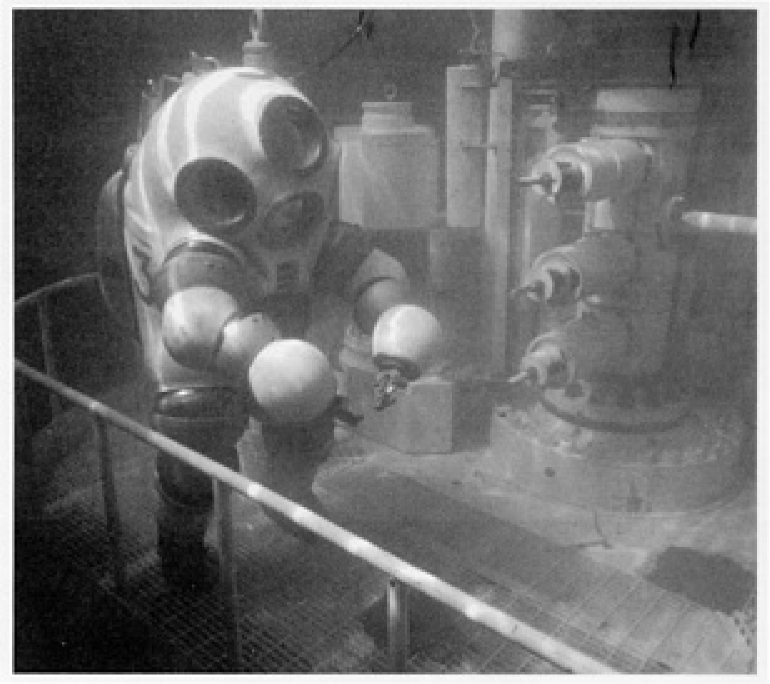

Fig. 16 Magnesium-bodied atmospheric deep-sea diving suit

Some special applications may require the metal plating of a magnesium component. Zinc and nickel can be directly plated onto magnesium from special electroless baths. Other metals may be electroplated from standard plating baths after surface cleaning, activation, zinc immersion coating, and a copper strike. It should be emphasized that metal plating of magnesium is not a corrosion-protective coating and that plated components should not be exposed to severely corrosive environments. Plated magnesium die castings are suitable, however, for such applications as interior automotive door handles and window cranks, where it is necessary to combine weight reduction with strength durability and good appearance.

Corrosion of Zinc

Dale C.H. Nevison, Zinc Information Center, Ltd.

Introduction

CORROSION LOSSES in the United States amount to approximately $167 billion annually. It is estimated that about 35% of this loss is avoidable through the application of corrosion control techniques already developed and available for use. More important, much greater savings could be realized if corrosion were more thoroughly understood and if proper specification for dealing with it were used at the initial stage of design.

Most of the money spent on corrosion control is used to protect steel. Approximately 40% of domestic steel production is devoted to replacing steel that has failed because of corrosion. Although steel is strong and easy to form and fabricate, it corrodes rapidly if left unprotected.

Therefore, it would appear that the simplest method of hindering corrosion on a metal surface is to seal it with a coating that prevents the access of moisture and oxygen. Such coatings need to be strongly resistant to the corrosive influence of their environment and sufficiently impermeable to prevent oxygen and water vapor from penetrating the metal surface. They also need to be tough, abrasion resistant, and strongly adherent to the surface they are required to protect.

Coatings of metallic zinc are generally regarded as the most economical means of protecting steel against corrosion. Zinc offers threefold protection in that it:

- Provides a rugged, lasting sheath that seals the underlying metal from contact with its corrosive environment
- Provides galvanic (sacrificial) protection when zinc-coated steels are subjected to mechanical damage and when the base metal is subsequently exposed to the environment
- Provides further protective action at minor discontinuities in the coating as a result of the selective dissolution of the coating, because comparatively bulky corrosion products accumulate in the damaged area and tend to form a barrier to further electrochemical action

It is not the purpose of this article to explicate the electrochemical reactions that occur at the surfaces of the anode and cathode in an electrolytic or galvanic cell. However, some discussion of the theory is necessary to provide information on corrosion principles that will illustrate why zinc is useful in commercial cathodic protection systems.

Galvanic Series for Metals

All metals and alloys can be arranged in decreasing order of activity, as shown in Table 1. When a metal near the anodic (tendency to lose electrons) end of the series is electrically connected to a metal below it and when both are immersed in an electrolyte, a galvanic cell is established, and electrical current flows from the more anodic metal and through the electrolyte to the other more cathodic (tendency to gain electrons) metal; this shifts the potential of the latter metal in a more electronegative direction. Current flows because of the natural potential difference that exists between different

metals. When two metals of a galvanic cell are widely separated in the galvanic series, there is a greater flow of current because of the larger potential difference that exists between them than when metals closer to one another are involved.

Table 1 Galvanic series of metals

Corroded End--Anodic or less noble (Electronegative)
Magnesium
Zinc
Aluminum
Cadmium
Iron or steel
Stainless steels (active)
Soft solders
Tin
Lead
Nickel
Brass
Bronzes
Nickel-copper alloys
Copper
Stainless steels (passive)
Silver solder
Silver
Gold

Platinum
Protected End--Cathodic or most noble (Electropositive)

Note: Any one of these metals and alloys will theoretically corrode while protecting any other that is lower in the series as long as both form part of an electric circuit.

Figure 1 illustrate a typical galvanic or sacrificial anode, corrosion cell that contains the four elements necessary for corrosion to proceed: an anode, a cathode, an electrolyte, and an electron path. Zinc ions that are positively charged go into solution, and the electrons migrate to the cathode through the electron path. When the electrolyte is water, the reduction of dissolved oxygen occurs first at the surface:

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \quad \textbf{(Eq 1)}$$

Once the dissolved oxygen has become depleted or current limited (that is, insufficient diffusion of oxygen to support an upper current limit) in the electrolyte, hydrogen ions react with electrons to form hydrogen gas:

$$2H^+ + 2e^- \rightarrow H_2 \quad \textbf{(Eq 2)}$$

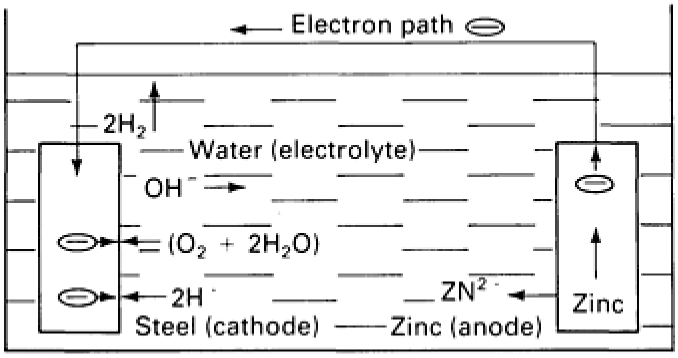

Fig. 1 Typical galvanic corrosion cell showing mechanism of sacrificial behavior of zinc in protecting steel against corrosion

The evolution of hydrogen gas at the cathode is generally visible evidence that a reaction (reduction) at the cathode has occurred. The evolution of hydrogen at the cathode increases the cell resistance because of hydrogen gas bubbles on the cathode, with a resultant decrease in current flow from the anode. However, dissolved oxygen may react with excess hydrogen ions (to form water) at the cathode and increase the reaction rate. Under these conditions, greater current will flow from the anode.

Thus, when the zinc metal ions of the anode enter the solution, a sacrificial corrosion of the anode occurs and the steel cathode is protected. The corroding areas on a metal surface are at the anode, where an electric current flows out of the metal, and the protected areas are at the cathode, where the current flows into the metal. This is what occurs in a cathodic (galvanic) protection system. This type of sacrificial or cathodic protection also occurs when zinc coatings on steel surfaces are subjected to mechanical damage in which the continuity of the zinc coating is broken and the steel surface is exposed.

The scale indicates that magnesium, aluminum, and cadmium should also protect steel. In most normal applications magnesium is highly reactive and is too rapidly consumed. Aluminum forms a resistant oxide coating, and its effectiveness in providing cathodic protection is limited. Cadmium provides the same cathodic protection for steel as zinc, but its applications are limited for technical and economic reasons to small electroplated parts, such as fasteners.

The galvanic series is typical of those for corrosive solutions, such as seawater. However, in the presence of certain electrolytes, the relative positions of some of the metals listed can be altered; an important example occurs when tinned steel is in contact with fruit juice, in which case tin is anodic to the base metal. In general, however, the protection afforded by tin or nickel coatings on steel is effective only as long as the coating is continuous and free from pores or other discontinuities. When there are breaks in the coating, electrolytic action between the coating and the basis metal accelerates the dissolution of the steel; such dissolution can proceed at the steel surface beneath the cathodically protected metallic coating until breakdown occurs over a large area.

Upon exposure to environments other than highly acidic atmospheric pollution, zinc forms a self-protecting film of fairly impermeable basic corrosion products. This protects the metal from further attack. If the coating is continuous, the rate at which the coating is attacked is the only factor. If the coating is not continuous or if it becomes discontinuous because of weathering, pores, flaws and cracks, then the electrochemical property or anodic nature of zinc becomes effective in providing protection.

Life of Zinc Coatings

There are different concepts regarding what constitutes the useful life of a zinc coating. These include the first visible evidence of rust, time to perforation, and time to breakage. Each concept has its relevance. In the latter two, the thickness and corrosion resistance of the base metal are factors in the useful life of the zinc-coated items. Another generally accepted criterion of the useful life of a protective coating, especially where appearance is of minor importance, is the period of time during which the coating prevents failure of the base metal.

Basically, the degree of corrosion protection or the life of a zinc coating can be evaluated in terms of the rate at which the coating loses weight or thickness in a given environment. The most practical way of expressing the corrosion resistance (the response of zinc coatings to different exposure conditions) is in terms of the area on which rust appears as a result of exposed steel.

The protective value of zinc coatings in American Society for Testing and Materials (ASTM) tests is expressed in terms of the percentage of the surface showing rust. This method of evaluation is realistic for several reasons. Corrosion takes place initially at the most vulnerable spots and then spreads, because of such influences as nonuniform coating thickness, the nonuniformity of wetting and drying of different parts of a specimen, the presence of bare metal where the steel has been sheared, and the presence in the coating of an alloy layer that may corrode at a rate different from that of the relatively pure zinc surface. The curves representing the progress of rust with time are S shaped.

Coating Thickness and Uniformity. Although the corrosion rate of zinc in atmospheres is low, it must be remembered that galvanized coatings are normally quite thin. The weight of a zinc coating is always expressed in terms of ounces per square foot of surface. For galvanized sheet, the weight of coating is given in ounces per square foot of sheet; because the sheet is coated on both sides, this is twice the average weight of coating per square foot of surface. Thus, a coating of 1.25 oz/ft^2 (380 g/m^2) has a total of 1.25 oz of zinc on the front and back surfaces of each square foot of sheet. Therefore, the average weight of coating per square foot of each surface of the sheet is 0.625 oz (17.7 g), or slightly more than 1 mil (0.025 mm) thick. It is important to specify a coating that is thick enough for the intended service. Uniformity of coating thickness is also significant, especially in light coatings. When coatings are uneven, the thinner areas fail even though there is ample zinc elsewhere on the surface. With a heavy coating, variations in thickness are less important, since the sacrificial protection of the exposed steel is more effective because of the increased zinc layer.

Comparison of the protective value of different zinc coatings may be expressed in terms of the average thickness or weight per unit area of zinc removed in a given area. Suggested units are millimeters per square decimeter per day, inches per year, and mils per year. This last unit is convenient because its reciprocal represents the life in years of a coating that is 1 mil (0.025 mm) thick.

To provide more complete information, these weight figures should be accompanied by equivalent thickness values. One ounce of zinc per square foot of surface is equivalent to a coating thickness of 1.7 mils (0.0017 in., or 0.043 mm). Any other coating thickness can be calculated from this value if the weight is given, or vice versa. The weights of coatings for many galvanized products are covered by various ASTM specifications. They do not represent the maximum weight of coating desirable for every application or the maximum obtainable. Specifications from ASTM should be consulted for a description of the methods of measuring properly the thickness of the coating.

In continuous or hand-dip galvanizing, the zinc coating consists of a relatively pure layer of zinc on the outside, followed by three layers of iron-zinc alloy phases with decreasing proportions of zinc and correspondingly higher percentages of iron from surface to interface. The aggregate alloy layer also provides corrosion protection to the base metal; when the pure zinc layer has finally corroded away, the reddish corrosion product of the exposed layer sometimes encountered should not be mistaken for rust of the underlying steel. On the contrary, this is the optimum stage at which paint should be applied.

Atmospheric Corrosion

The behavior of zinc and zinc coatings during atmospheric exposure has been closely examined in tests conducted throughout the world. The performance of zinc in a specific atmospheric environment can be predicted within reasonable limits.

Precise comparison of corrosion behavior in atmospheres is complex because of the many factors involved, such as prevailing wind direction, type and intensity of corrosive fumes, the amount of sea spray, and the relative periods of moisture or condensation and dryness. However, it is generally accepted that the corrosion rate of zinc is low; it ranges from 0.13 μm/yr (0.005 mil/yr) in dry rural atmospheres to 0.013 mm/yr (0.5 mil/yr) in more moist industrial atmospheres. Zinc is more corrosion resistant than steel in most natural atmospheres, the exceptions being ventilated indoor atmospheres where the corrosion of both steel and zinc is extremely low and certain highly corrosive industrial atmospheres. For example, in seacoast atmospheres, the corrosion rate of zinc is about $\frac{1}{25}$ that of steel.

Zinc owes its high degree of resistance to atmospheric corrosion to the formation of insoluble basic carbonate films. Environmental conditions that interfere with the formation of such films may attack zinc quite rapidly. The most important factors that control the rate at which zinc corrodes in atmospheric exposures are:

- The duration and frequency of moisture contact
- The rate at which the surface dries
- The extent of industrial pollution of the atmosphere

The latter is the most important because the formation of basic corrosive films is prevented when the zinc is attacked by acidic moisture. This effect of industrial pollutants is well illustrated by considering that in highly industrial environments a 2-oz/ft^2 (610-g/m^2) zinc coating will begin to exhibit rusting after 4 years and may be 80% rusted in 10 years. A similar coating would not be expected to display rusting after 30 to 40 years of exposure in rural atmospheres and after 15 to 25 years in marine environments.

In dry air, zinc is slowly attacked by atmospheric oxygen. A thin, dense layer of oxide is formed on the surface of the zinc, and a porous outer layer then forms on top of it. Although the outer layer breaks away occasionally, the thin under layer remains and protects the metal by restricting its interaction with the oxygen. Under these conditions, which occur in some inland tropical climates, the zinc oxidizes very slowly.

The rate of drying is also an important factor because a thin moisture film with higher oxygen concentration promotes corrosion. For normal exposure conditions, the films dry quite rapidly, and only in sheltered areas are drying times slow enough to accelerate the attack of the zinc significantly.

In coastal districts and industrial areas, the air is contaminated with water containing considerable amounts of dissolved salts. Sodium chloride (NaCl) is of course the main salt present in marine atmospheres, and oxides of sulfur are the most important pollutants in industrial and urban atmospheres. The oxides of sulfur dissolve in water to form sulfuric acid (H_2SO_4), which in turn reacts with the zinc hydroxide ($Zn(OH)_2$) or zinc carbonate ($ZnCO_3$) formed on the surface to produce zinc sulfate ($ZnSO_4$). Because this salt is very soluble, it is easily removed by rainwater, and this leaves the zinc surface relatively unprotected. This solubility of the zinc corrosion products is one of the most important factors affecting the rate of corrosion of zinc in industrial atmospheres, and it primarily accounts for the fact that this rate may be as much as four or five times greater than that in rural or marine atmospheres, depending on the amount of sulfur present.

If a fresh zinc surface is allowed to stand with large drops of dew on it, as may easily happen if it is stored in a closed space in which the temperature varies periodically, it will be attacked by the oxygen dissolved in the drops of water. These drops of water conduct electricity slightly, and because the oxygen concentration is greater at the outer edges of the

drops than at their centers, some electrochemical action results. Therefore, bulky deposits of porous zinc oxide (ZnO) or $Zn(OH)_2$ form on the surface instead of forming a protective layer all over it. This oxide quickly takes up carbon dioxide (CO_2) to form a basic carbonate, commonly known as wet-storage stain. This may form on any new zinc surface unless care is taken to store the metal in a dry airy place until the protective layer has formed over the entire surface. The formation of wet-storage stain may also be prevented by a simple chromate treatment.

Influence of Atmospheric Variables

Atmospheric corrosion has been defined to include corrosion by air temperatures between -18 to 70 °C (0 to 160 °F) in the open and in enclosed spaces of all kinds. Deterioration in the atmosphere is sometimes called weathering. This definition encompasses a great variety of environments of differing corrosivities. The factors that determine the corrosivity of an atmosphere include industrial pollution, marine pollution, humidity, temperature (especially the spread between daily highs and lows that influences condensation and evaporation of moisture) and rainfall. The atmosphere, as far as corrosion is concerned, is not a simple invariant environment. The influence of these factors on the corrosion of zinc is related to their effect on the initiation and growth of protective films.

Relative Humidity and Rainfall. In relatively dry air, the initial film formed in zinc surfaces is ZnO from the reaction of the zinc with atmospheric oxygen. This will be converted to a hydroxide in the presence of moisture. These films have a relatively minor protective effect. The $Zn(OH)_2$ reacts further with CO_2 in the atmosphere, which forms a basic $ZnCO_3$. This film is very protective and is mainly responsible for the excellent resistance of zinc to ordinary atmospheres.

The significance of atmospheric humidity in the corrosion of zinc is related to the conditions that may cause condensation of moisture on the metal surface and to the frequency and duration of the moisture contact. If the air temperature drops below the dew point, moisture will be deposited. Similarly, lowering the temperature of a metal surface below the air temperature in a humid atmosphere will cause moisture to condense on the metal. If the water evaporates quickly, corrosion is usually not severe, and a protective film is formed on the surface. On the other hand, water that remains in contact with zinc at high humidities, and particularly under poorly ventilated conditions, may cause severe corrosion.

Rainfall is not considered to be a source of serious corrosion unless it remains in contact with the zinc for some time, particularly if access to air is limited. The weight losses sometimes observed after a heavy rainfall indicate the washing away of soluble corrosion products that formed before the rainfall.

In some short-term tests, zinc kept under a roof, but otherwise exposed to the atmosphere, corroded at about the same rate as completely exposed zinc. Sulfur dioxide (SO_2), not rain, is the significant factor in the corrosive attack. In long-term tests, however, the specimens protected from falling rain corroded at a rate considerably slower than that for completely exposed specimens. This is attributed to the formation of a $ZnSO_4$ film on the samples under the roof that is not washed away by the rain. The surface is more acid and absorb less SO_2 from the air. The higher corrosion rate in the open is not attributed directly to rainfall, but is attributed indirectly to the washing away of the protective film by the rain.

Results of tests on the effect of atmospheric pollution and rainfall on the corrosion of zinc conducted by the Corrosion Committee of the Iron and Steel Institute proved that the pH of the rainwater and the total solids contents of the air have some significance (Ref 1). In highly industrialized localities, the rainwater is contaminated by acidic sulfur compounds and becomes acidic enough to interfere with the formation of a protective film. This pH value is very significant because it interferes with the zinc formation of protective coatings of carbonates, sulfates, or oxides.

In acid rain environments, such coatings are never stabilized, because they are in a constant flux of dissolution. The United States and Canadian governments, as well as the Electric Power Research Institute, began investigations in the early 1980s on the acid rain corrosion of zinc and galvanized steel. These studies will provide detailed information on the long-term effects of acid rain on these metals.

Industrial and Marine Pollutants. In industrial or marine locations, condensed dew is likely to be contaminated with impurities that are corrosive to zinc. In such circumstances, the corrosivity of the contaminant may be more important than the degree of moisture condensation. Sulfur dioxide is one of the most harmful pollutants in the atmosphere, and it plays a major part in the corrosion of steel and zinc. Exposure tests showed that the correlation between sulfur pollution and corrosion is high for copper-bearing steel and for zinc, and these tests demonstrated that the SO_2 concentration in the air is the determining factor for the intensity of the corrosion of these metals.

Another series of tests found that even at lest sites situated far from industrial towns the corrosion products contained a strong sulfate component derived from atmospheric sulfur compounds. This indicates that the effects of this type of pollution are far reaching (Ref 2).

Atmospheric Exposure Tests on Zinc

Several atmospheric exposure programs have been conducted throughout the world to obtain corrosion rate data for zinc exposed to representative natural atmospheres. These programs have provided quantitative evidence of the excellent resistance of zinc over a wide range of atmospheric conditions. Although there is considerable spread in terms of percentage in the corrosion rates observed, the actual corrosion rate rarely exceeded about 8 μm/yr (0.3 mil/yr) in average metal loss, even under the more severe conditions. This is well within all standards of acceptable corrosion performance.

A quantitative assessment of the relative corrosivity of different atmospheres can be seen from the results of the exposure tests reported by ASTM (Ref 3). The results calculated from ASTM data provide a comparison of the corrosion of steel and zinc on the basis of 45 worldwide locations (Table 2). From a cross-section of these exposure sites, it can be noted that the corrosion rates of steel and zinc vary significantly with different locations and climates.

Table 2 Comparative rankings of 45 locations based on steel and zinc losses

Source: Ref 3

The amount of zinc corrosion with increasing time of exposure depends on the type of atmosphere. In semi-industrial and rural atmospheres, the corrosion rate is approximately constant. On the other hand, the corrosion rate decreases with time in marine atmospheres and increases with time in industrial atmospheres. In all cases, the yearly change in corrosion rate decreases with time and approaches a steady rate. The equilibrium corrosion rate also depends on the environment. The rate in a rural atmosphere is only about one-fifth that in an industrial atmosphere and one-third that in a marine atmosphere.

Although neither iron nor zinc corrodes appreciably in the rural climate of Norman Wells Northwest Territory (N.W.T.), the atmosphere at the Geleta Point Beach site in the Panama Canal zone appears to be the most corrosive to these metals (Ref 4). Corrosivity can vary appreciably over very short distances. For example, a comparison of the corrosion rates for two Kure Beach, NC, sites shows that the corrosion rate for zinc at the 25-m (80-ft) site is roughly three times that of the 250-m (800-ft) site, although the sites were only 225 m (720 ft) apart.

The corrosion rate data for steel in the same atmosphere show that steel, in general, corrodes at a greater rate than zinc in all atmospheres. The progress of corrosion with time, however, may be quite different for the two metals; therefore, direct comparison of corrosion rates should specify the duration of exposure for which the comparisons are made. For example, the corrosion rate of zinc decreases with time in a severe seacoast environment (Kure Beach: 25-m, or 80-ft, site), but that of steel increases with time. On the other hand, the reverse is true in an industrial environment. The effect of the nature of the atmosphere on the relative corrosion rates as influenced by duration of exposure is indicated in Table 3.

Table 3 Comparison of corrosion rates of zinc and steel in various environments

Location	Ratios of corrosion of steel to corrosion of zinc after indicated exposure	
	1 year	**8 years**
State College, PA	20:1	13:1
New York, NY (spring start)	17:1	4:1
New York, NY (autumn start)	32:1	6:1
Middletown, OH	28:1	12:1
Kure Beach, NC (25-m, or 80-ft, site)	47:1	168:1 (4 years)
Norman Wells, N.W.T.	2:1	1.6:1 (2 years)

Similar results were obtained in the very comprehensive series of tests conducted by ASTM (Ref 3). Table 4 presents a summary of the corrosion behavior of zinc based on 20-year ASTM exposure data.

Table 4 Corrosion of zinc in various environments based on 20-year ASTM exposure data

Environment	Years to corrode 0.025 mm (1 mil)

Rural	22
Southwestern seacoast	14
Heavy industrial seacoast	4.6
Heavy industrial	3.4

Source: Ref 3

Another important result was revealed in a series of tests by the Swedish Committee on Corrosion (Ref 2). A zinc-coated surface was found to be much less likely to suffer pitting attack than unprotected steel. The depth of pits on unprotected steel was up to six times the average loss of metal, but for zinc-coated steel, the ratio was only two or three.

Atmospheric Exposure Tests on Zinc Coatings. Measurements of the corrosion rates of zinc and zinc coatings have been made simultaneously in many parts of the world, and it has been found that the rates are substantially the same.

Therefore, the same figures can be used to calculate the estimated lives of zinc coating of a given weight that have been exposed in a particular environment.

The life of a zinc coating is difficult to define. Quantitative weight loss data are not always meaningful, because of the complicating effects of interface alloy layers and perforation of the coatings. Furthermore, the criterion for failure many vary with the type of coating and its intended applications. If a steel specimen were coated with a perfectly uniform zinc coating and if all parts were exposed to the same corrosive influences, the zinc coating would suddenly disappear from the entire surface, after which the exposed steel would corrode at its normal rate. This situation obviously does not exist in practice, because of the nonuniform distribution of the zinc coating over the surface and the resulting irregular penetration of the coating by corrosion. Therefore, arbitrary values, such as time to initial rusting or to some percentage of the total surface showing rust, have been used as a measure of the life of zinc-coated components.

In general, the underlying ferrous metal is protected along as it can fulfill the intentions of the designer. Therefore, a galvanized roof has not failed as long as it keeps rain out of a building, nor has a fence failed as long as its strands are strong enough to keep animals from straying. However, in other applications, slight discoloration of the surface may be unacceptable, even though the zinc layer is intact.

The behavior of zinc coatings of different thicknesses and applied by different methods was examined in tests under actual outdoor service conditions. Results showed that for a particular exposure condition the life of a zinc coating is approximately proportional to the weight of zinc and is independent of the method by which it is applied (Fig. 2).

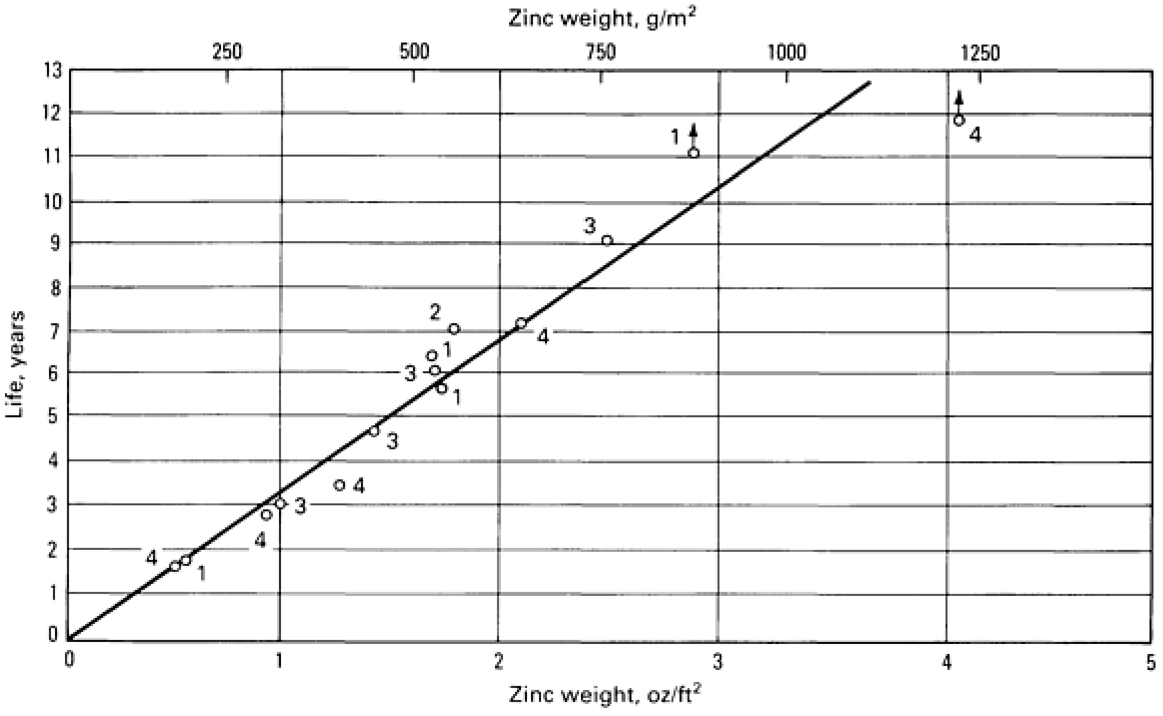

Fig. 2 Service lives of various zinc coatings according to the weight of the zinc present. Results are for exposure in a very aggressive industrial atmosphere. 1, electrodeposited; 2, electrodeposited (passivated with chromate solution); 3, hot-dip galvanized; 4, sprayed

This is a very important result that should always be kept in mind when protective coatings are specified for a particular service application. If a steel structure or component is expected to have a long service life, it is always more economical to apply a sufficiently heavy zinc coating at the start than to renew the coating later on because the initial zinc coating was of inadequate weight. The amount of surface preparation required is nearly always less with the new structure than with an old one and is the same whether a thick or thin coating is to be applied. On the other hand, there is no point in applying a heavy zinc coating to an article that will be discarded for other reasons after a short period of service under mildly corrosive conditions.

The thickness of coating that can be obtained depends on the process and to some extent on the part to be coated. Table 5 lists typical coating thicknesses applied by normal practice. There are variations in thickness, uniformity, density, and composition of the coatings applied by different methods, and these variations should be considered in evaluating the corrosion performance of coatings. As long as the coatings remain continuous and intact, the corrosion behavior is generally equivalent to that of metallic zinc, but galvanic action begins when the zinc layer is penetrated to the steel interface. The original thickness, density, and uniformity of the zinc coating determine the progress of sacrificial corrosion and the protection of the steel.

Table 5 Typical zinc coating thicknesses applied by various processes

Method	Process	Specification	Coating thickness		Applications

Atmospheric Exposure Tests on Zinc Die Castings. The corrosion behavior of zinc die castings in various natural atmosphere was investigated by ASTM in a program extending over a 20-year period (Ref 5). Because mechanical properties have an important effect on the practical applications of die castings, changes in these properties were taken as a measure of corrosion damage rather than weight loss. Specimens of alloys AG41A (1% Cu) and AG40A (copper free) were exposed at several locations, and their mechanical properties were determined after 5, 10, and 20 years of exposure. The average properties after the 20-year exposure at two industrial, one rural, and two indoor locations are given in Table 6.

Table 6 Change in mechanical properties of zinc die cast alloys upon exposure to several natural atmospheric environments.

Results are from 20-year exposure tests at the following sites: outdoor/industrial (New York, NY, and Altoona, PA), outdoor/rural (State College, PA), and indoor

Alloy	Property	Original value	After 20-year exposure					
			Outdoor/industrial[a]		**Outdoor/rural**[a]		**Indoor**[a]	
AC41A	Tensile strength	305 MPa (44.3 ksi)	211 MPa (30.6 ksi)	[-31%]	259 MPa (37.6 ksi)	[-15%]	254 MPa (36.9 ksi)	[-17%]
	Elongation in 50 mm (2 in.), %	7	3.7	[-50%]	9	[+28%]	12	[+71%]
	Hardness, HRE	91	78	[-14%]	80	[-10%]	83	[-8%]
	Charpy impact	56J (41 ft·lb)	12J (9 ft·lb)	[-78%][b]	45J (33 ft·lb)	[-20%]	27J (20 ft·lb)	[-52%][b]
AG40A	Tensile strength	254 MPa (36.9 ksi)	206 MPa (29.9 ksi)	[-19%]	225 MPa (32.6 ksi)	[-12%]	228 MPa (33.1 ksi)	[-10%]
	Elongation in 50 mm (2 in.), %	15	7	[-47%]	18	[+20%]	21	[+40%]
	Hardness, HRE	83	72	[-13%]	67	[-19%]	74	[-11%]
	Charpy impact	53J (39 ft·lb)	16J (12 ft·lb)	[-69%]	51J (38 ft·lb)	[-3%]	40	[+3%]

Source: Ref 5

(a) Bracketed figures are the percentage changes from the original values caused by exposure.

(b) Large change between 10 and 20 years of exposure.

Round specimens measuring 6.4 mm ($\frac{1}{4}$ in.) in diameter were used for tensile tests, and 6.4-mm ($\frac{1}{4}$-in.) square bars were used as impact specimens. The percentage changes from the original values are included. As in all previous tests on zinc sheet, the industrial atmospheres appeared to be the most harmful. The differences between the rural and the mild indoor atmospheres were relatively minor. In the summary of the original publication, the data for all locations were averaged, and no distinction was made between the atmospheres.

Table 6 demonstrates that a rather large decrease in the impact strength of both alloys occurred in the interval between the 10- and 20-year exposures in the industrial atmospheres. This also occurred for alloy AC41A exposed to the indoor atmospheres. Such decreases in mechanical properties are probably caused by intergranular corrosion, to which die casting alloys are often very susceptible. Intergranular attack can reduce cross-sectional areas and create stress-raising notches, but it does not reduce the overall specimen dimensions significantly.

Effect of Alloying Additions

Hot-dip galvanized zinc coatings seldom consists of high-purity zinc. Lead is often added to the plating bath to produce a smoother finish, and aluminum is included to reduce the thickness of the iron-zinc diffusion zone. Numerous other elements may be present in the bath as additions or impurities.

Improved coating performance over normal galvanized zinc coatings has been realized with Zn-55Al-1.5Si compositions. Also Zn-5Al containing 0.05% mischmetal has proved effective.

Electrodeposited coatings may also contain impurities, which originate in the plating solution. Die casting alloys often include several percent each of aluminum and copper as strengtheners. These alloying elements, whether added deliberately or not, can have a considerable effect on the corrosion of the resulting zinc-base alloys. Composition specifications for slab zinc, rolled zinc, and zinc-base die castings are given in Tables 7, 8, and 9, respectively.

Table 7 ASTM composition specifications for slab zinc

(a) Maximum composition.

The mechanisms behind the effects of various alloying elements on zinc corrosion are complex and not completely understood. In some cases, the alloying elements may become concentrated in the coating surface as zinc dissolves away, leaving behind a more corrosion-resistant coating. Alloying elements may affect the corrosion sales and their corresponding electronic and diffusion properties, as is known to happen during oxidation of several metals at very high temperature. Most of the recent literature, however, points toward the effects of alloying elements on the intergranular corrosion of zinc. Although general surface corrosion and intergranular attack both contribute to coating performance, severe intergranular corrosion can clearly lead to the deterioration of thin zinc coatings during weathering. Intergranular attacks creates sites for pitting corrosion and opens pathways for the environment to reach the substrate.

Several elements have various effects on the corrosion resistance of galvanized coatings. The effects of aluminum, lead, copper, magnesium and other elements are discussed below.

Aluminum. Small additions of aluminum decrease the corrosion resistance of zinc, especially if lead is also present. The maximum decrease occurs at 0.3% Al (in an alloy containing 0.2% Pb). Aluminum appears to increase intergranular attack in zinc alloys. Large amounts of aluminum (5 and 55%) improve the performance of the coating.

Lead by itself is not particularly harmful. However, in conjunction with any concentration of aluminum, it appears to accelerate corrosion.

Copper improves atmospheric-corrosion resistance and retards intergranular attack. This effect may be only temporary and may not make any significant difference in long-term corrosion.

Magnesium improves the corrosion resistance of zinc somewhat. It is especially useful for counteracting the adverse effects of aluminum. Again, this effect may be only temporary.

Other Alloying Additions. Small amounts of chromium, nickel, or titanium may be beneficial to the corrosion resistance of zinc.

Corrosion of Zinc in Water

The corrosion of zinc in water is largely controlled by the impurities present in the water. Naturally occurring waters are seldom pure. Even rainwater, which is distilled by nature, contains nitrogen, oxygen, CO_2, and other gases, as well as entrained dust and smoke particles. Water that runs over the ground carries with it eroded soil, decaying vegetation, living microorganisms, dissolved salts, and colloidal and suspended matter. Water that seeps through soil contains dissolved CO_2 and becomes acidic. Groundwater also contains salts of calcium, magnesium, iron, and manganese. Seawater contains many of these salts in addition to its high NaCl content.

All of these foreign substances in natural waters affect the structure and composition of the resulting films and corrosion products on the surface, which in turn control the corrosion of zinc. In addition to these substances, such factors as pH, time of exposure, temperature, motion, and fluid agitation influence the aqueous corrosion of zinc.

As in the atmosphere, the corrosion resistance of a zinc coating in water depends on its initial ability to form a protective layer by reacting with the environment. In distilled water, which cannot form a protective scale to reduce the access of oxygen to the zinc surface, the attack is more severe than in most types of domestic in river water, which do contain some scale-forming salts.

The scale-forming ability of water depends principally on three factors: the hydrogen ion concentration (pH value), the total calcium content, and the total alkalinity. If the pH value is below that at which the water would be in equilibrium with calcium carbonate ($CaCo_3$), the water will tend to dissolve rather than to deposit scale. Waters with a high content of free CO_2 also tend to be aggressive toward zinc.

Water hardness is an important variable in zinc corrosion. The corrosion rate of zinc in hard water may be 15 μm/yr (0.6 mil/yr), but in soft water, it can be 150 μm/yr (6 mils/yr). Hard waters are usually less corrosive toward zinc because they deposit protective scales on the metallic surface, but softer waters would not deposit these scales. Similarly, seawater also deposits protective scales on zinc and is less corrosive that soft water.

Softer waters, with their higher content of dissolved oxygen and CO_2, generally attack zinc more vigorously than the fairly hard waters. River waters have been found to deposit scale more easily than well waters. The normal corrosion product on zinc in water is $ZnCo_3$.

Corrosion of Zinc by Distilled Water

Agitation, Aeration, and Co_2. Under conditions in which the oxygen content cannot be replaced as quickly as it is consumed by the corrosion process, such as in stagnant water, zinc is attacked rapidly at local areas, and this causes pitting. As more oxygen is made available, the corrosion becomes more uniform. With further increases in the oxygen content of the water, the corrosion rate increases. For example, when thin films of moisture condense on a zinc surface, the concurrent rapid supply of oxygen at the corroding surface has a decided accelerating effect on the corrosion rate.

Both this and the stagnant-water types of attack can be minimized by the use of chromate films. Experimentation has shown that with testpieces immersed in water though which oxygen was bubbled, corrosion occurred about eight times as fast as with specimens in water that was boiled to remove gases and then cooled out of contact with air. Effects of concentration of dissolved oxygen and temperature on corrosion in distilled water are shown in Table 10. Although the corrosion rate increased when oxygen was bubbled through the water, the attack was uniform. The presence of oxygen in the water accelerates the corrosion by depolarization of the cathodic areas. The rate of corrosion is then controlled by diffusion oxygen through the film of $Zn(OH)_2$ corrosion products.

Table 10 Effect of oxygen on the corrosion of zinc in distilled water

Test condition	Temperature		Corrosion rate[(a)]	
	°C	**°F**	**mg/dm^2/d**	**mils/yr**
Boiled distilled water; specimens immersed in sealed flasks	Room	Room	5.0	1.0
Boiled distilled water; specimens immersed in sealed flasks	40	104	9.4	1.9
Boiled distilled water; specimens immersed in sealed flasks	65	149	16.5	3.3
Oxygen bubbled slowly through the water	Room	Room	43.0	8.6
Oxygen bubbled slowly through the water	40	104	68.6	13.7
Oxygen bubbled slowly through the water	65	149	62.0	12.4

(a) High-grade zinc specimens, in duplicate, immersed for 7 days. The corrosion rate was calculated after removal of corrosion products.

Temperature. In practical applications, the temperature of the water has been shown to be a vert important factor affecting the rate of corrosion of zinc in water. In one study, a marked increase in corrosion rate was found to occur at a temperature of about 60 °C (140 °F), followed by a decrease in corrosion at higher temperature (Ref 8). At temperatures near 70 °C (160 °F), a reversal in potential may occur where zinc coatings become cathodic to iron. Low oxygen and high

bicarbonate contents favor reversal, but the presence of oxygen, sulfates, and chlorates tends to maintain the natural anodic state of the zinc.

The results of this study were obtained on 99.9% pure zinc immersed for 15 days in aerated distilled water and rotated at 56 rpm. The water was continuously aerated by air bubbling through it, and no attempt was made to remove CO_2 from the air. Also, the specimens were supported on a wooden disk that was rotated through the test water at 56 rpm. Thus, all of the factors that cause increased corrosion as discussed above were present in these tests. The temperature, however, seems to have been the controlling factor in this experiment.

Table 11 lists metal loss and penetration and describes the appearance of corrosion products on the zinc surfaces. There was a direct relationship between the character of the corrosion film and the extent of corrosion. At the temperatures of maximum corrosion, the film is granular and nonadherent, but at the lower temperatures, it is gelatinous and adherent. At higher temperatures, it is compact and adherent. From this it might be concluded that the granular coating is more permeable to oxygen, which would account for the increased corrosion.

Table 11 Effect of temperature on the corrosion of zinc in distilled water

Rolled high-grade zinc immersed for 15 days in water aerated by air bubbles

Temperature		Corrosion rate		Appearance of corrosion film
°C	**°F**	**mg/dm^2/d**	**mils/yr**	
20	68	3.9	0.78	Gelatinous, very adherent
50	122	13.7	2.74	Less gelatinous, adherent
55	131	76.2	15.2	Mostly granular, nonadherent
65	149	577.0	115.4	Granular to flaky, nonadherent
75	167	460.0	92.0	Granular, flaky, nonadherent
95	203	58.7	11.7	Compact, dense, nonadherent
100	212	23.5	4.7	Very dense and adherent

Tests showed that the observed corrosion peak at approximately 65 °C (150 °F) occurs both in waters under a pure oxygen atmosphere and under a CO_2-free air atmosphere (Fig. 3). In contrast, under an oxygen-free nitrogen atmosphere, the peak disappears completely. Additional experiments showed that as the partial pressure of oxygen over the water was reduced from that in air the peak decreased in magnitude and shifted to lower temperatures that involve the decreased solubility of oxygen in water at elevated temperature. This theory holds that the corrosion of zinc proceeds by the reaction:

$$Zn + 2H_2O \rightarrow Zn(OH)_2 + H_2 \qquad \textbf{(Eq 3)}$$

Oxygen, when present, depolarizes and accelerates the reaction by combining with the evolved hydrogen:

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O \qquad \textbf{(Eq 4)}$$

As the temperature increases, the reaction rate initially increases; but the increasing temperature decreases the O_2 supply, and the depolarizing effect of the oxygen is decreased. Thus, at elevated temperature, the reaction polarizes and its rate slows. The stable film at elevated temperature is ZnO, not $Zn(OH)_2$. If ZnO is formed from $Zn(OH)_2$ by this reaction:

$$Zn(OH)_2 \rightarrow ZnO + H_2O \qquad \textbf{(Eq 5)}$$

then the process is still limited by the rate of $Zn(OH)_2$ formation, which is limited by the rate of Eq 3 and 4, which depend on the oxygen supply.

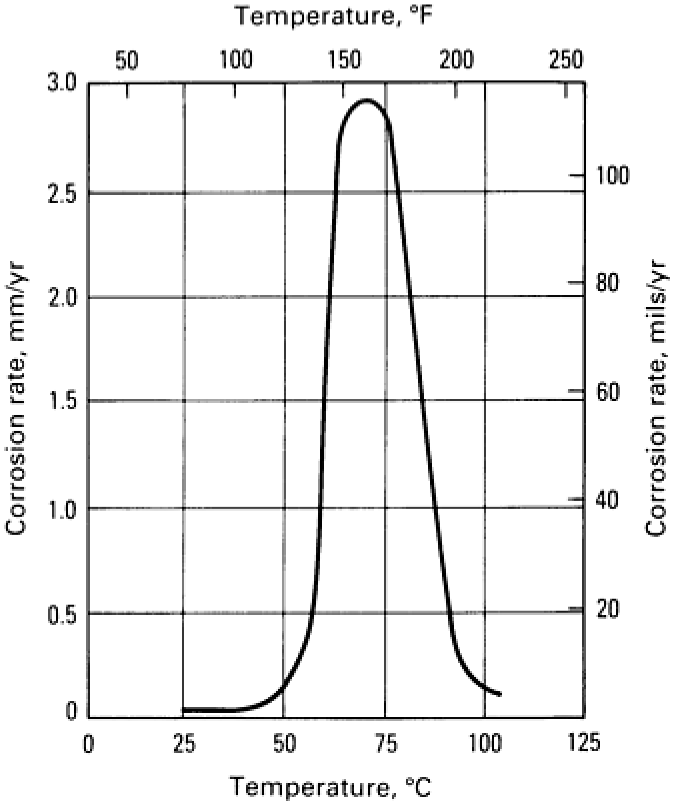

Fig. 3 Effect of temperature on corrosion of zinc in distilled water. Source: Ref 9

This is consistent with the observation that decreased oxygen supplies (caused by reduced oxygen pressure over the water) lower the corrosion peak temperature (Ref 10). As the oxygen partial pressure is lowered, the equilibrium oxygen content in the water is lowered for any temperature. The reduced oxygen content of the water thus lowers the temperature at which depolarization (Eq 5) becomes rate limiting, because the critical oxygen level for depolarization is reached at a lower temperature.

Corrosion Inhibitors

When zinc is used in contact with water in a closed system, inhibitors are frequently employed to minimize corrosion. Various inorganic inhibitors are available for use with zinc, such as sodium dichromate, sodium silicate, borax, and hexametaphosphate. Mechanical exclusion films provided by adsorptive-type organic compounds, such as lanolin, are also useful for the corrosion inhibition of zinc. For most purposes, the adjustment of the pH to the mildly alkaline range and the addition of sodium dichromate are preferred.

There is some danger of intensified pitting when too little of this type of inhibitor is added. If zinc-coated parts are stored for significant periods of time under conditions in which moisture may be entrapped between closely adjacent surfaces, the part may become defaced by the appearance of a whitish reaction product powder on the surface. This is known as

wet-storage stain. Although it affects appearance, this product is generally not harmful to the zinc coating. Unchecked, wet-storage stain can shorten the service life before the underlying ferrous metal rusts.

To avoid the occurrence of wet-storage stain, it is essential to store zinc-coated material under conditions of free circulation of air and to avoid the large periodic temperature change that causes condensation of moisture on the metal. The reaction causing this white staining does not occur in the normal use of zinc-coated products once they have aged at the surface, but new parts must be stored carefully to avoid this problem.

Corrosion of Zinc in Domestic Waters

Cold Water. Galvanized pipe is widely used in handling domestic water supplies, and the results have been satisfactory. Therefore, quantitative corrosion rates are not of primary interest, and very few data are found in the literature. Hard waters contain dissolved salts that may affect the corrosion of zinc. Carbonates and bicarbonates tend to deposit protective films that stifle corrosion, and it is generally agreed that soft or distilled waters are more corrosive than hard water. For example, the corrosion rates of two grades of zinc in distilled and tap water of moderate hardness are given in Table 12.

Table 12 Corrosion of zinc in distilled water and tap water

Alloy	Corrosion rate			
	Distilled water		**Tap water**	
	mg/dm^2/d	**mils/yr**	**mg/dm^2/d**	**mils/yr**
High-purity grade	27	5.4	3.5	0.7

Hot Water. In domestic water systems, for which zinc is widely adopted as a protective coating, the sacrificial dissolution of zinc at discontinuities in the coating in the presence of calcium bicarbonate (a normal constituent of hard water supplies) leads to the deposition of an insoluble layer of $CaCO_3$ on the exposed surfaces. Because this layer is impervious to the passage of ions and electrons, it inhibits any further corrosive action. This reaction, which depends on the presence of dissolved calcium bicarbonate in the water, cannot occur in systems in soft water areas, and it is generally agreed that soft or distilled water is more corrosive than hard water. Other constituents in natural waters, such as nitrates, sulfates, and chlorides, may tend to increase corrosion, but their effect is usually overcome by the carbonates that form films of relatively low solubility in close contact with the zinc surface.

Changing the temperature of a solution can influence the corrosion tendency. For example, historically, household water heater tanks were made of galvanized steel. The zinc coating on the carbon steel base offered some cathodic protection to the underlying steel, and the service life (usually judged by how long it took to produce red, or rusty, water) was considered to be adequate. Water tanks were seldom operated above 60 °C (140 °F).

With the development of automatic dishwashers and automatic laundry equipment, the average water temperature was increased so that temperatures of approximately 80 °C (175 °F) are not unusual in household hot-water tanks. Coinciding with the widespread use of automatic dishwashers and laundry equipment was a sudden upsurge of complaints about the short service lives of galvanized steel water heater tanks. Electrochemical measurements showed that in many cases iron was anodic to zinc at 77 °C (170 °F), but zinc was anodic to iron at temperatures below 60 °C (140 °F). This explained why zinc offered no cathodic protection at 77 °C (170 °F) and why red water and premature perforation of galvanized water tanks had occurred. The problem was reduced by the use of magnesium anodes and protective coatings as well as the development of new alloys.

In 1974, the International Lead Zinc Research Organization (ILZRO) patented a method for protecting galvanized steel used in fabricating domestic hot-water systems, electric water heaters and distribution piping (Ref 11). This method is

based on the formation of a passivating coat of zinc pyrophosphate ($Zn_2P_2O_7$), which is partly formed at the expense of the zinc coating. This compound is insoluble and a good electrical insulator because of its covalent property. It prevents the formation of electrochemical cells and thus prevents attack on the zinc coating. The $Zn_2P_2O_7$ coating can be applied by a chemical or an electrochemical method, depending on the application.

Corrosion of Zinc in Natural Water and Seawater

The factors influencing the corrosion of zinc by tap or supply waters discussed in the preceding section also apply to natural waters, such as lake or river waters. Few data have been reported on the corrosion rate of zinc in natural freshwaters. In the case of seawater, however, dissolved salts, principally chlorides and sulfates, determine the corrosion behavior of zinc. The high chloride content of seawater would normally tend to increase corrosion, but the presence of magnesium and calcium ions inhibits the attack. The effect of time of exposure on the corrosion rate in natural waters indicates that the corrosion rate in seawater initially exceeds that in freshwater, but after about 2 years of exposure, the rate in seawater decreases so that it is approximately the same as that in freshwater.

The frequency with which seaside piers and ship hulls require repainting testifies to the corrosivity of seawater and the importance of taking adequate protective measures. The salts present in the North Sea amount to about 3.5% of the total, mainly NaCl with smaller amounts of magnesium and calcium salts. This produces a solution with a pH of about 8.

The corrosion resistance of zinc compares very favorably with that of other coating materials when totally immersed in seawater, possibly because of the slightly inhibitive action of the magnesium salts present. In tests, aluminum-, cadmium-, lead-, tin-, and zinc-coated specimens were immersed for 2 years. All except the zinc-coated specimens failed in this time. The zinc-coated specimens were then transferred to another test site and immersed for another 4 years. At the end of this time--a total of 6 years--the 3-oz/ft^2 (915-g/m^2) coatings were just ceasing to give complete protection to the basis steel. Therefore, it was concluded that the consumption of zinc is approximately 0.5 oz/ft^2 (150 g/m^2) of steel surface protected per year.

In most cases, zinc coatings would not be used alone when applied to steel immersed in seawater, but would form the first layer of a more elaborate protective system. Conditions within a few hundred yards of the surf line on beaches are intermediate between total immersion in seawater and normal exposure to a marine atmosphere. Such conditions have been studied in a series of tests carried out at Lighthouse Beach in Nigeria. At the high-water mark, about 45 m (50 yd) from the surf line on the tropical beach, conditions were extremely severe, and iron and zinc both corroded more rapidly than if they had actually been immersed in the sea.

Upon moving inland, however, it was found that both the salt content of the atmosphere and the rates of corrosion of iron and zinc fell off very rapidly. The values obtained only 1 km ($\frac{3}{4}$ mile) from the sea were similar to those obtained at inland sites.

Corrosion Resistance of Zinc in Soils

Galvanized pipe is frequently used to provide underground water service for farms, hot houses, and so on. Inspection of the plain galvanized pipe used in culverts and in storm drains will show a long service life and durability that is often surprising to the engineer unfamiliar with such structures. Pipe with only a galvanized coating can often be used to handle runoffs from rainstorms for more years than the facility above the pipe will be used.

More than 200 soil series have been categorized in the United States according to texture, color, and natural drainage. The physical properties of importance in corrosion are those that determine the permeability of the soil to air and water. Soils with a coarse texture, such as sands and gravels, permit free circulation of air. The corrosion under such conditions approaches that occurring in the atmosphere. Clay and silt soils are generally characterized by a fine texture and high water-holding capacity, resulting in poor aeration and drainage. The aeration characteristics of a soil depend on particle size and distribution and on the apparent specific gravity. The latter is a measure of the compactness of the soil.

Numerous chemical elements are present in soils, but the ones of interest in corrosion studies are those that are soluble in water. Analyses are usually made for base-forming elements, such as sodium, potassium, calcium, and magnesium, and for the acid-forming groups, such as carbonate, bicarbonate, chloride, nitrate, and sulfate.

However, corrosion engineers have determined that the best measure of the potential corrosivity of a given soil is its electrical resistance measured in ohms per cubic centimeter. The electrical resistivity of the soils is determined by the nature and concentration of the ions formed by the chemical salts dissolved in the soil moisture. These ions may also determine the progress of corrosion. If the primary product of corrosion is relatively insoluble and deposits as a film on the metal surface, further corrosion may be reduced or completely stifled. Numerous inspections of existing structures have established that in sandy and loamy soils with resistivity of 4500 Ω· cm and higher the engineer need not be concerned with the corrosion on the soil side of galvanized steel pipe (Table 13).

Table 13 Relationship of soil corrosion to electrical resistivity

Soil Class	Corrosion resistance	Electrical resistivity, Ω·cm
Sandy	Excellent	6000-10,000
Loams	Good	4500-6000
Clays	Fair	2000-4500
Peat/muck	Bad	0-2000

When the engineer wishes to confirm his judgment of service life requirements or when the corrosion and abrasion aspects of the proposed site may be in question, reference to the California Division of Highways method for determining service life is recommended. This comprehensive method uses measurable environmental corrosion criteria and is applicable to all parts of the country. The California method correlates pH with the electrical resistivity of soils to determine the number of years necessary to perforate a galvanized steel sheet. For example, an engineer considering a typical site environment with a resistivity of 10,000 Ω· cm and pH of 7 can refer to Fig. 4 and determine that it would take 40 years to perforate 16-gage (~1.5-mm, or 0.06-in.) galvanized steel pipe.

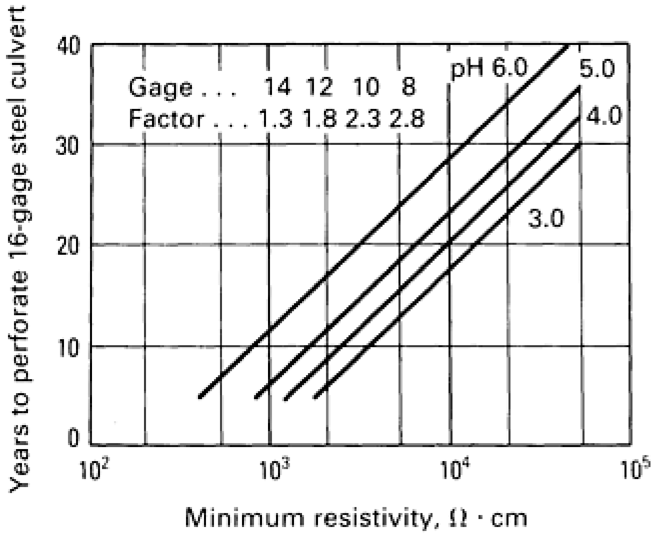

Fig. 4 Method of estimating service life as developed by the California Division of Highways. This correlates pH with the electrical resistivity of soils to determine years to perforate a steel sheet. Local durability records are used for confirmation or control. Multiply years to perforation by factor for increase in metal gage. This figure is based on 16-gage galvanized steel pipe with a coating thickness of 1.6 mm (0.064 in.). Source: Ref 12

The engineer can determine the years to perforation for other gages of pipe by using the appropriate multiplying factor. For example, years to perforation for 8-gage (~4.2-mm, or 0.16-in.) pipe would be 40 times 2.8, or 112 years. Moreover, perforations resulting from the pitting action of galvanic cells will not affect the useful service of a storm drainage structure, as compared to a pressure conduit from which a valuable or dangerous product would be lost. With proper maintenance, the life of corrugated steel pipe can be extended indefinitely.

Except in the most corrosive soils, the maximum depth of pitting in steel specimens exposed for approximately $12\frac{1}{2}$ years was more than 11 times that in zinc specimens, although the ratio for the rates of corrosion was only approximately one-half that figure (Ref 13). This resistance to pitting, combined with the fact that rusting does not appear to start until nearly all of the zinc and zinc-alloy layers have corroded away, reduces the risk of premature failure in galvanized piping. It cannot be overemphasized that, although these results serve as a useful guide to the performance of zinc coatings in particular soils, local experience should always be sought.

The Corrosion of Zinc in Chemical Environments

As indicated previously, the use of zinc for corrosion-resistant applications accounts for about one-half of the total consumption of the metal. However, the available information reveals that in most applications the resistance of zinc to the atmosphere and in various waters is the primary corrosion criterion. In one sense, these may be considered chemical environments, because the chemical reactions between zinc and the constituents of pure or polluted atmospheres and waters determine the life of the zinc exposed to air or water.

Zinc is usually not considered to be a useful metal in the acidic or strongly alkaline chemical environments encountered, for example, in the chemical-processing industries (see the article "Corrosion in the Chemical Processing Industry" in this Volume). The corrosion of zinc increases in aqueous chemical solutions on either side of the 6 to 12 pH range. This should not be considered a fixed rule, because many other factors, such as agitation, aeration, temperature, polarization, and, in some cases, the presence of inhibitors, may have considerable influence on the corrosion.

There is considerable interest in the use of zinc in milder chemical environments. For example, zinc in used in contact with many organic chemical and chemical specialties, such as detergents, insecticides, and agricultural chemicals. In most cases, zinc comes in contact with such chemicals during the handling, packaging, and storage of the commercial products.

The corrosion resistance of zinc to the chemicals is usually the primary consideration, but in some cases, the effect of zinc corrosion on a consumer product or chemical is of greater concern than the actual corrosion rate of zinc. For example, zinc in contact with certain organic chemicals may in rare cases cause polymerization or catalyze some other undesirable change that would alter the original composition of properties of the product. In other cases, some change in the appearance or texture of a consumer product may be caused by the relatively slight corrosion of zinc. Thus, zinc would be considered incompatible, although it does not corrode excessively.

There are many situations in the chemical industry in which zinc serves a useful purpose. Zinc-coated tanks and cylinder are widely used in oil refineries and other plants for storing oil and petroleum products, chlorine, CO_2, and other industrial gases (see the articles "Corrosion in Petroleum Production Operations" and "Corrosion in Petroleum Refining and Petrochemical Operations" in this Volume). Refrigerating plants and cooling equipment, as well as degreasing plants, are almost universally protected by zinc coatings. Zinc-coated steel is also used on structural steelwork around chemical plants, where it is exposed to high humidity and a variety of chemical fumes. Galvanized steel is extensively used for roofing and siding on pulp and paper processing buildings (see the article "Corrosion in the Pulp and Paper Industry" in this Volume).

Other uses of zinc-coated steel in the chemical industry include applications in floating roof type storage tanks for volatile liquids as well as galvanized wire cloth and mesh belts for the movement of chemicals through various production stages. Galvanized steel containers are used to store strategic chemicals in outdoor locations. From these representative examples it is apparent that zinc and zinc-coated steel are definitely useful in the chemical industry.

Corrosion in Dissolved Salts, Acids, and Bases

Zinc is not used in contact with acid and strong alkaline solutions, because it corrodes rapidly in such media. The section "Corrosion of Zinc in Water" in this article indicates the safe range in which it may be used.

Very dilute concentrations of acids accelerate corrosion rates beyond the limits of usefulness. Alkaline solutions of moderate strength are much less corrosive than corresponding concentrations of acid, but are still corrosive enough to impair the usefulness of zinc.

Zinc-coated steel is used handling refrigeration brines that may contain calcium chloride ($CaCl_2$). In this case, the corrosion rate is kept under control by adding sufficient alkali to bring the pH into the mildly alkaline range and by the addition of inhibitors, such as sodium chromate (Na_2CrO_4). Certain salts, such as the dichromates, borates, and silicates, act as inhibitors to the aqueous corrosion of zinc.

Nonaqueous Corrosion

Organic Compounds. Many organic liquids that are nearly neutral in pH and substantially free from water do not attack zinc. Therefore, zinc and zinc-coated products are commonly used with gasoline, glycerine, and inhibited trichlorethylene. The presence of free water may cause local corrosion because of the lack of access to oxygen. When water is present, zinc may function as a catalyst in the decomposition of such solutions as trichlorethylene, with acid attack as the result. Some organic compounds that contain acidic impurities, such as low-grade glycerine, attack zinc. Although neutral soaps do not attack zinc, there may be some formation of zinc soaps in dilute soap solutions.

Gases. Zinc may be safely used in contact with most common gases at normal temperatures if water is absent. Moisture content stimulates attack. Dry chlorine does not affect zinc. Hydrogen sulfide (H_2S) is also harmless because insoluble zinc sulfide (ZnS) is formed. On the other hand, SO_2 and chlorides have a corrosive action because water-soluble and hygroscopic salts are formed.

Indoor Exposure. Zinc corrodes very little in ordinary indoor atmospheres of moderate relative humidity. In general, a tarnish film begins to form at spots where dust particles are present on the surface; the film then develops slowly. This attack may be a function of the percentage of relative humidity at which the particles absorb moisture from the air. However, moisture has little effect on the tarnish formation up to 70% relative humidity. The degree of corrosion is related to the relative humidity at and above this point because the zinc corrosion products absorb enough moisture or stimulate the attack to a perceptible rate.

Rapid corrosion can occur where the temperature decreases and where visible moisture that condenses on the metal dries slowly. This is related to the ease with which such thin moisture films maintain a high oxygen content because of the small volume of water and large water/air interface area. Considerably accelerated corrosion can then take place with the formation of a film that is too thick. Chromate protective films are used to a considerable extent to prevent attack where accidental or limited contact with water is expected. Atmospheres inside industrial buildings can be corrosive, particularly where heated moisture and gases, such as SO_2, condense near a cool room.

Contact With Food Products. Zinc should not be used in contact with acidic foodstuffs unless they can be expected to remain dry. Otherwise, the zinc must be adequately protected by copper-nickel-chromium plating or another satisfactory impervious coating. The slight acidity present in many foodstuffs can attack the zinc, and this may give the food a metallic taste. For the same reason, the zinc die casting used in any equipment to hold or dispense drinks should also be plated or otherwise protected. Consumption of food contaminated with zinc may cause nausea but is not dangerous, and this rarely arises because of the taste. A summary of the compatibility of untreated zinc with various media is presented in Table 14.

Table 14 Compatibility of untreated zinc with various media

Medium	Media descriptor	Compatibility
Aerosol propellants	. . .	Excellent
Acid solutions	Weak, cold, quiescent	Fair
	Strong	Not recommended
Alcohols	Anhydrous	Good
	Water mixtures	Not recommended
	Beverages	Not recommended
Alkaline solutions	Up to pH 12.5	Fair
	Strong	Not recommended
Carbon tetrachloride	. . .	Excellent
Cleaning solvents	Chlorofluorocarbon	Excellent
Detergents	Inhibited	Good
Diesel oil	Sulfur free	Excellent
Fuel oil	Sulfur free	Excellent
Gas[(a)]	Towns, natural, propane, butane	Excellent
Glycerine	. . .	Excellent
Inks	Printing	Excellent
	Aqueous writing	Not recommended
Insecticides	Dry	Excellent
	In solution	Not recommended

Lubricants	Mineral, acid free	Excellent
	Organic	Not recommended
Paraffin	. . .	Excellent
Perchlorethylene	. . .	Excellent
Petroleum[(a)]	. . .	Excellent
Refrigerants	Chlorofluorocarbon	Excellent
Soaps	. . .	Good
Trichloroethylene	. . .	Excellent

(a) Chromate passivation treatment recommended because of the possible presence of moisture traces.

Stress-Corrosion Cracking and Corrosion Fatigue

Stress-Corrosion Cracking (SCC). The effects of corrosion and stress on the performance of a material are often treated as separate concerns. However, in conjunction, the two can cause the phenomenon of SCC, which can destroy a metallic component faster than either stress or corrosion separately. In essence, SCC is a process in which cracks in the metal grow under the combined effects of tensile stress and a corrosive environment. When the cracks become sufficiently large, the component fractures. Often, but not always, the stress-corrosion resistance of an alloy is very dependent on its microstructure. Information on the mechanisms of SCC is provided in the article "Environmentally Induced Cracking" in this Volume. Testing and interpretation of SCC data can be found in the article "Evaluation of Stress-Corrosion Cracking" in this Volume.

Corrosion Fatigue. When metal is subjected to vibration or cyclic stress, fatigue strength is more important than ultimate tensile strength. Under corrosive conditions, even the advantages of alloy additions and heat treatments that considerably increase the tensile strength and fatigue limit of steel have only a minor effect on corrosion fatigue behavior. Corrosion fatigue is the weakening that occurs in a metal after it has been stressed repeatedly in the presence of corrosive agents. Generally, the corrosion fatigue characteristics of low-alloy steels are little or no better than those of ordinary low-carbon steel unless the metal has a protective coating.

The plastic deformation that occurs in the metal at the bottom of a crack during repeated stressing raises its energy and thus increases its susceptibility to chemical attack. The strengthened material that would otherwise prevent the cracks from spreading is therefore destroyed by corrosion in preference to the surrounding metal, and the crack continues to grow. This process continues by further plastic deformation of metal, which is in turn destroyed.

In addition to this basic mechanism of corrosion fatigue, certain subsidiary effects also play a part. For example, the strains occurring in the surface of the stressed metal tend to disrupt such protective films as would otherwise be formed by the corrosion products, with the damage to the protective film often taking the form of small cracks or crevices. The small areas of metal exposed by these cracks are anodic to the surrounding film and corrode at an accelerated rate with the formation of pits; this sets the mechanism of corrosion fatigue in motion. The total amount of corrosion involved in corrosion fatigue is often extremely small. It is important to prevent corrosion from the start because once it has begun cyclic stressing may lead to early failure even though further attack is prevented.

These facts clearly point to the necessity of sacrificial, electrochemical protection as a means of preventing corrosion fatigue. Steel components can be protected throughout their life by a sacrificial zinc coating to give them complete protection. If a coating with no sacrificial properties is used, a surface fault may well lead to fatal pitting.

Steel and Corrosion Fatigue. Detailed investigations into the corrosion fatigue resistance of steels in moist air and saline solutions have give some surprising results. The ultimate tensile strength and indeed the pure fatigue limits of steels are increased considerably by alloying or special heat treatments, but these have only a minor effect on corrosion fatigue behavior.

Thus, under practical conditions the behavior of a special steel may be little better than that of ordinary carbon steel unless it has a protective zinc coating. These are significant considerations in determining what preventive measures to adopt in practice, and that explain why sacrificial or electrochemical protection is of major importance. Because corrosion fatigue cracks may be difficult to detect until they have reached dangerous proportions, a practical safeguard is to protect steel components throughout their service lives by a sacrificial coating of zinc, which gives them complete cathodic protection. When zinc coatings are used, small to medium-sized imperfections in the coating are of relatively little importance, and corrosion is prevented even at the growing points of the microscopically small crevices that cause corrosion fatigue.

Any type of coating that covers the surface completely and retards the onset of corrosion may help, but if it is not anodic to steel, it cannot exert cathodic protection at coating defects. In many general uses, the fact that nonanodic coatings cannot prevent corrosion at small defects may be unimportant. When fatigue failure is not a consideration, a very small amount of corrosion has no significant effect.

Wherever corrosion fatigue can occur, however, the situation is very different. Coatings that cannot protect sacrificially may, as a result of discontinues, cause serious pitting, and trouble may be accentuated by concentrating the corrosion in small areas, thus stimulating the growth of fatigue cracks. Additional information on corrosion fatigue can be found in the articles "Mechanically Assisted Degradation" and "Evaluation of Corrosion Fatigue" in this Volume.

Corrosion Protection With Zinc Anodes

Historical Development of Cathodic Protection. Historically, zinc was one of the very first metal to be used as a galvanic anode; early in the 19th century, Sir Humphrey Davy secured pieces of zinc to the copper sheathing on wood hulls of British Navy vessels to prevent severe underwater corrosion of the copper. The latter was used as a barrier shield to stop penetration and destruction of the wood hulls by marine borers and to prevent attachment of barnacles to hulls.

Sir Humphrey thus became the first practitioner of cathodic protection and is credited with developing the concept of the electrochemical series of the elements. He concluded from actual sea trials aboard ship that corrosion of the copper sheathing could be arrested by using zinc protectors, but the fouling problems by marine organisms were not entirely resolved. Further experiments demonstrated that by varying the area of the protector metal in relation to the copper the latter would corrode at a low, tolerable rate that was insufficient to cause perforation but adequate to exhibit antifouling characteristics. The electrolytic protection of metals from corrosion in a bulk electrolyte, as demonstrated by Sir Humphrey, has developed into a universally accepted method of corrosion control known as cathodic protection.

Cathodic Protection Systems. In practice, cathodic protection is applied to potentially corrodible metals underground or underwater by galvanic anodes (self-generated current) or power-impressed systems. Galvanic anode systems do not require an external source of current, because the protective current is self-generated when the galvanic anode is electrically connected to the structure to be protected in a bulk electrolyte.

The most commonly used power-impressed systems employ anodes with low anodic corrosion rates that are electrically connected to a rectifier that converts alternating current (ac) to direct current (dc). The negative terminal of the rectifier is grounded to the structure to be cathodically protected, and the positive terminal is connected to the relatively inert anodes. When the system is activated, current flows from the rectifier to the anodes, through the electrolyte to the structure (cathode) to be protected, and back to the rectifier through the return path. The anodes commonly used in impressed-current systems include, but are not limited to, high-silicon cast iron, graphite, platinized titanium, and lead-silver alloys (seawater only). The cathode, or structure to be protected, does not recognize the source of protective current, because it is possible to polarize most structures by using galvanic anodes or impressed-current systems.

Other power sources used in impressed-current systems include, but are not limited to, the following: engine generator sets, wind-powered generators, thermoelectric generators, gas turbines, solar cells and fuel cells. Although the sources of power for supplying protective current in cathodic protection systems are numerous, zinc is the one that is most frequently used; therefore, the rest of this section will discuss the details relating to the function of zinc as a galvanic anode.

Applications of Zinc Anodes. The use of zinc in commercial cathodic protection systems involves environments as diverse as seawater, brackish water, freshwater, and a wide variety of soils. Because the environment plays a significant role in determining the success or failure of zinc galvanic anode systems, seawater and soils will be treated separately.

The application of cathodic protection to reduce or prevent corrosion damage occurring on the steels hulls of marine craft, such as ships, launches, barges, floating docks, buoys, and pontoons, makes it possible to increase substantially the interval between dry dockings and to reduce the amount of maintenance work to be accomplished during each dry docking period. The material and labor costs of installing a zinc anode cathodic protection system are usually small compared to such maintenance work as chipping, painting, and replacing hull plates.

The economic benefits that accrue from marine cathodic protection depend to a large extent on the duty cycle of the craft under consideration. Maximum savings are obtained when cathodic protection is applied to vessels that are dry-docked only for reasons of anticorrosion maintenance. Included in this category would be most barges, dredges, buoys, pontoons, and stored ships. It is not unusual under these conditions for a cathodic protection system, designed for a 3-year life, to pay for itself within 1 year. Even in the case of merchant ships, which must be dry-docked annually for removal of marine growths and reapplication of antifouling paint, cathodic protection, if properly applied, can prove economical because it reduces or eliminates corrosion damage to exposed steel propeller shafts and to areas on the hull where the paint has become damaged.

Zinc is an ideal metal for cathodic protection in seawater because it does not subject the adjacent painted surfaces of the hull to high potentials, which are injurious to many commonly used paints. Nevertheless, good marine paints, application practice, and reasonable maintenance are of course necessary. Zinc has a high ampere-hour capability per unit volume (530 $A \cdot yr/m^3$, or 15 $A \cdot yr/ft^3$). This means that the total volume of zinc required is not large; therefore, the effect of the installation on the speed of the ship is generally very small if the anodes are correctly installed. The installation of zinc anodes on marine craft is straightforward, particularly if it is accomplished when the vessel is in dry dock.

Table 15 lists the chemical composition and impurity limits of the current United States Government (MIL-A-18001H) and ASTM (B 418) zinc anode specifications. The basic zinc anode specification containing aluminum and cadmium as alloying elements has become the worldwide standard for zinc anodes used in cathodic protection systems in seawater and brackish water at ambient temperatures. Committee B-2 of ASTM cautioned that the threshold level for intergranular corrosion of type I composition zinc-aluminum-cadmium alloy is particularly severe above a temperature of about 50 °C (120 °F). For additional information on anode selection, see the articles "Marine Corrosion," "Corrosion of Magnesium and Magnesium Alloys," "Corrosion of Aluminum and Aluminum Alloys," and "Cathodic Protection" in this Volume.

Table 15 Zinc anode composition specifications for seawater use

Element	MIL-A-18001H composition, %	ASTM B 418 Type 1 composition, %
Aluminum	0.10-0.50	0.10-0.4
Cadmium	0.025-0.15	0.03-0.10
Iron[(a)]	0.005	0.005
Lead[(a)]	0.006	. . .
Copper[(a)]	0.005	. . .
Silicon[(a)]	0.125	. . .

Prevention of Intergranular Corrosion. The zinc industry has long been aware of the susceptibility of zinc alloys containing aluminum to intergranular corrosion when exposed to elevated temperatures. Committee B-2 of ASTM on nonferrous metals and alloys recognized this potential problem when zinc alloy anodes were exposed to service conditions involving elevated temperatures and recommends the use of unalloyed low-iron zinc anodes, ASTM Type II (up-dated zinc anode specification, ASTM B 418), shown in Table 16 to avoid intergranular corrosion at elevated temperatures.

Underground Zinc Anodes. The cost of installing cathodic protection as a means of stopping the corrosion of coated steel distribution piping is usually small when compared to the cost of repairing leaks and making replacements. The perforation of the pipe wall as a result of corrosion may occur sooner on a well-coated pipe than on a bare pipe, because corrosion current is concentrated at holidays or damaged areas in the coating. The total metal loss, however, of a coated pipe will usually be negligible compared to that which would occur on a bare pipe, and the danger of developing general structural weakness is therefore greatly reduced.

Fortunately, it is relatively easy and inexpensive to apply cathodic protection to a coated pipeline as compared to a bare pipeline, because the current requirements are only a small fraction of that required for the bare pipeline. The combination of a good pipe coating plus cathodic protection has proved to be both economical and successful to such an extent that the current practice is to provide both a coating and cathodic protection on virtually all new transmission pipelines. This practice is often carried out even in areas where there is no certainty that severe corrosion would occur.

Because the environment around an anode is significant when determining the type and nature of anodic films or coatings, successful anode performance is related to the presence of a friendly environment in contact with the zinc. Soils containing significantly more dissolved sulfates and chlorides than carbonates, bicarbonates, nitrates, and phosphates are often compatible with zinc anodes. However, by packing a prepared backfill consisting of hydrated gypsum, bentonite clay, and sodium sulfate (Na_2SO_4) around an anode, a friendly environment is created, and such a packaged anode can be used in almost all soils. The most popular consists of 75% gypsum, 20% bentonite clay, and 5% Na_2SO_4; this environment provides a relatively low resistivity and thus permits high current output levels. In time, however, the Na_2SO_4 tends to leach out of the backfill, and higher resistivity occurs.

The principal zinc specification (ASTM B 418 Type II) used for underground cathodic protection systems given in Table 16 is the unalloyed high-purity zinc with iron controlled to 0.0014% maximum. The literature does not show any long-term field tests comparing the unalloyed Type II materials, with the zinc-aluminum-cadmium composition of MIL-A-18001H, or the ASTM B 418 Type I given in Table 15. Although the latter alloy anodes prepackaged in prepared backfill have been installed, comparative results are lacking.

Zinc Coating Processes

Seven methods of applying a zinc coating to iron and steel are in general use: hot dip galvanizing, continuous-line galvanizing, electrogalvanizing, zinc plating, mechanical plating, zinc spraying, and painting with zinc-bearing paints. This section and the section "Painting With Zinc-Bearing Paints" in this article contain brief descriptions of each process, the nature of the coating formed, and the practical advantages and limitations of each method. There is usually at least one process that is applicable to any specific purpose. Because the processes are complementary, there are rarely more than two processes to be seriously considered as the best choice for a particular application. Additional information on zinc coating processes can be found in the articles "Hot Dip Coatings" (continuous and batch processes are described), "Electroplated Coatings," "Thermal Spray Coatings," "Corrosion of Carbon Steels," and "Corrosion in the Automotive Industry" in this Volume. Reference to *Surface Engineering,* Volume 5 of the *ASM Handbook* is also recommended.

Hot Dip Galvanizing

In hot dip galvanizing, the steel or iron to be zinc coated is usually completely immersed in a bath of molten zinc. It is by far the most widely used of the zinc coating processes and has been practiced commercially for almost two centuries. The modern hot dip galvanizing process is conducted in carefully controlled plants by applying the results of scientific research, and it is far removed from that of years ago, although it is still dependent on the same basic principles.

The process is primarily applied to finished parts and to semifabricated materials, such as sheet, strip, wire, and tube, on the continuous automated lines of the steel producers. There is an obvious advantage in galvanizing after fabrication in that the zinc completely seals edges, rivets, and welds so that there are no uncovered parts at which rusting can begin.

Continuous Galvanizing. In 1936, a revolutionary new process for continuously coating coils of sheet steel by hot dipping was introduced in the United States. This process, known as the Sendzimir process, uses a small amount of aluminum in the zinc bath and produces a coating with essentially no iron-zinc alloy and with sufficient ductility to permit deep drawing and folding without damage to the coating. Other processes for continuous zinc coating of sheet steel without alloy layer formation were later developed and joined the Sendzimir process. Today, nearly all hot dip galvanized sheet steel is produced by continuous methods.

Machines measuring 150 m (500 ft) or more in length that galvanize the sheet at speeds frequently exceeding 90 m/min (300 ft/min) are producing at the rate of more than 9,000,000 Mg/yr (10,000,000 tons/yr) in the United States. A variety of coating weights and types are produced that vary from as little as 0.5 oz/ft^2 (150 g/m^2) of sheet to a maximum of 2.75 oz/ft^2 (840 g/m^2) of sheet. The standard product is 1.25 oz/ft^2 (380 g/m^2) of sheet. The most dramatic advance in the use of galvanized steel sheet in the automotive industry. Corrosion problems, intensified by accelerated usage of salt on the highways in the winter months, have resulted in an increase to current levels of over 900,000 Mg (1,000,000 tons).

The annual production of galvanized pipe is being increasingly mechanized and should in the near future approximate the speeds of, and apply coatings comparable to, those of the continuous lines for sheet. The product is broadly used for fencing, sign poles, playground equipment, plumbing, and other construction purposes.

The steel industry also galvanizes steel wire or bridge cables, fencing, armored conductor cable, and general steel wire strand--for hundreds of uses. The product is woven into wire used in armored cable with aluminum or copper conductors and manufactured into many products.

In addition, continuous lines were developed to apply heat-cured organic finishes to metal strips. Prepainted galvanized strip products are now used for roofing and siding, interior partitions, rain goods, furniture, appliances, and other applications.

The Galvanizing Process. Before the iron or steel parts are dipped in the molten zinc, it is necessary to remove all scale and rust. This is usually done by pickling in an inhibited acid. To remove molding sand and surface graphite from iron castings, shot- or gritblasting is generally used, usually followed by a brief pickling operation.

In the dry galvanizing process, the work is prefluxed by dipping in a flux solution of zinc ammonium chloride, then passed to a low-temperature drying oven. It is then ready for dipping into the molten zinc bath, the surface of which is kept relatively clear of flux. In contrast, in wet galvanizing, the pickled articles are dipped into the molten zinc bath through a substantial flux blanket.

In all processes, as the work enters the bath, the protective layer that has prevented oxidation of the freshly pickled surface peels off, and the work is immediately wetted by the molten zinc. This involves interpenetration of the iron and zinc with the formation of the alloy layers.

Current galvanizing baths are adapted to close thermostatic control. In some of these, hot gases are circulated around the sides of the bath; in others, direct gas or electric heating systems are used. The usual operating temperature is 445 to 460 °C (830 to 860 °F).

Developments in galvanizing resulted in improved quality through better fluxes, better temperatures control, and better cleaning practices. Larger kettles and improved materials made it possible to galvanize large structural pieces. Methods were developed for continuously coating wire and pipe in semicontinuous lines.

Nature of the Hot Dip Galvanized Coating. Figure 5 shows a photomicrograph of a typical hot dip galvanized coating consisting of a series of layers. Starting from the base steel at the bottom of the section, each successive layer contains a higher proportion of zinc until the outer layer, which is relatively pure zinc, is reached. Therefore, there is no real line of demarcation between the iron and the zinc; instead, there is a gradual transition through the series of iron-zinc intermetallics, which provide a powerful bond between the base metal and the coating.

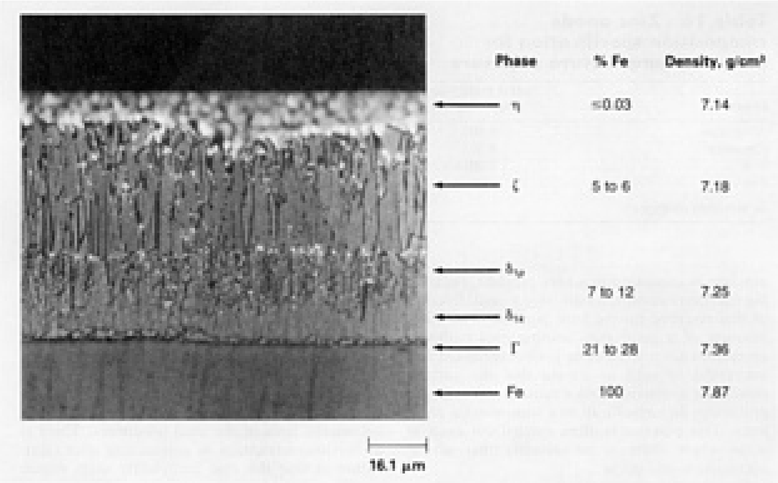

Fig. 5 Typical hot dip galvanized coating. Note the gradual transition from layer to layer, which results in a strong bond between base metal and coating.

The structure of the coating (that is, the number and extent of the alloy layers) and its thickness depend on the composition and physical condition of the steel being treated and on a number of factors within the control of the galvanizer. For example, heavier coatings tend to be deposited on rough-surface and coarse-grain steel, and the total thickness of the alloy layer tends to be slightly greater at corners than at hollows, or shallow areas.

The total thickness of the coating may be controlled by varying the time for which the work is immersed in the molten zinc and the speed at which it is removed. If only a thin coating is required, as is sometimes the case in sheet or wire galvanizing, the work is mechanically wiped upon being withdrawn from the bath in order to remove excess zinc. The temperature of the bath has little effect on the nature of the coating if it is kept between 430 and 470 °C (805 and 880 °F). Small or threaded parts are often centrifuged after being hot dipped galvanized in order to remove excess zinc and to produce a more uniform coating.

The ratio of the total thickness of the alloy layers to that of the outer zinc coating is also affected by varying the time of immersion and the speed of withdrawal of the work from the molten zinc bath; the rate of cooling of the steel after withdrawal is another factor to be taken into account. Sheet galvanizers operating continuous-strip processes usually suppress the formation of alloy layers by adding 0.1 to 0.2% Al to the bath; this increases the ductility of the coating and makes the sheet more amenable to fabrication.

Other elements may be added to galvanizing baths to improve the characteristics and appearance of the coating. Tin and antimony give rise to well-defined spangle effects, and the presence of some lead in the bath is generally considered desirable. The addition of 1% Pb reduces the surface tension by more than 40% when compared with pure zinc. This reduction in surface tension tends to help the drainage of the bath metal as the workpiece exits the bath. Aluminum also improves the appearance of the coating and the corrosion resistance.

Advantages and Limitations. An important advantage of hot dip galvanizing is that, unless zinc is removed by mechanical devices (a practice confined to the automated galvanizing of sheet, strip, wire, and tube) or by centrifuging, the work will probably be thoroughly covered and will carry a thick coating usually weighing 1.8 to 2.2 oz/ft^2 (550 to 670 g/m^2). All edges, rivets, seams, and welds are thus sealed by the hot dip process. Furthermore, it will often be found to be the most economical process when large amounts of steel are to be treated. The size of galvanizing baths does of course limit the size of articles that may be treated, but large parts can be protected by suitable double dipping (one end at a time).

Heating fabricated parts to 450 °C (840 °F) by immersion in molten zinc baths occasionally has undesirable effects, but these can usually be overcome. For example, warping can be eliminated by paying careful attention to welding techniques so as to balance stresses. Possible embrittlement of malleable cast iron, which is likely only if its phosphorus content exceeds 0.07%, can be avoided by quenching in water from 650 °C (1200 °F) before galvanizing. The danger of

embrittlement in galvanizing articles that have previously undergone severe localized cold working can be overcome by suitable stress relieving.

Electrogalvanizing

The additional development of continuous electrogalvanizing lines added another dimension to zinc-coated steel, that is, very thin, formable coatings ideally suited to deep drawing or painting. Zinc is electrodeposited on a variety of mill products by the steel industry: sheet, wire, and, in some cases, pipe. Electrogalvanizing at the mill produces a thin, uniform coat of pure zinc with excellent adherence. The coating is smooth, readily prepared for painting by phosphatizing, and free of the spangle that is characteristic of some other zinc coatings.

Electrogalvanized steel is produced by electrodepositing an adhering zinc film on the surface of sheet steel or wire. These coatings are not as thick as those produced by hot dip galvanizing and are mainly used as a base for paint.

The coating produced on strip coils or sheets has a coating weight in the range of less than about 0.06 to 0.2 oz/ft^2 (18 to 60 g/m^2), or 1.3 to 4.3 μm (0.05 to 0.17 mil) thick on each side. A small amount carries considerably less--approximately 0.025 oz/ft^2 (7.6 g/m^2), or 0.5 μm (0.21 mil) on each side.

Zinc is usually electrodeposited on steel wire in the range of 0.3 to 3 oz/ft^2 (90 to 915 g/m^2). The diameter of plated wire (including wire that is cold drawn after plating usually ranges from 0.23 to 4.9 mm (0.009 to 0.192 in.). Steel carbon contents range from 0.08 to 0.85%. Tensile strengths range from 345 to 2070 MPa (50 to 300 ksi). Heat-treated and coated wire can be cold drawn to approximately 95% reduction in area, depending on chemical composition, heat treatment, and diameter.

Nature of the Electrogalvanized Coating. The pure zinc coating deposited is highly ductile. Because of its excellent adhesion, electrogalvanized steel strip and wire have good working properties, and the coating remains intact after severe deformation.

Electrodeposited zinc coatings are simpler in structure than hot dip galvanized coatings. They are composed of pure zinc and have a homogeneous structure. Surfaces have a smooth texture whose appearance can be varied by additives and special treatments in the plating bath. They can be used where a fine finish is needed.

Electrogalvanizing provides adequate protection for many types of mild exposures. These coatings are frequently treated with chromate conversion solutions to improve appearance, reduce staining, and retard the formation of white corrosion products under high-humidity conditions.

Advantages and Limitations. In electrogalvanizing, steel strip or wire is continuously fed through suitable entry equipment, a series of washes and rinses, and a plating bath. Either an acid sulfate zinc or cyanide zinc bath is used as the plating bath. Both produce even, adhering zinc deposits. Although brighteners are not used for electrogalvanizing, grain refiners are usually added to help produce a fine, tightknit zinc surface on the steel.

Zinc electrodeposits are considered to have the best adhesion of any metallic coating. Good adhesion depends on very close physical conformity of the coating with the basis metal. Therefore, particular care must be taken during initial cleaning. Electrodeposition affords a continuous process for applying zinc coatings to parts that cannot be hot dipped. They are especially useful where a high processing temperature could damage a part.

Applications. Electrogalvanized sheets are produced in various tempers suitable for simple bending or forming, for curving, and for rolling into cylinders without fluting. Spot welding is easily accomplished if care is taken.

Electrogalvanized steel is easily prepared to receive decorative finishes. Much of it is produced with a phosphate treatment or an organic coating. The phosphate treatment provides an adequate surface for a good bond with organic finishing materials. Organic coating applied over electrozinc thus treated maintains good adhesion in adverse conditions, such as sudden changes in temperature and high humidity. Phosphated electrogalvanized steel is used for parts subject to atmospheric corrosion or salt spray and for parts that will be lacquered or painted. Phosphate treatment increases corrosion resistance markedly, particularly in atmospheres with a high sulfur content.

Electrogalvanized sheet is used for manufacturing water cooler housings, exterior panels of ranges, freezers, dryers, washers, air conditioners, and other major appliances. It is used for deep-drawn parts for kitchen cabinets, refrigerators,

and allied products instead of plain cold-rolled sheet because zinc holds better in this dies and reduces breakage significantly. Bakery goods and other merchandizing display cases, stud systems for steel building construction, acoustical ceiling members, and television antennas are also made of electrogalvanized steel.

A new application that should greatly benefit the automotive industry is one-side electrogalvanizing. The galvanized side protects against corrosion, and the bare side can take the baked enamel finish required by the outer automobile surface (see the article "Corrosion in the Automotive Industry" in this Volume).

Electrogalvanized wire is especially useful in applications in which the wire must be bent, twisted, or wrapped around its own diameter. When formed, the coating does not rack, peel, or flake. Many chain link fences are made from zinc-electrocoated wire because it is not rough and therefore is safe to handle. The wire is used for conveyor belts, twisted wire brushes, chains, baskets, kitchen utensils, staples, cages, bobby pins, clotheslines, and telephone and transmission wire.

Zinc Plating

Coatings of zinc may also be applied to iron and steel surfaces by electroplating. The article to be plated is made the negative electrode in an electrolytic cell containing a solution of a zinc salt through which an externally generated dc current is passed. Zinc is supplied to the cell as expendable positive electrodes or as zinc salts added directly to the plating solution.

Surface Preparation. The adherence of electrodeposited zinc coatings depends on the metal-to-metal bond between the plated coating and the underlying steel surface. Therefore, particular attention must be given to the preparation of the surface before plating to obtain a coating in true physical contact with the entire steel surface.

The usual method of removing all rust, scale, and grease from the steel surface involves cleaning the surface thoroughly in a hot alkaline bath by soaking the parts for a short period of time. This is often followed by use of an electrolytic alkaline cleaner and a spray alkaline cleaner. An acid dip is then carried out to remove oxides and scale. There must be adequate rinsing between the alkaline/acid baths and the acid/plating baths to avoid contamination of the plating bath by carryover from the cleaning baths.

Zinc Plating Baths. Zinc plating is done in an acid or an alkaline bath. Although the alkaline-cyanide zinc baths are the most efficient and have the best throwing power, they do create a serious pollution problem. Therefore, more alkaline, hydrochloric acid (HCl), and H_2SO_4 zinc baths are being used. The H_2SO_4 baths are primarily used in the tubing, wire, and sheet electrogalvanized areas. All of the other baths are used for barrel plating. Barrel plating is used to plate a large volume of small articles. These are placed in a suitably constructed rotating barrel that is immersed in the plating solution.

Various brightening agents may be added to the baths to give a deposit that is more lustrous than that obtained from normal zinc plating baths. The amount of brightening agent requires very careful control, and the bath and the zinc anode must both be kept particularly pure when brighteners are used.

Nature of the Electroplated Zinc Coating. The normal electroplated zinc coating is dull gray with a matte finish, but whiter and more lustrous deposits an be produced by adding special agents. The coating consists of pure zinc and is of uniform composition throughout. It adheres by metal-to-metal bonds.

Advantages and Limitations. Electroplating is the most precise of all zinc coating processes and therefore is particularly suitable for coating delicate articles, such as instrument parts, on which a fine finish is essential. Furthermore, the parts need never be heated to a temperature above the boiling point of water.

Because the pure zinc coating is extremely ductile, it is quite easy to form zinc-plated sheets without damaging the coating. On simply shaped articles, it is possible to control the thickness of electroplated zinc coatings within fine limits. Barrel-plated articles have coatings that are more uniform in thickness than those normally obtained.

Zinc electrodeposits expand very slightly during plating; therefore, if the deposit does not adhere properly, blistering may develop. The effect develops slowly and takes several hours or even days for completion; it is most marked in acid-sulfate deposits.

Mechanical Plating

This process is used to deposit a specified thickness of zinc on a steel surface in a uniform manner, even in threaded areas. Parts plated by the process do not encounter hydrogen embrittlement. The plate thickness can be varied from 2.5 to 125 μm (0.0001 to 0.005 in.).

In the plating of fasteners, a large, lined, steeled tumbling container is used for the complete process. A predetermined amount of parts, glass beads, and water are added to the tumbler, and the following system is used. First, an inhibited acidic powder cleaner and an acid copper salt are added and maintained at a pH to 1.8. The parts are then tumbled to achieve proper cleaning and an immersion coating of copper. Second, the catalyst (promoter chemical) and zinc powder (8 to 20 μm) are added and tumbled.

The resulting zinc deposit is cold welded to the copper by the peening action of the glass beads. By regulating the amount of zinc, it is possible to predetermine the film thickness of zinc that will result.

Zinc Thermal Spraying

Zinc thermal spraying consists of projecting atomized particles of molten zinc onto a prepared surface. Two types of spray guns are in commercial use today: the powder gun and the wire gun.

Surface Preparation. The surface preparation of the work is the same for each process and involves cleaning and then roughening the surface to be sprayed. The usual method of roughening is coarse gritblasting.

Whatever method of surface preparation is used, the sprayed zinc coating should be applied as soon as possible after the surface has been prepared in order to reduce the possibility of oxidation and thus increase the effectiveness of the metal-to-metal bond. The time lag is reduced to a minimum in mechanized plants that have been built for production line work and for treating construction steelwork before assembly.

Two Methods of Spraying Zinc. Two methods of spraying zinc produce coatings of comparable quality. They are the powder process and the wire process.

The Powder Process. Zinc particles are suspended in a gaseous medium and driven through a blowpipe flame. The stream of powder-laden gas is heated by the flame surrounding the nozzle, and outside this, a cone of compressed air gives impetus to the stream of molten droplets.

There are four feeds to the gun: combustible gas, oxygen, compressed air, and zinc powder suspended in air or a gas. A wide choice of fuel gases is available because the gas does not have to function as an atomizer.

The Wire Process. Zinc wire is fed axially into the center of a blowpipe flame issuing from a ring of small gas ports. A stream of compressed air disintegrates the film of molten metal as it forms and sprays it out of the nozzle. The oxygen and fuel gas supplied for the flame are at the same pressure so that they may be simply mixed in a small chamber.

In hand tools, such as those used for zinc coatings, a compressed air turbine is used to drive the wire feed through worm reduction gearing. Nozzles often consist of a sleeve of hard steel surrounded by copper to disperse the heat generated by the blowpipe flame. Various types of wire-spraying guns have been developed in which electricity is used in place of gas for heating.

The Nature of the Thermally Sprayed Zinc Coating. The sprayed coating is slightly rough and slightly porous. The specific gravity of a typical zinc coating is about 6.35 as compared to 7.1 for cast zinc. This slight porosity does not affect the protective value of the coating, because the zinc is anodic to steel. The zinc corrosion products that form when the coating is in service fill up the pores to produce a solid coating. The slight roughness of the surface makes it an ideal base for paint.

The mechanism by which the zinc adheres to the underlying surface has been the subject of many experiments and much speculation. Although no alloy layer is formed and the bond is purely mechanical, the adhesion of zinc to a properly prepared iron or steel surface is excellent. Recently, it has been suggested that pre-heating the base metal gives even greater values for adhesion. In the ordinary process, the impact of the particles of molten zinc on the surface causes only a very slight increase in temperature of the base metal.

Advantages and Limitations. Zinc spraying has a significant advantage over most other methods of zinc coating in that it can be applied to work of almost any shape or size on the site. When applied to finished parts, the welds, ends, and rivets receive adequate coverage. Moreover, it is the only satisfactory method of depositing unusually heavy zinc coatings with thicknesses of 0.25 mm (0.01 in.) and greater.

Zinc spraying is usually not suitable for depositing coatings inside cavities, although special types of nozzles are available for applying coatings inside short lengths of tube. The process is seldom economical for treating open structures, such as wire mesh, because of the large loss of metal that would result.

The mechanized plants, such as those used for treating construction steelwork before assembly, make it possible to deposit completely uniform coatings. In hand spraying, the degree of uniformity achieved depends entirely on the skill of the operator.

Painting With Zinc-Bearing Paints

Although zinc coatings can be applied in several ways, the size of a structure or piece of equipment places limitations on the method used. On very large structures, painting is often the only practical method. Two types of zinc pigment coatings are available for corrosion control: zinc dust/zinc oxide and zinc-rich coatings.

Zinc Dust/Zinc Oxide Coatings

Zinc dust/zinc oxide paints, also known as metallic zinc paints, contain a pigmentation of approximately 80% zinc dust, 20% ZnO, and approximately 80% pigment by weight. These paints offer excellent rust-inhibitive properties, adhesion, film distensibility, and abrasion resistance. Because they adhere tightly to zinc and other metals, they are ideal for prime and finish coat applications and may be used as a primary first coat even over primarily rusted surfaces.

Zinc dust/zinc oxide paints are used for the protection of many types of steel structures under a variety of service conditions. They are particularly well suited to use on galvanized steel; are highly satisfactory for priming steel for atmospheric and underwater exposure; and can be used on many outdoor structures, such as bridges, water tanks, and dams, where rusting must be prevented.

In accordance with Federal Specification TT-P-641 which covers primer paints and zinc dust/zinc oxides for galvanized surfaces, there are three types of zinc dust/zinc oxide paints:

- *Type I:* zinc dust/zinc oxide linseed oil for outdoor exposure, recommended as a primer or finish coat for broad, general use, especially when there is widespread rusting of the steel surfaces; should be air dried only
- *Type II:* zinc dust/zinc oxide alkyd resin paint, a heat-resistant paint sometimes sold as a stack paint, may also be used for outdoor exposures where rust is not severe; quick drying; can be air dried or baked at temperatures to 150 °C (300 °F)
- *Type III:* zinc dust/zinc oxide phenolic resin paint; used for water immersion and other severe moisture conditions; may be air dried or baked at temperatures to 150 °C (300 °F)

These paints, when properly formulated and prepared, can be applied by brushing, dipping, or spraying. Although the presence of ZnO prevents rapid or hand settling, adequate agitation of the paint in the dip tank is necessary to ensure the coating homogeneity necessary for maximum metal protection. Pressure equipment should be used when spraying, and the distance between the paint reservoir and the spray gun should be as short as possible to ensure the proper rate of feed to the nozzle. Again, some agitation of the paint in the reservoir is recommended.

Zinc dust/zinc oxide paints possess high covering power and can hide backgrounds of almost any color when spread at the rate of approximately 20 m^2/L (800 ft^2/gal). However, because the protection afforded by a paint coating is directly related to its thickness, the necessary protection cannot be guaranteed unless the dry film is thick enough for the specific environmental conditions. Therefore, care must be taken to avoid spreading the paints too thin. The natural blue-gray color of zinc dust/zinc oxide paints provides an aesthetic appearance, but if another color is desired, red, buff (orange-yellow), and green can be obtained by varying the pigment.

To prepare surfaces for zinc dust/zinc oxide paints, rust (or scale) and any accumulation of leaves, dirt or other foreign materials should be removed. This may be accomplished on large structures by sandblasting and on small structures or areas with a deck or wire brush.

Zinc-Rich Coatings

In recent years, a number of paints have been developed that will deposit a film of metallic zinc having many properties in common with zinc coatings applied by hot-dip galvanizing, electro-plating, metal spraying, and mechanical plating. Such paint films will protect the underlying steel sacrificially if they contain 92 to 95% metallic zinc in the dry film and if the film is in electrical contact with the steel surface at a sufficient number of points. They are effective where steel is subjected to high humidity and water immersion. Under normal conditions, zinc-rich coatings are long lasting and most effective where a regular maintenance program may be difficult. In applications in which steel is immersed in brackish or salt water, zinc-rich coatings, along with a suitable top coat, should be used. Most zinc-rich paints are of the air-drying type, although oven-cured primers containing a high content of zinc dust are available.

The type of zinc dust used is a heavy powder, light blue-grey in color, with spherically shaped particles having an average diameter of approximately 4 μm. Such powder normally contains 95 to 97% free metallic zinc with a total zinc content exceeding 99%.

Surface Preparation. Zinc-rich primers must be applied over clean steel surfaces to provide the metal-to-metal contact essential to successful performance of the coating. Abrasive blasting is the most effective method of cleaning steel. Although white metal blast-cleaning (NACE No. 1) is preferred, near-white SSPC-SP-10 or Commercial Blast Cleaning SSPC-SP-6 is acceptable (Ref 14).

Where the zinc is supplied as a separate component, it should be added slowly to the vehicle with constant agitation. After a homogeneous mix is obtained, the primer may be applied with air spray. Airless spray may also be used, but the nozzles may wear quickly. Because zinc settles rapidly, continuous agitation of the paint is essential during application, and fluid lines should be kept as short as possible.

To obtain a wet coat, the gun should be kept within 30 cm (1 ft) of the surface. Uneven film thickness due to brushing or rolling may result in mudcracking in the thick portions. Zinc-rich primers should be applied at a dry film thickness of 0.06 to 0.08 mm (2.5 to 3.5 mils).

The Nature of the Zinc-Rich Coating. Depending on the binder, zinc-rich coatings fall into two classes: organic and inorganic. The inorganic solvent-base types are derived from organic alkyl silicates, which become totally inorganic upon curing. Each offers particular protection characteristics, and each requires different preparation of the steel surface. The following comparisons should be helpful in selecting the most useful binder system.

The organic zinc-rich coatings are formed by using zinc dust as a pigment in an organic binder. This binder may be any of the well-known coating vehicles, such as chlorinated rubber and epoxy. The zinc dust must be in sufficient concentration so that the zinc particles are in particle-to-particle contact throughout the film. Thus, zinc provides cathodic protection. In the case of the organic binder, there is no reaction with the underlying surface other than for the organic vehicle to wet the steel surface thoroughly and to obtain mechanical adhesion.

Organic zinc-rich coatings do not require a white blast preparation of the steel surface, although a commercial blast should be included if the application is heavy service. For mild-service applications, the organic coating can be applied to a well-hand-cleaned surface, even if traces of rust are present.

Some proponents feel that maintaining proper humidity during surface preparation, application, and curing is not necessary. Because this type of coating is more flexible than inorganic coatings, exacting surface preparation for bonding to a substrate is not required. Finally, although organic coatings are more compatible with top coats, they are somewhat less abrasion resistant than the inorganic types.

As to the advantages of these coatings, organic zinc-rich coatings require less critical surface preparation, allow greater variation in application techniques, are less sensitive to varying climatic conditions during application and curing, and are more flexible and more resistant to chemical environments. Their disadvantages include flammability, blistering, harmful solvent effects, sensitivity to atmospheric influences, and relatively low heat resistance.

For better resistance against continuous exposure to salt water and to acid or alkali chemical fumes, zinc-rich coatings should be top coated with organic topcoats to provide a totally organic system, with optimum intercoat compatibility. A top coating may also be applied to provide color or to prevent gradual erosion of the zinc coating. Although zinc-rich coatings vary in application characteristics, they can be applied by brush or spray, and depending on the specific formulation, one coat can vary in thickness from 2 to 7 mils.

Inorganic Zinc-Rich Coatings. Many inorganic zinc-rich coatings use water solutions of alkali silicates as vehicles. Others use phosphates, silicones, and modifications of these groups.

Self-cured coatings are two-package materials consisting of zinc dust and a vehicle; they are mixed immediately before application. Postcured coatings are three-package materials that consist of zinc dust, the vehicle to be mixed with it before application, and a curing agent that is applied on top of the coating.

The inorganic zinc coating forms its film and its adhesion to the steel surface methods quite different from those of the organics. The coating system is a chemically reactive system, and the chemical activity is similar for either the water-or the solvent-base inorganic. Zinc is the principal reactive element in the inorganic coating systems and is primarily responsible for the development of initial insolubility. Depending on the formulation, other metal ions may be present in the system that also react and aid in the insolubilization of the coating. The silicate vehicle can also react with underlying iron surface to form a chemical bond with the iron or steel substrate.

Inorganic zinc-rich coatings commonly require a white metal blast as preparation for the steel surface. Because inorganic coatings generally have limited flexibility and tend to break or crack upon bending or impact, careful preparation of the steel surface is required to ensure a good bond between the coating and the steel. However, despite the difficulties of preparation, these inorganic coatings are unaffected by solvents, oils, petroleum products, aliphatics, aromatics, ketones, and alcohols. They do not chalk, peel, or lose thickness over long periods of time. Also, they are easier to weld through and have excellent abrasion resistance and surface hardness.

Inorganic zinc-rich coatings offer good conductivity; good adhesion to clean steel; excellent resistance to weather, sunlight, and variations in temperature; resistance to radiation, heat, and abrasion; and reduced undercutting. Conversely, these coatings require unusually good surface preparation, display a lack of distensibility and adhesion to some metals other than steel and zinc, require moderate temperatures and atmospheric humidity for cure, and exhibit unsatisfactory durability under conditions of continuous immersion in electrolytes and a lack of resistance to strong acids and alkalies.

Zinc Dust/Zinc Oxide Paint Versus Zinc-Rich Coating

Whether to use a zinc dust/zinc oxide paint or a zinc-rich coating depends on a number of factor, including cost of surface preparation, paint application, and anticipated length of surface. Zinc dust/zinc oxide coatings are ideal for rural or semi-industrial atmospheres. They are particularly effective on galvanized surfaces.

The widely used zinc dust/zinc oxide primers based on ordinary drying oil media do not give general electrolytic protection against corrosion and therefore do not fall in the category of zinc-rich paints.

Zinc-rich coatings are preferred for the protection of steel or galvanized steel structures exposed to marine environments or immersed in seawater. Applications include interiors of floating roof tanks, cooling tower piping, pipe racks and exterior piping in refineries, chemical plant maintenance, offshore drilling platforms, aboveground pipelines, structural steel before erection, exterior of pressure vessels, ammonia tanks, ship holds, and air conditioning equipment.

A top coat finish may be necessary in aggressive atmosphere. The top coat must adapt to the environment and must guarantee compatibility with, and adhesion to, the zinc-rich primer.

Advantages and Limitations of Zinc-Rich Paints. Zinc-rich primers offer a more versatile form for applying zinc to steel galvanization; large, continuous complex shapes and fabricated new or existing structures can be easily coated at manufacturing shops or in the field. Their performance has earned them a prominent place in the field or corrosion protection coatings. However, the limitations of zinc-rich paints include cost, difficulty in applying, and the requirement of clean steel surfaces. They must be top coated in severe environments (pH under 6.0 and over 10.5).

Zinc Chromate Paints

Zinc chromate pigments are unique in that they are useful as corrosion inhibitors for ferrous and nonferrous metals. Zinc chromate was developed just before World War II and was the major pigment in marine primers. It is yellow in color, but can be tinted green. Zinc chromate paints are used as an after-pickling coating on steel and as a primer for steel and aluminum. Federal Specification TT-P-645 covers zinc chromate paints.

Corrosion of Tin and Tin Alloys

Daniel J. Maykuth and William B. Hampshire, Tin Research Institute, Inc.

Introduction

TIN is a soft, brilliant white, low-melting metal that is most widely known and characterized in the form of coating for steel, that is, tinplate. In the molten state, it reacts with and readily wets most of the common metals and their alloys. Because of its low strength, the pure metal is not regarded as a structural material and is rarely used in monolithic form. Rather, the metal is most frequently used as coating for other metals and in alloys to impart corrosion resistance, enhance appearance, or improve solderability. It also finds wide use in alloys, the most important of which are tin-base soft solders and bearing alloys and copper-base bronzes.

Pure Tin

Pure tin is subject to two phenomena that are sometimes confused with the corrosion process in the ordinary atmosphere. These are its low-temperature allotropic modification and its susceptibility to whisker growth. To avoid this confusion, these processes are discussed below.

Allotropic Modification. At temperatures from 13.2 °C (55.8 °F) to its melting point of 232 °C (449.6 °F), tin exists in a body-centered tetragonal (bct) structure commonly known as β-tin. Below 13.2 °C (55.8 °F), the β form can change to a diamond cubic structure known as α-tin, which lacks cohesion and appears as a friable gray powder. This is sometimes called the tin pest. This transformation does not occur spontaneously unless the tin is of extremely high purity and is exposed to subzero temperatures. The transformation can be accelerated by inoculating the β with α crystals or by deforming the β-tin at low temperatures (Fig. 1). Some details of the mechanisms and kinetics of this process are discussed in Ref 1.

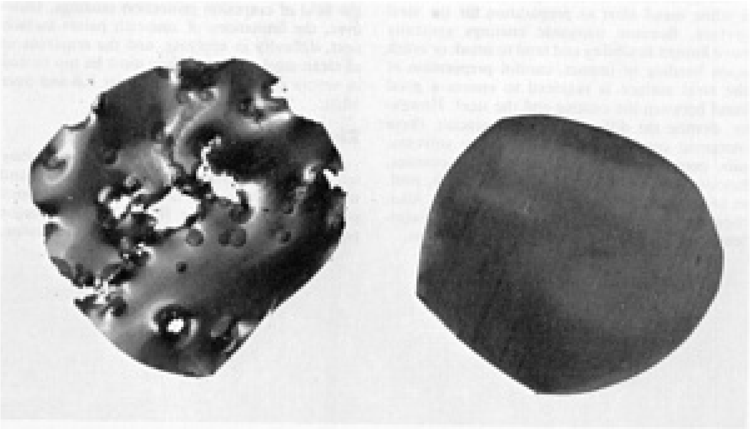

Fig. 1 Gray tin transformation on pure tin. Both samples were stored at -20 °C (-4 °F), but the sample on the left was bent at this temperature and the other was left undisturbed.

The transformation is inhibited by the presence of small amounts of bismuth, antimony, or lead. Hot-dipped tin coatings and most electrodeposited coatings seem to be immune to this phenomenon, probably because of impurity effects. Thus, no traces of transformation were evident on hot-dipped tinplate cans after burial for 46 years in arctic snow or on electroplated tin coatings on refrigerator parts (Ref 2). However, transformation has occurred with thicker deposits; when such low-temperature exposure is anticipated, the incorporation of about 0.1% Bi is recommended to avoid the problem (Ref 3).

Tin Whiskers. Tin is subject to a form of recrystallization at room temperature that manifests itself as a growth of thin (1- to 2-μm, or 0.04- to 0.08-mils, diam) single-crystal filaments from the surface of tin coatings. These can begin to form in as little as 5 weeks and may grow at a rate up to 1 mm/mo (0.04 in./mo). Although the mechanism is not clearly understood, formation of tin whiskers appears to be favored by residual or applied stress, by the presence of a brass substrate, and by high-purity electrodeposited tin (Ref 4, 5, and 6). The potential for whisker growth can be minimized if not completely eliminated by reflowing the tin coating or by incorporating 2 to 10% Pb into the electrodeposited tin.

Atmospheric Corrosion. In clean dry air, tin retains a bright appearance for many days. In one study, a light dulling was observed after 100 days, and noticeable, faint yellow-gray tarnish film was seen after 150 days (Ref 7). However, it was also reported that the reflectivity of tin remains practically unchanged over long periods when the tin is washed with soap and water (Ref 8). Thus, at ordinary temperatures, the surface oxide film on tin is very thin and exhibits a very slow rate of growth. The rate of oxidation increases with temperature. Above 190 °C (375 °F), a film thickness sufficient to produce interference colors is reportedly produced in a few hours; at 210 °C (410 °F), this film thickness is produced in 20 min (Ref 2).

The results of a comprehensive 20-year study of the atmospheric corrosion resistance of bulk tin were reported by an ASTM Committee (Ref 9-13). Sheets of commercial 99.85% purity tin, measuring 230 × 300 mm (9 × 12 in.) were exposed at seven sites in the United States, including industrial, seacoast, and rural atmospheres. Results are listed in Table 1.

(a) Converted from weight loss data, assuming a tin density of 7.29 g/cm^3.

Ancient tin coins from Malaysia were found to be covered with successive layers of brown and gray scale that were principally stannic oxide (SnO_2) that contained sulfate plus traces of silica and iron (Ref 14). Examination of seventeenth

and eighteenth century sarcophagi in Vienna revealed some evidence of deterioration that was suspected to be the tin pest. It was found, however, that the casting was porous and that air and moisture produced corrosion products of stannous oxide (SnO) and SnO_2, causing the observed swelling, blistering, and cracking.

Oxidation. At extremely low temperatures, the oxidation of tin is very superficial. In one investigation, resistivity measurements were used on tin condensation films formed at 1.5 to 300 K; in all cases, a step function indicating that the growth of tin oxide first began at 23 K was found (Ref 15). No further growth of the oxide was detected at 50 to 150 K.

The most comprehensive studies of interactions between tin and oxygen were those discussed in Ref 16, 17, 18, and 19, in which 99.994% pure foils and a vacuum microbalance were used to measure oxidation rates at oxygen pressures between 10^{-3} and 500 torr (0.13 and 6.7×10^4 Pa) and temperatures from 150 to 220 °C (300 to 430 °F). The essential features of oxidation behavior were found to be explainable in terms of the microstructure of the oxide. With oxygen pressure under 1 torr (133 Pa), dendritic α-SnO crystallites grew at an increasing rate, with the rate-determining factor apparently being the dissociation of oxygen. Above 1 torr (133 Pa), the oxidation rate curves had a characteristic sigmoid shape, in which the initial stages corresponded to the lateral spread of oxide from numerous nuclei to form α-SnO platelets. Subsequent growth followed a logarithmic law and was consistent with control by tin diffusion through an oxide film under a parabolic or cubic law, while the formation of cavities in the oxide film progressively reduced the area through which diffusion could take place. For long oxidation times, the thick oxide film was subject to random fracture, leading to erratic results.

The oxidation of tin containing 0.17% Pb and 0.024% Sb was examined at 168 to 211.5 °C (335 to 413 °F) and oxygen pressures of 4 to 9 torr (533 to 1200 Pa) (Ref 20). These oxidation rate data were not significantly different from those given in Ref 16, 17, 18, and 19.

The effects of impurities on the oxidation rate of tin were also studied by using microbalance techniques under conditions similar to those described in Ref 16, 17, 18, and 19 (Ref 21). The results are summarized in Table 2. These results were later rationalized in terms of the relative thermodynamic stability of the oxides formed, as follows. If the oxide of the alloying element is less thermodynamically stable than SnO, the oxidation rate of the alloy remains unchanged for additions whose ions have the same valence as the tin. However, when the formal ionic charge of the alloying element exceeds that of the tin--for example, antimony, bismuth, iron, and titanium--then the oxidation rate of the tin increases. Those alloying elements forming an oxide more stable than SnO--for example, zinc, indium, phosphorus, and germanium--undergo preferential oxidation at the surface, thus inhibiting the oxidation of tin (Ref 22).

Table 2 Effect of alloy additions of 0.1 at.% on the oxidation rate of tin at 190 °C (375 °F) and an oxygen pressure of 10 torr (1330 Pa)

Alloying element	Increase in weight after 1000 min, μg/cm^2
Manganese	2.7

The oxidation rate of molten tin was studied at 400 to 800 °C (750 to 1470 °F) with oxygen pressures of 50 to 500 torr (6.7 to 67 kPa) (Ref 23). The rate varied greatly from specimen to specimen at any one temperature, but was apparently linear under all conditions. The variability was attributed to crystal orientation in the oxide film, which was in apparent agreement with the results of other investigations (Ref 24). One researcher commented that another possibility is the continuous conversion of SnO to a nonprotective SnO_2 (Ref 25). In one experiment conducted at 800 °C (1470 °F), the initially formed jet-black film of SnO became incandescent at one end of a boat, and the incandescence traveled rapidly to the other end of the boat, leaving an orange coating.

Another study investigated the effects of alloying additions at levels of 0.01, 0.1, and 1% on the oxidation of molten tin (Ref 26). Antimony, lead, bismuth, and copper had negligible effects, while higher concentrations of lead increased the temperature at which significant oxidation occurs. Magnesium, lithium, and sodium significantly increased the oxidation rate, but zinc, phosphorus, indium, and aluminum decreased the rate. The oxidation of an alloy containing 0.01% Al was about the same as that of pure tin at 425 °C (795 °F).

Other laboratory oxidation studies were concerned with tin in contact with air. The formation of an oxide film was shown in Ref 27 and 28, and weight increment curves were developed in Ref 29. In another study, the oxidation rate was determined to be linear after the first few days and was nonprotective (Ref 6). Lastly, the oxidation of tin and tinplate was investigated by using coulometric and x-ray techniques (Ref 30, 31). Up to 130 °C (265 °F), the oxidation followed a

logarithmic rate law that tended to become parabolic at higher temperatures. At room temperature, the oxide film appeared to be amorphous, but at higher temperatures, α-SnO was detected, possibly with some SnO_2.

One study found that SnO forms on tin immediately above its melting point and that SnO_2 forms at higher temperatures (Ref 32). This effect was demonstrated by spot heating a piece of tinfoil (Ref 33). Stannic oxide was found at the center and was surrounded by SnO, which was in turn ringed with an amorphous oxide. According to other researchers, the disproportionation of SnO to tin and SnO_2 is a slow process, even at 300 °C (570 °F) (Ref 34). The need for extreme care in oxidation studies, especially with regard to surface preparation, was emphasized in Ref 22. This was demonstrated by using cathodic cleaning to show the effects of humidity (Ref 35).

Minor impurities in tin also affect its oxidation behavior in air. Small amounts of indium, phosphorus, or zinc were found to slow the oxidation (Ref 30). In addition, traces of aluminum were shown to cause embrittlement as a result of intercrystalline attack (Ref 36). Antimony additions, however, counteracted this effect.

Reaction With Other Gases. Tin does not react with hydrogen or nitrogen below its melting point, nor is it reactive with dry ammonia (NH_3). Molten tin reacts with carbon dioxide (CO_2) according to:

$$Sn + 2C_2 \rightarrow SnO_2 + 2CO \quad \textbf{(Eq 1)}$$

Above 650 °C (1200 °F), molten tin reacts with water vapor to form SnO_2 and hydrogen.

From 25 to 100 °C (75 to 212 °F), hydrogen sulfide (H_2S) has little apparent effect on tin, but above 100 °C (212 °F), stannous sulfide (SnS) forms. Stannous sulfide and stannic sulfide (SnS_2) are also formed by reacting tin with sulfur at high temperatures. Tin also reacts readily with SCl_2, S_2Cl_2, NOF, and hydrofluoric acid (HF). Tin is readily attacked by chlorine, bromine, and iodine at room temperature, but fluorine reactions become significant only above 100 °C (212 °F).

Water. In hot or cold distilled water, the only action of tin is the slow growth of an oxide film, with a negligible amount of metal entering solution. Water that was freshly distilled in a tin was found to have less than 1 ppb Sn in solution (Ref 2). Storage in tin-lined or tinned copper tanks for 24 h produced, in the worst instances, only a few ppb, but in some cases, the tin content remained below 1 ppb.

In tap water of 7.2 pH at 25 °C (75 °F), specimens of 99.99% cold-rolled tin showed a weight gain of 0.023 $mg/dm^2/d$ (1.2×10^{-4} mm/yr, or 0.04 mils/yr) in 50 days and the formation of an insoluble film (Ref 37). With harder tap waters of 7.4 and 8.6 pH, weight losses of the order 0.046 and 0.01 $mg/dm^2/d$ (2.3×10^{-4} and 5×10^{-5} mm/yr, or 0.09 and 0.02 mils/yr), respectively, were incurred in 50 days. Precipitated carbonate was mainly responsible for localized water line attack with hot and cold hard waters because no attack occurred without the precipitate. Addition of 5% Sb to the tin prevented localized attack by hard water.

The results of corrosion test data on tin and several tin alloys in seawater under conditions of total immersion are shown in Table 3. It was also observed that application of a fairly thick 60Pb-40Sn alloy coating over copper will protect it from erosion by seawater at high velocity (Ref 38).

Table 3 Corrosion of tin and tin alloys totally immersed in seawater

Material	Form	Exposure time, years	Penetration rate[(a)]		Test location
			mm/yr	**mils/yr**	
99.75 tin	Cast bar	4	0.0022	0.087	Bristol Channel
99.2 tin	Cast bar	4	0.0008	0.03	Bristol Channel

Solder (Sn-60Pb on copper)	Plate	2.1	0.011	0.43	Kure Beach, NC

Source: Ref 38

(a) Converted from weight loss data, assuming cast densities of 7.29 g/cm^3 for tin, 7.39 g/cm^3 for babbitt, 8.90 g/cm^3 for 50-50 solder, and 9.28 g/cm^3 for 40-60 solder.

Acids. Tin may be corroded by acidic aqueous solutions of pH less than 3 or by less acidic solutions containing compounds that form stable complex ions with tin. The corrosion rate is also highly influenced by oxygen concentration and the presence of metallic impurities in the tin or by the acid that can concentrate on the surface and facilitate the cathodic half reaction.

Table 4 compares the corrosion rates for tin samples exposed vertically in various acids open to the air at 30 °C (85 °F). The greater weight loss over the 96-h period was largely attributed to the access of oxygen to the solutions.

Table 4 Corrosion rate of tin in 0.1 *N* acids at 30 °C (85 °F) exposed vertically in solutions open to air

Acid	Average penetration rate[(a)]

Lactic	0.24	9.4	0.21	8.3

Source: Ref 39

(a) Converted from weight loss data, assuming a tin density of 7.29 g/cm^3.

The following general comments concern the effects of other acids (Ref 25). Hot hydrobromic (HBr) and hydroiodic (HI) acids rapidly attack tin, but the rate of attack is slow with HF. Tin is slowly attacked by $HClO_2$ and is readily attacked by $HClO_3$. Sulfurous acid (H_2SO_3) attacks tin, but sodium acid sulfite ($NaHSO_3$) is noncorrosive. Pyrosulfuric acid ($H_2S_2O_7$) and chlorosulfonic acid (SO_2ClOH) react rapidly with tin; nitric acid (HNO_3) reacts rapidly with tin over a wide range of concentrations, and the reaction is complex.

Bases. Tin may be dissolved by alkaline solutions, with the production of soluble stannates or stannites. Corrosion will usually follow if the surface oxide layer can be dissolved; this will occur with pH greater than 12 and may occur at pH values down to 10. When corrosion is possible, its rate is governed by the temperature and the rate of arrival of oxygen or other oxidizing agents to the initial surface and is not greatly affected by the character of the alkali in long periods of immersion. However, in intermittent immersion, the corrosion rate is affected by the nature of the alkali and its concentration because these affect the time for removal of the oxide film. The corrosion rates of tin in various alkaline solutions exposed to air at 60 °C (140 °F) are summarized in Table 5.

Table 5 Corrosion rate of tin in alkaline solutions exposed to air at 60 °C (140 °F)

Concentration of solution, %	Penetration rate[(a)]							
	Na_3PO_4		Na_2CO_3		Na_2SiO_3		NaOH

0.25	0.26	10.2	0.27	10.6	0.12	4.7	0.24	9.4

Source: Ref 40

(a) Converted from weight loss data, assuming a tin density of 7.29 g/cm^3.

Hydrogen evolution does not occur on a tin surface in alkaline solutions. Thus, exclusion of oxidizing agents, including air, can provide complete protection unless the tin is in contact with another metal on which hydrogen evolution can occur. Additions of oxygen absorber can prevent corrosion even without the exclusion of air, but they must be replenished. Small additions of oxidizing agents to alkalies stimulate corrosion, but sufficiently large additions can be completely effective. Soluble chromates are particularly effective in this way. Saturated NH_3 solutions do not attack tin, but more dilute solutions behave like other alkaline solutions of comparable pH.

Other Liquid Media. Milk and milk products are usually nonreactive with tin, although a long period of stagnant contact may produce local corrosion (Ref 41). Sulfide solutions and materials containing sulfur dioxide (SO_2) as a preservative produce sulfide stains, but the rate of metal loss in low. Beer dissolves a trace of tin from freshly exposed metal. Although this may cause an objectionable haze in the beverage, the action usually ceases within a short period. To avoid this effect, the tin surfaces can be passivated by using alkaline chromate solutions.

Most organic liquids, including ethers, alcohols, ketones, esters, hydrocarbons, and chlorinated hydrocarbons, are inert toward tin in the absence of water (Ref 25). However, a reaction was reported between tin and lower alcohols at elevated temperatures, and when mineral acidity can arise, as with chlorinated hydrocarbons containing water, there may be some corrosion (Ref 42). Animal, vegetable, or mineral oils and fatty acids are also essentially inactive, and the absence of any catalytic action of tin on their oxidation makes tin or tin-coated vessels suitable for these products.

Galvanic Behavior. When immersed in electrical contact with a more noble metal, such as copper or nickel, tin is much more likely to be corroded, and any loss of metal will be faster, with an increase in the number of locally corroded spots in conditions favorable to local corrosion. However, contact with such metals as aluminum or zinc can prevent corrosion of tin entirely, and a tin coil or vessel can be protected by joining it to a strip of one of these metals. The

galvanic-corrosion behavior of tin and tin-lead alloys in contact in seawater with numerous alloy steels and other structural materials is summarized in Table 6.

Table 6 Seawater corrosion of galvanic couples

Source: Ref 38

□ The corrosion of the metal under consideration will be reduced considerably in the vicinity of the contact.
○ The corrosion of the metal under consideration will be reduced slightly.
△ The galvanic effect will be slight with the direction uncertain.
■ The corrosion of the metal under consideration will be increased slightly.
▲ The corrosion of the metal under consideration will be increased moderately.
● The corrosion of the metal under consideration will be increased considerably.

S Exposed area of the metal under consideration is small compared with the area of the metal with which it is coupled.
E Exposed area of the metal under consideration is approximately equal to that of the metal with which it is coupled.
L Exposed area of the metal under consideration is large compared to that of the metal with which it is coupled.

Source: Ref 38

Passivation of Tin. Tin can be readily passivated with or without an applied potential. The solutions most frequently used are the strongly oxidizing chromate solutions, which produce a thin, tenacious oxide layer that is quite protective. This film is 40 to 50 Å (16 × 10^{-8} to 20 × 10^{-8} in.) thick when prepared by immersion in an alkaline chromate solution at 80 to 90 °C (175 to 195 °F) for 15 min (Ref 43). Anodic passivation with a current density of 500 A/dm^2 (32 A/$in.^2$) for 5 s in 0.5% sodium hydroxide (NaOH) forms a 300-Å (12 × 10^{-7}-in.) thick film. In 0.005 *M* potassium chromate (K_2CrO_4) solution, SnO is oxidized to SnO_2 above a potential of 0.2 V versus an Ag/AgCl electrode, and the oxide continues to thicken even after the oxygen evolution potential is reached. The passivation behavior of tin in solutions of phosphoric acid (H_3PO_4) (Ref 44), NaOH (Ref 45), sodium borate ($NaBO_2$), and sodium carbonate (Na_2CO_3) (Ref 46) has also been studied, and is reviewed in detail in Ref 25.

Soft Solders

Most soft solders contain from 2 to 100% Sn, with the balance consisting of lead, although some special-purpose solders substitute silver or antimony for some or all of the lead. Two features are particularly relevant to the corrosion behavior of solders with regard to their function as a joining material. First, fluxes are usually used, and, second, the solder exposure areas are usually much smaller than the area of the materials being joined.

By nature, fluxes function as oxide removers and may contain hygroscopic products that, if not removed, will promote corrosion. A mild flux, such as pure natural resin, is inactive at normal (room) temperatures and therefore has a harmless residue.

More powerful fluxes may consist of natural resin with additions--for example, chlorides and bromides--or mixtures of chlorides, H_3PO_4, and derivatives. Residues from such fluxes must usually be completely removed by mechanical wiping or with solvents.

The area effect can be minimized by coating the joined metals with tin or tin-lead alloys. However, the suitable design of joints and the formation of protective corrosion products over the solder often permit the satisfactory use of soldered joints in conditions that may at first appear hostile.

Simple binary tin-lead solders consist essentially of eutectic mixtures, and their corrosion behavior is similar to that for either metal, with the overall behavior similar to that of the predominant metal. Both metals are attacked by acids and alkalies, but the presence of lead, which forms many more insoluble compounds than tin, creates further possibilities for the formation of protective layers in near-neutral aqueous media. The addition of other elements has not been found to affect the corrosion resistance of tin-lead alloys appreciably (Ref 2). Also, the behavior of lead-free solders containing silver or antimony with tin does not differ greatly from that of pure tin.

Atmospheric Corrosion. Even small additions of lead to tin impair the retention of its bright reflective surface in common atmospheres. With increasing lead content, the appearance of soldered joints becomes increasingly dull, like that of lead. However, destructive corrosion (except effects from flux residues) is highly unusual. On rare occasions, within enclosed spaces, condensed pure water may extract lead, but more common causes of trouble are volatile organic acids. Acetic acid (CH_3COOH) vapors from wood or insulating materials and formic acid (HCOOH) or other acids that may come from insulating materials may attack lead-containing solders to produce a white incrustation and cause serious destruction of metal. Where such attack occurs, substitution of a solder with a higher tin content may eliminate the problem.

Contact of solder with other metals can impose a serious risk in conditions of exposure to sea spray or where pockets or crevices can trap moisture or flux residues. In most atmospheric conditions, the formation of lead sulfate ($PbSO_4$) protects the solder. However, in chloride pollution conditions, nickel, copper, and their alloys are likely to be cathodic to solder. Zinc tends to be strongly anodic to soft solders, but correctly designed zinc roof coverings appear to suffer no deterioration at the soldered joints (Ref 2).

Immersion. Natural waters and commercial treated waters that are aggressive to lead are likely to corrode solder at a rate that increases slowly, in proportion to its lead content, up to about 70% Pb, then more rapidly at higher lead contents. Selective dissolution of lead can also occur in distilled, demineralized, or naturally soft waters, causing serious weakening of joints (Ref 2). In the general run of commercial waters, the ability of lead to form insoluble oxides, sulfates, and carbonates usually protects solders against serious attack. Although rare, selective dissolution of tin has been reported during prolonged contact of solders with solutions of anionic surface-active agents.

When freshly exposed to water, solders are anodic to copper, but soldered joints in copper pipes are widely used without trouble in conventional commercial and domestic cold- and hot-water systems. Despite this generally good corrosion resistance, it has been demonstrated that, under adverse conditions, lead may be leached from the commonly used 50Sn-50Pb plumbing solder into water traveling through the pipe; this is a cause of increasing concern (Ref 47, 48). The lead content of water passing through soldered copper pipes is usually less than that recommended by various regulatory authorities, although higher values may be found in new installations and in some soft water areas (Ref 48). Public concern about all sources of lead in the human diet is well documented in numerous publications, and in some countries, including the United States, legislative action has been undertaken to prohibit the use of lead-containing solders and to tighten existing water quality standards (Ref 49).

Soldered joints in brass usually perform well in domestic waters, but good joint design is imperative. In automobile radiators in which there are no inhibitors, ethylene glycol, although not directly aggressive, does appear able to detach protective deposits that may form on soldered joints. Properly tested and approved inhibitors avoid this problem. Sodium nitrite ($NaNO_2$), which is used as an inhibitor for some metals, will attack solders and must be used in conjunction with sodium benzoate ($NaC_7H_5O_2$).

In seawater or uninhibited brines, the high conductivity and predominance of chloride makes galvanic action at a soldered joint more likely to continue destructively, and soldered joints in copper, nickel, and their alloys may need protection by coatings. Although tin or tin-coated metals can be used in contact with aluminum alloys even in salt water, the soldering process introduces sufficient aluminum to the solder to render it susceptible to intergranular corrosion. If tin-zinc solders are used, the zinc can prevent the serious embrittling action, although some corrosion will still occur under moist conditions.

Pewter

By definition, modern pewter is an alloy that contains 90 to 98% Sn, 1 to 8% Sb. 0.25 to 3% Cu, and a maximum of 0.05% Pb and As (Ref 50). Material that conforms to these standards has about the same degree of corrosion resistance to ordinary atmospheres as pure tin. Alloys within this range are widely used for decorative items, containers, and flatware. Indoors, they retain a bright, white luster in the same manner as pure tin. Because contamination from fabrication residues can deteriorate the protective oxide, care should be exercised in finishing to remove residues from soldering fluxes and cleaning solutions. Regular, simple washing with a mild soap solution will ensure that the surface remains in good condition.

Pewter tankards and plates also have about the same degree of corrosion resistance to foods and drinks as tin does. With the normal contact time, the amount of tin dissolved by beer is insufficient to cause a haze. However, citrus juices or vinegar will etch a pewter surface if contact is maintained for more than an hour. Undisturbed neutral salt solutions may produce black spots and, later, local pitting. Strong alkaline cleaning agents may also etch the surface.

In years past, pewter alloys contained lead in sufficient quantities to affect its corrosion resistance significantly, for example, by producing a dark patina during atmospheric exposure. Modern pewter can be chemically treated to reproduce this patina. Several proprietary processes are available, including those based on immersion in iron chloride ($FeCl_3$) or sodium nitrate (Na_2NO_3) solutions or acidic solutions of copper and arsenic (Ref 51, 52).

Bearing Alloys

The most widely used babbitt bearing alloys are usually classified as tin- or lead-base and have composition ranges within the following limits:

Alloy addition	Composition, %	
	Tin-base	**Lead-base**
Tin	65-91	0-20
Lead	0.35-18	63 (min)
Antimony	4.5-15	10-15
Copper	2-8	1.5 (max)

The tin-base alloys are much more corrosion resistant against the action of the acids contained or formed in lubricating oils (see the article "Tin and Tin Alloys" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Volume 2, *ASM Handbook*). An addition of as little as 3% Sn in lead appears to prevent corrosion from the development of oil acidity (Ref 53).

In some instances of marine use, the formation of a hard, crusty oxidation product has been observed on tin-rich bearings (Ref 54). When free access of salt water to a bearing is possible, the cathodic relationship of the babbitt alloys to steel renders them unsuitable, and bearing alloys such as Zn-70Sn-1.5Cu are preferred (Ref 2).

Some aluminum-base alloys containing 5 to 40% Sn and 0.7 to 1.3% Cu have also found use as bearing alloys in automobiles. These alloys are manufactured using thermal treatments designed to produce structures that avoid a continuous network of the tin in order to obviate the risk of susceptibility to corrosion by the presence of moisture (Ref 55). With normal lubrication, the aluminum-tin alloys appear to be as fully resistant to corrosion as the tin-base babbitt alloys. The aluminum-tin alloys, however, are not suitable for exposure to wet conditions.

Other Tin Alloys

Tin-Copper. Alloys in this group are all copper-base and consist mainly of bronzes, gunmetal, and brass that contains tin additions. Understandably, their corrosion behavior in air is based on the behavior of copper, which tends to develop a layer of basic green salts (mainly sulfates), that is adherent, protective, and has a pleasing appearance. More information on the corrosion resistance of copper alloys is available in the article "Corrosion of Copper and Copper Alloys" in this Volume.

Atmospheric Corrosion. Early studies were conducted on Cu-6.3Sn-0.08P wire and Cu-6.3Sn-0.08P-0.5Zn sheet in rural, suburban, urban, industrial, and marine environments for 1 year (Ref 56). Evaluations included weight gains as well as changes in tensile strength and electrical resistance. The bronze samples ranked consistently high among the materials tested, as indicated by the tensile strength data shown in Table 7.

Table 7 Tensile strength loss in copper alloys after exposure for 1 year in various environments

Environments included industrial, marine, rural, suburban, and urban locations; data are averages for all five environments.

Alloy	Strength loss, %
Tin bronze (6% Sn)	1.2
High-conductivity copper	2.4
Aluminum bronze (3.5% Al)	2.1
70-30 nickel-copper	3.2
60-40 copper-zinc	18.4
70-30 copper-zinc	8.6

Source: Ref 57

A more extensive study covering 20 years and seven sites compared the behavior of a variety of alloys, including phosphor bronze (Cu-7.85Sn-0.03P), admiralty brass (Cu-29.01Zn-1.22Sn), and a nickel-tin bronze (Cu-28.6Ni-1.04Sn-0.55Zn) (Ref 58). Weight changes were used to assess corrosion behavior, along with changes in electrical resistance and tensile strength. Some representative data are given in Table 8. Small tin additions also impart dezincification resistance to brass.

Table 8 Tensile strength loss in copper alloys after exposure for 10 years at four sites

Exposure site	Strength loss, %			
	Copper	**Tin bronze (8% Sn)**	**70-30 copper-zinc**	**70Cu-29Zn-1Sn**
Heavy industrial	5.9	7.2	30.9	9.0
Marine, heavy industrial	6.3	8.0	28.2	7.9
Severe marine	7.6	5.7	8.0	2.5
Rural	3.1	3.1	3.2	2.2

A similar study involved exposure of screen wire cloth at four sites for up to 9 years (Ref 59). A Cu-2Sn bronze was found to exhibit the lowest strength losses at all sites from a group of alloys that included brasses, aluminum bronze, and nickel-copper. Outstanding corrosion resistance of a Cu-2Sn bronze exposed to sulfur-bearing gases in railway tunnels was also reported (Ref 60.)

Another investigation compared the behavior of five stainless steels and a low-alloy steel with that of a Cu-4.38Sn-0.36P bronze exposed at tropical inland and seacoast sites for 8 years (Ref 61). The coastal site was more aggressive toward the bronze, which showed higher weight losses at both sites than the stainless, but the low-alloy steel was more severely attacked. However, the bronze was free of pitting and suffered no loss in strength, which was not the case with some of the stainless steels. In Ref 62, these researchers summarized the results of 16-year exposures on three tin-containing alloys (Cu-4.38Sn-0.36P, Cu-39Zn-0.84Sn, and Cu-40Zn-1Fe-0.65Sn) exposed at marine, inland semirural, and two tropical sites. In general, the copper alloys resisted corrosion in the tropical zones, although less so at coastal sites as compared to inland sites. The tin-containing alloys were as good as, or slightly superior to, the other alloys.

More recent work by the same investigators included previous data plus additional information on the following cast bronzes: Cu-5Sn-5Pb-5Zn, Cu-6Sn-2Pb-3Zn-1Ni, Cu-9Sn-3Zn-1Ni, and Cu-3Sn-2Zn-6Ni (Ref 63). The conclusions were much the same as before. The later work included a study of the effect of coupling phosphor bronze to equal areas of numerous other metals, and this work indicated that the coastal sites were 4 to 8 times more aggressive than the inland sites. Evaluation of the effect of corrosion on the solderability of a Cu-2Sn-9Ni alloy was reported by workers at Bell Telephone, who found this material to be superior to both nickel-silver and an 8% Sn phosphor bronze (Ref 64).

Alloys in the Cu-Sn-Al system were evaluated, and those alloys containing at least 5% each of tin and aluminum were found to have good corrosion resistance in rural, urban, and industrial environments (Ref 65). The most promising material was Cu-5Sn-7Al. Another researcher noted that such alloys could be brittle, but that the addition of 1% Fe and 1% Mn overcame this difficulty without detracting from the corrosion resistance of the alloy (Ref 66).

Tin-Silver. In the mid-1930s, tin-silver alloys were assessed as potential replacements for sterling silver (silver-copper alloy) in decorative applications (Ref 67). In this work, an Ag-7.5Sn alloy was found to show improved corrosion resistance over pure silver in several environments. In a later extension of this work, alloys with up to 10% Sn were tested in atmospheres containing H_2S, SO_2, and indoor air as well as for resistance to salt and oxidation upon heating in air (Ref 68). Comparison to sterling silver showed the tin-silver alloys to be at least as good as the sterling alloys, and in some cases even better. Specifically, their resistance to chloride attack was considerably better, and less discoloration occurred upon heating in air. Also, preoxidation of the tin-silver alloys improved resistance to attack by sulfur-containing atmospheres.

Tin and Tin-Alloy Coatings

Tin coatings can be applied by various processes, including hot dipping, electrodeposition, spraying, and chemical displacement. Electrodeposits can be matte or bright as plated, and matte deposits less than 8 μm (0.3 mils) thick can be brightened by momentary fusion. The latter can be effected by conductive or resistive heating in air or by immersion in a suitable oil.

In the standard electrodeposition process, alkaline stannate, acid sulfate, or fluoborate solutions are all widely used. The alkaline solutions give smooth, matte deposits, but the acid solutions usually require organic addition agents to produce smooth, coherent coatings. If improperly controlled, these agents can increase the risk of dewetting during soldering or flow melting.

The ranges of coating thicknesses that are practical for the various processes are as follows (Ref 2):

Process	Thickness	
	μm	**mils**
Chemical replacement	Trace-2.5	Trace-0.1
Flow-melted electrodeposition	0.4-7.5	0.02-0.3
Electrodeposition, general	2.5-75	0.1-2.9
Hot dipping	1.5-25	0.06-1
Spraying	75-350	2.9-13.6

Coatings applied by any method may contain pores that will expose the base metal. Porosity should be minimal for electrodeposited and hot-dipped coatings thicker than 15 μm (0.6 mils) (Ref 2). However, the behavior of the coating will be strongly influenced by the relative polarity of tin and substrate, by the nature of any intermetallic layers formed by reactions between these, and by the extremely low rate of corrosion of tin in alkaline and mildly acidic media in the absence of oxygen or other cathode depolarizers.

Because deposits less than about 12 μm (0.5 mils) thick are not likely to be pore free, the heaviest practical deposits should be used when tin is specified for corrosion resistance. Table 9 lists recommended tin coating thicknesses for quality tin coatings for various service conditions.

Table 9 Recommended tin coating thicknesses for typical applications

Service condition	Thickness range		Typical applications
	μm	mils	
Very mild (little or no exposure to atmospheric conditions)	1.3-2.5	0.05-0.1	Insulated copper wire; pistons and other lubricated machine components
Mild (exposure to relatively clean indoor atmospheres)	2.5-5.0	0.1-0.2	Connectors, wires, etc., plated primarily for immediate solderability or where storage periods are short
Moderate (exposure to average shop and warehouse atmospheres)	3.8-7.6	0.15-0.3	This range is considered best for parts that must be reflowed: connectors, circuit boards, wire, busbars; deposits heavier than 7.5 μm (0.3 mil) may dewet.
	7.6-12.7	0.3-0.5	Connectors, fasteners, busbars, wire, transformer cans, chassis frames; adequate for good shelf life and in service
Severe (exposure to humid air, mildly corrosive industrial environments)	12.7-25.4	0.5-1.0	Connectors, wire, gas meter components, automotive air cleaners; adequate as a nitride stop-off
Very severe (exposure to seacoast atmospheres; contact with certain chemical corrosives)	25.4-127	1.0-5.0	Water containers; oil-drilling pipe couplings

Source: Ref 69

Tests conducted by the Metal Finishing Supplies Association (MFSA) showed that bright acid tin deposits generally perform better than the matte tin deposits in salt spray corrosion tests (Ref 69). However, no published specifications recognize any difference between the corrosion performance of these processes. Similarly, because tin is cathodic to almost all of the commonly used base metals and undercoating metals, the MSFA recommends that the same in tin coating thicknesses be applied to any of the common base metals. Also, the use of a copper or nickel undercoating does not justify the use of thinner tin deposits (Ref 69).

Tin Coatings on Steel. Tin on steel is widely used in packaging. The single most important product of this type is tinplate. Modern tinplate is a highly developed, sophisticated product that is produced at high speeds to yield a coiled, thin, low-carbon steel strip carrying a very thin (0.1 to 2 μm, or 0.004 to 0.08 mils) tin coating on each side. Because of the importance of tinplate, its preparation and properties as well as its performance as a container for food and food products will be discussed in the section "Tinplate" in this article.

This section will primarily deal with heavier tin coatings that are usually applied to individual components by batch processing for nonpackaging applications, such as food-processing equipment, electrical and electronic components, wire, and fasteners. Unless otherwise stated, these coatings, unlike tinplate, have not been subjected to fusion or reflow treatments and are therefore free of the iron-tin intermetallic layer, which can exert profound effects.

One study compared the behavior of 25-μm (1-mil) thick plated layers of tin, 80Sn-20Zn, and zinc on steel at three sites in Nigeria for 2 years (Ref 70). Samples were exposed at 30° to the horizontal, about 1.2 m (47 in.) above ground, facing south and in sheltered exposure where they were supported vertically inside ventilated box. The test results are given in Table 10.

Table 10 Corrosion rate of 25-μm (1-mil) thick coatings on steel at three tropical sites after 2 years of exposure

Coating	Material loss, full exposure test					
	Jungle		**Town**		**Coast**	
	μm/yr	**mils/yr**	**μm/yr**	**mils/yr**	**μm/yr**	**mils/yr**
Tin	0.18	0.007	1.02	0.04	3.02	0.12
80Sn-20Zn	0.46	0.018	1.35	0.053	2.87	0.113

Source: Ref 70

An evaluation of various protective coatings based on many years of testing is summarized in Ref 71, in which a 12-μm (0.5-mil) thick coating is concluded to be a practical minimum for reasonable protection of steel in a mild indoor exposure; for outdoors, the minimum coating thickness should be 50 μm (2 mils).

The Protective Coatings (Corrosion) Subcommittee of the Corrosion Committee of the British Iron and Steel Research Association reported test results after 12 years of exposure in an industrial area (Sheffield), two marine atmospheres (Colshot and Congella, South Africa), and a rural area with heavy rainfall (Flanwryted Falls) (Ref 72, 73). These data, listed in Table 11, indicated that tin deposited by any of several methods appeared more protective in the industrial area than at the other sites. This behavior was attributed to the production of protective corrosion products in the pores of the coatings. Similar observations have been reported (Ref 74), and similar evaluations have been conducted using accelerated corrosion tests and outdoor exposure in urban Berlin (Ref 75). One conclusion, based on 1 year of exposure, was that reflowing of tin coatings improved their corrosion resistance, except in salt spray exposure. Also, deposits from an acid electrolyte were said to be better than those from a stannate bath.

Table 11 Summary of atmospheric corrosion tests on tin-coated steel at four exposure sites

Coating method	Sheffield		Flanwryted Falls		Colshot		Congella	
	T[(a)]	***L***[(b)]	***T***	***L***	***T***	***L***	***T***	***L***

(b) *L*, Lifetime in years of coating as determined by rust appearing on more than 5% of the specimen.

(c) Average of duplicate results that did not agree well.

Additional atmospheric corrosion test results have been reported (Ref 76, 77, 78, 79). In one study, data were summarized from 10 years of exposure for tin-plated steel in industrial, marine, and rural atmospheres that included estimates of the added cost of SO_2 pollution. Another study included tropical exposures of samples in China in two environments. In the first environment, samples were mounted at 45° outdoors facing south. In the second, the racks were sheltered from solar radiation, wind, and rain. Recommendations based on 58 months of testing were that matte tin coatings 25 μm (1 mil) thick should not be exposed to either environment for more than 1 year and that the life of similar coatings 32 μm (1.2 mils) thick would be less than 2 years (Ref 79).

The general conclusion, based on results of most of the above outdoor studies, was that the corrosion resistance of tin coatings, that is, their protection of steel, was not very high (Ref 22). In addition, this is reflected in the international standard ISO 2093-1973 covering tin coatings, which carries the following tin coating thickness recommendations:

Type of service	Minimum tin thickness			
	On steel		**On nonferrous metals**[(a)]	
	μm	**mil**	**μm**	**mil**
Exceptionally severe	30	1.2	30	1.2
Severe	20	0.8	15	0.6
Moderate	12	0.5	8	0.3
Mild	4	0.2	4	0.2

(a) Except brass

Tin Coatings on Nonferrous Metals. Tin coatings are widely used on nonferrous substrates, usually for one or more of the following reasons:

- Improvement and retention of solderability
- Excellent compatibility (low toxicity) with foods
- Prevention of galvanic effects between dissimilar metals
- Low electrical resistance

Not surprisingly, copper and copper-base alloys are the most frequently tinned nonferrous materials. Tin tends to be anodic to copper and copper alloys, including the intermetallic tin-copper compounds. Therefore, accelerated corrosion of the tin coating might be expected in aqueous environments. Indeed, this is sometimes evidenced by black spots on a tin coating that result from localized corrosion around discontinuities. Although normally associated with total aqueous immersion, these black spots can also appear on outdoor exposure involving cyclic condensation (Ref 22).

Deterioration of the solderability of tinned copper during aging has been studied by many researchers, and accelerated test procedures have been devised to simulate the effect (Ref 80, 81, 82). Similarly, changes in the contact resistance of tin coatings have been related to increases in the thickness of the oxide film on its surface (Ref 83).

Special mention should be made of the corrosion behavior of tin coatings on brass in ordinary atmospheres. Zinc diffuses through tin coatings fairly rapidly; significant zinc levels are reached on the surface of a coating thickness of 7.5 μm (0.3 mil) in about 1 year (Ref 34). Zinc at the surface oxidizes readily to form white corrosion products that adversely affect its solderability and contact resistance. To avoid such problems, a 2.5-μm (0.1-mil) thick barrier layer of either copper or nickel is recommended over the brass (Ref 84).

Immersion Tin Coating. Contrary to the standard electromotive force (emf) series of metals, tin can be applied by immersion (chemical displacement) on copper. This is done by using a cyanide or a thiourea type of solution.

An outstanding application is tinning of the inside of copper tubing. Such tubing in coil form is used in water coolers. The tin prevents delivery of greenish water from new coolers and eventually disappears. By then, the copper surface has become conditioned to deliver water appearing as it did when it entered the cooler.

Tin-cadmium alloy coatings for the corrosion protection of tin were first studied by plating duplex coatings of tin on cadmium and then heat treating. These and later electrodeposited surfaces (Ref 85) were found to have phenomenal resistance to salt spray tests, and they were successfully used for some time to protect the engine components of naval aircraft (Ref 86).

Tin-cadmium coatings resemble tin-zinc coatings in appearance and behavior. Because cadmium is less effective at sacrificially protecting steel exposed at pores, the optimum cadmium content in the coating ranges from 25 to 50%. The initial electrolyte development discussed in Ref 85 was followed by an investigation of a range of alloys; it was concluded that the alloys performed better than cadmium alone in marine environments (Ref 87). Another study found that the attack on tin-cadmium coatings by organic vapors was less than for pure cadmium (Ref 88). In addition, tin-cadmium was found to be superior to tin-zinc when in contact with jet fuels or in hot synthetic oils. This work was supplemented by that described in Ref 89, which suggests that tin-cadmium alloys, particularly with a chromate surface treatment, performed better than cadmium coatings of the same thickness.

More recently, tin-cadmium alloy coatings were shown to provide better corrosion resistance to steel than duplex coatings of tin and cadmium (Ref 90). Lastly, zinc or tin-zinc coatings were found to be more protective to steel in industrial atmospheres than tin on cadmium or cadmium on tin, but this behavior was reversed in a marine environment (Ref 91).

Tin-Cobalt Coatings. As expected, the properties of tin-cobalt electrodeposits are similar to those for tin-nickel. Intermetallic deposits of SnCo (Ref 92, 93) or SnCo mixed with Sn_2Co (Ref 94) have been produced, and proprietary plating systems have been patented. These deposits are bright and are similar to chromium plate; most studies of their performance have concerned systems of steel coated by nickel, with a thin film of tin-cobalt applied to obtain a bright finish.

An evaluation of tin-cobalt coatings for their resistance to salt spray, NH_3, and in copper-accelerated salt spray (CASS) tests revealed that the deposit was resistant to all of these environments and was more ductile than tin-nickel electrodeposits (Ref 95).

Two researchers also tested systems of nickel plus tin-cobalt in CASS and outdoor exposure tests (Ref 96, 97). Their conclusions were similar even though different baths were used and minor differences in the deposits were obtained. Thus their corrosion resistance was comparable to that for a nickel-chromium system in all but the more severe conditions.

Corrosion tests on coatings of 0.2-μm (0.8-mil) tin-cobalt over duplex bright nickel were compared with the same thickness of chromium (Ref 98). The tin-cobalt appeared markedly inferior to chromium in outdoor exposure and wear resistance, but was reasonably satisfactory as a substitute for decorative chromium for indoor use.

Tin-Copper Coatings. Tin alloys close to the Cu_3Sn intermetallic composition (40 to 45% Sn) were once used as a material for mirrors; hence the name speculum. These alloys resemble silver in brightness and appearance; they find some use as tableware and on bathroom fixtures, but are not used outdoors, where they rapidly turn dull and gray. However, even the indoor corrosion resistance of the alloy is seriously impaired if the composition is not optimum ($\sim$42% Sn), and the subsequent need for close control of plating conditions has prevented large-scale development of the coating.

Tin-bronze deposits containing about 12% Sn were reported to be superior to copper as an undercoat for nickel-chromium coatings with regard to weathering behavior (Ref 99, 100). Some results were also reported with tin-copper coatings over steel in industrial and marine environments (Ref 101).

Tin-lead coatings with a wide range of composition are applied by hot dipping or electrodeposition. Steel strip coated with tin-lead alloys by hot dipping and sold as sheet or coil carries the general designation of terneplate. The tin content varies from 2 to 20%. In general, the higher the tin content, the lower the porosity of the terneplate and therefore the greater the protection afforded to the substrate. Like tin coatings, tin-lead does not offer any galvanic protection to steel in the atmosphere; protection against rusting depends on coating continuity and on the formation of protective corrosion products. A comparison of the behavior of a Pb-12Sn coating with pure tin and lead revealed that both lead-containing coatings developed white films believed to be $PbSO_4$ (Ref 72).

In a more comprehensive study, a range of electrodeposited tin-lead coatings obtained with different bath additives was evaluated (Ref 57). The performance of a Pb-5.5Sn coating in salt spray and outdoor testing was found to be superior to pure lead and lead-tin alloys containing tin additions of 7, 10, or 15%. The Pb-10Sn and Pb-15Sn alloys were comparable in behavior to pure tin. These results were partially supported by those of another study, which consisted of atmospheric exposures at three sites on electrodeposited lead and coatings of Pb-5Sn and Pb-14Sn (Ref 102). Superior protection was achieved with the tin-containing alloys at all sites, which included severe industrial, rural, and marine environments.

The results of tests on a number of commercial terneplate compositions in accelerated corrosion tests, SO_2, humidity, and salt spray as well as outdoor exposure in both industrial and marine environments are given in Ref 103. Performance was assessed largely on the degree of rusting of the underlying steel after 12 months of exposure. Lead-tin alloys showed greater resistance to chloride attack than lead-antimony alloys. It was also noted that coverage of the steel increased with the tin content of the alloy and that resistance of the coating to attack appeared to increase in both chloride-rich and humid conditions.

Tin-Nickel Coatings. Alloys containing 18 to 25% Ni can be deposited from a cyanide-stannate bath to give bright coatings with good resistance to HNO_3 (Ref 104). However, because of their high hardness and brittleness, no interest has been shown in these coatings. Similar results have been reported with a complex pyrophosphate bath (Ref 105). Primary commercial interest has centered on the intermetallic compound NiSn (containing about 67% Sn), which is readily deposited from mixed chloride/fluoride electrolytes (Ref 106, 107).

The NiSn intermetallic is metastable and does not transform to a mixture of other intermetallics unless it is heated (Ref 108). The deposit is hard, bright, and has reasonable solderability. It also has good wear resistance and remarkable resistance to attack by a wide range of solutions. For these reasons, tin-nickel coatings have found use as decorative corrosion-resistant finishes for balance weights, drawing instruments, pistons in automobile braking systems, and some food contact applications. Recommended coating thicknesses for this alloy coating have been specified in ISO 2179 1972 as follows:

Intended duty	Thickness	
	μm	**mils**
Severe environments	25	1
Moderate environments	15	0.6
Mild environments	8	0.3

For coatings on steel intended for moderate or severe service, an undercoat of copper, tin, or bronze with a minimum thickness of 8 μm (0.3 mils) is also specified, and porosity tests are required.

Studies of tin-nickel coatings showed them to be unaffected by atmospheres containing SO_2 or H_2S (Ref 109, 110, 111). This work also indicated that these coatings retained their brilliance more readily than nickel-chromium in positions sheltered from rain. Similar conclusions were reached in other investigations (Ref 112, 113), taking into consideration the undercoatings used for both alloy deposits on steel. On the other hand, nickel-chromium deposits were reported as superior to tin-nickel in marine environments (Ref 114).

Within the past 10 years, studies of the corrosion resistance of tin-nickel deposits have centered on their effect on the electrical contact resistance of this alloy, either alone or with a thin coating of gold. The contact resistance of tin-nickel is sufficiently low to merit consideration for moderate-voltage applications (about 50 V), but too high for low-voltage uses. Several extensive studies have been reported in this field (Ref 115, 116). This effect on contact resistance is largely a

result of the insulating passive film that forms on SnNi and the high hardness of the material. An excellent review of the work in this field is available in Ref 22. It is generally agreed that tin tends to concentrate at the surface of tin-nickel electrodeposits, but no adequate explanation of the oxidation behavior of this alloy is currently available.

The resistance to attack of the coating by various acids and chemicals has been studied, and the results are given in Table 12, which also compares these with coatings of tin and nickel (Ref 117). Generally, the results show that tin-nickel has a high resistance to attack by acids, alkalies, and several neutral salt solutions. This behavior is attributed to the presence of a passive air-formed film.

Table 12 Corrosion resistance in various media of tin, nickel, and tin-nickel alloy

Solution[(a)]	Weight losses, mg			Change in appearance of tin-nickel coating
	Tin	**Nickel**	**Tin-nickel**	
1 *M* hydrochloric acid	61.5	41.5	24.8	Covered by adherent brown film
0.5 *M* sulfuric acid	19.5	25.6	14.5	Slightly darkened
1 *M* nitric acid	205.0	97.6	1.1	None
0.05 *M* sulfurous acid	0.2	725.0	0.5	None

Tin-Zinc Coatings. The general shortage of cadmium after World War II led to an interest in the possibilities of tin-zinc coatings for the protection of steel. One of the first studies to explore this possibility compared the behavior of tin-zinc alloy coatings containing 8 to 72% Zn with that of electrodeposited coatings of tin, zinc, and cadmium and with hot-dipped zinc (Ref 118). Coatings 8 to 25 μm (0.3 to 1 mil) thick were compared to exposures to a humidity cabinet, salt spray, and hot water. Coating failure occurred as a result of zinc dissolution such that deposits containing low percentages of zinc did not protect the steel from rusting at pores, but coatings with more than 40% Zn soon developed voluminous white corrosion products at the surface. The best overall results were indicated for tin-zinc coatings with compositions near Sn-25Zn, which were superior to zinc and cadmium in salt spray and were superior to zinc but about equal to cadmium in the humidity test. This work also suggested that chromate passivation treatments improved the overall performance of tin-zinc coatings, making them less susceptible to staining by finger or grease marks. This study was followed by a number of others that reached the same general conclusion about the usefulness of tin-zinc coatings for protecting steel against atmospheric corrosion (Ref 71, 75, 119, 120).

Another comprehensive study compared coating corrosion resistance in urban and marine environments (Ref 121). The order of merit (best to worst performance) in urban exposures was zinc, 50Sn-50Zn, 80Sn-20Zn, and cadmium. For marine exposures, 50Sn-50Zn and zinc were superior, while 80Sn-20Zn and cadmium performed about the same. Details on the results of the marine exposures are given in Table 13.

Table 13 Relative ability of different coatings to prevent the rusting of steel in a marine atmosphere

Coating	Months to first appearance of rust for coating thicknesses indicated, μm		
	7.5	**12.5**	**25**
Zinc	18	33	36
Passivated zinc	18	18	36
50-50 tin-zinc	25	35	>48
Passivated 50-50 tin-zinc	29	35	>48
80-20 tin-zinc	9	18	36
Passivated 80-20 tin-zinc	13	21	36
Cadmium	8	21	34
Passivated cadmium	13	21	25
Tin	1	1	1

Source: Ref 121

The effectiveness of tin-zinc coatings in protecting steel nuts and screws was studied by exposing these coatings to suburban, industrial, and marine environments in contact with aluminum plates (Ref 122). Although failure of the 80Sn-20Zn coating was indicated by rusting of the steel more quickly than with zinc or cadmium, the presence of the 80Sn-20Zn was observed to prevent rapid attack of the aluminum. Another advantage was the absence of hygroscopic products on the tin-zinc; that is, rings of moisture tended to form around the corrosion products on nuts and screws coated with zinc and cadmium, but this behavior was not noted with the 80Sn-20Zn.

Tin-zinc alloys have also been used to solder aluminum (Ref 123). Again, it was found that corrosion resistance of the solders in a tropical atmosphere was a function of zinc content. After 9 months of exposure, the 80Sn-20Zn alloy appeared to be the most resistant to attack and had the best retention of strength.

In another study, contact resistance measurements were used to follow the progress of corrosion on binary alloys of tin with zinc, lead, antimony, and cadmium on steel in a rural outdoor atmosphere (Ref 124). It was noted that tin-zinc and tin-cadmium coatings maintained a lower contact resistance than equal thicknesses of tin, tin-lead, or tin-antimony alloys after 2 months of exposure.

The most recent studies with tin-zinc coatings explored the effects of four passivation treatments on the resistance to attack of a Sn-25Zn coating by a salt fog and in cyclic humidity (Ref 125). An electrolytic treatment using sodium dichromate ($Na_2Cr_2O_7$) was found to be superior to the others and was particularly outstanding in the salt fog. The other

treatments, in decreasing order of merit, used passivation based on electrolytic molybdate, electrolytic tungstate, and nonelectrolytic chromate solutions.

Another investigation concluded that tin-zinc solders exhibit a significant decrease in shear strength after immersion in 3% sodium chloride (NaCl)-0.1% hydrogen peroxide (H_2O_2) solutions (Ref 123). However, other soft solders, including tin-cadmium and tin-antimony alloys, also behaved in the same manner.

Tinplate

As noted earlier, the term tinplate is reserved for a low-carbon steel strip product coated on both sides with a thin layer of tin. For almost 200 years, tinplate has been the primary material used to make containers (tin cans) for the long-term storage of food. Most of the tinplate manufactured is used to make food cans, and nearly all food cans are made of tinplate.

Modern tinplate is much more sophisticated than a simple coating of tin on steel. To achieve the demanding deep-drawing properties necessary for the production of can bodies for two-piece can manufacture, the steel base for tinplate is often continuously cast using the most current technology. Inclusions or other defects in the steel may otherwise cause breakage in the can-body drawing operation. Because the economics of canmaking depend on high-speed operation using a continuous coiled strip, such breakage cannot be tolerated due to the lost production time; therefore, the steel must be as clean as possible.

In preparing the base steel, the metal is processed to strip form, the final step being a cold reduction that brings the strip to a thickness that is typically from 0.15 to 0.50 mm (6 to 20 mils). Next, the strip is annealed and then temper rolled to obtain the desired mechanical properties. At the final stage of temper rolling, textured rolls can be used to produce a special surface finish for particular applications. A cold reduction in place of temper rolling yields a product that is termed double reduced.

The coiled steel is now ready for the tinplate line. It is first welded to the end of the previous coil to form a continuous strip for processing. The strip passes through cleaning and pickling sections to prepare it for plating, then immediately through the plating cells, where up to 11.2 g/m^2 (1 g/ft^2) of tin is deposited. Any one of three different electrolytes can be used, depending on the other details of the installation, and strip speeds typically approach 600 m/min (1970 ft/min). More details of tinplate production and commerce are available in Ref 126, 127, 128, 129.

The production steps that typically follow plating create additional layers in the tinplate structure that significantly affect corrosion properties. Upon exiting the plating cells, the tinplate has a matte surface that is usually reflowed by momentarily melting the tin coating in a resistance or induction heating unit. In doing so, a thin layer of tin-iron intermetallic compound is formed at the tin/steel interface. Next, an extremely thin passivation film based on chromium oxide is created by immersion or spraying of chromic acid (H_2CrO_4) on the tinplate surface or by passing the tinplate through a solution of $Na_2Cr_2O_7$, with or without the simultaneous application of electrical current. Finally, a very thin, uniform layer of lubricant, usually either dioctyl sebacate or acetyl tributyl citrate, is electrostatically applied.

Therefore, as supplied to the canmaker, the typical tinplate product consists of five layers, the innermost being a steel sheet about 200 to 300 μm (7.8 to 11.7 mils) thick. This steel is covered on each side with perhaps 0.08 μm (0.004 mils) of tin-iron intermetallic compound. The next layer is free tin that is perhaps 0.3 μm (0.012 mils) thick, with a passivation film of about 0.002 μm (0.00008 mils) and an oil film also about 0.002 μm (0.00008 mils) thick. All five layers affect corrosion behavior.

General Properties. Although the unique corrosion properties of tinplate have kept it the material of choice for food cans, other useful properties should be mentioned. Until a few years ago, all food cans were soldered, and tin coatings were used quite often for their excellent solderability. Can welding has recently replaced soldering, and the favorable electrical contact properties of tinplate have made it very amenable to high-speed resistance welding.

The strength of the steel base gives tin cans the durability to withstand the filling, sterilization, and transportation phases of processing. Because a wide range of mechanical properties is possible, the steel base properties can be adjusted, for example, to maximize strength and stiffness, to maximize ductility and elongation, or to minimize directional properties.

Corrosion Resistance in Sealed Cans. A cursory glance at a seawater galvanic series would lead one to expect tin to be cathodic to steel. Therefore, with a very thin coating of tin, the rapid dissolution of iron at any plating pores, scratches, or other breaks in the coating would be anticipated, resulting in pitting corrosion and eventual perforation of the tinplate. Fortunately, inside the sealed can of food, the situation is very different.

The good performance of the tinplate food can begins with the ability of tin to form chemical complexes with a variety of organic liquids, especially those found in foodstuffs. This fact reverses the situation described in the preceding paragraph; therefore, tin becomes a sacrificial anode, greatly diminishing the rate of dissolution of the iron. Once in solution, the tin ions have a very strong inhibiting effect on iron dissolution because the tin may actually plate out on the exposed steel to form a thin surface layer of tin-iron intermetallic that would be more noble than the steel surface it covers (Ref 25).

With the available atmospheric oxygen limited to only that in the headspace (the volume between the top of the contents and the bottom of the can lid), dissolution of tin is usually rapid only at the very beginning of storage, that is, until the cathodic reaction involving this small amount of oxygen has gone to completion. This effect is desirable because it provides quick protection of the steel. Too large a headspace, however, might allow too much tin to be dissolved, which would allow iron dissolution and probably hydrogen evolution. Hydrogen evolution usually leads to swells, or bulging can ends, a condition the consumer has come to recognize as the sign of can failure. A similar situation applies if a leak in the can allows the free entry of oxygen; the contents are spoiled by iron dissolution, but swelling is not expected to occur.

The small amount of tin dissolved in the food passes easily and quickly through the human body with no known effect, although there is circumstantial evidence that tin is an essential element for human well-being. Too much tin, that is, of the order of 1000 ppm, in the food may cause gastric distress in sensitive individuals. This distress lasts only as long as the irritant is present, and no permanent damage is expected. As a precaution, most governmental regulations limit the tin content of food containers to well below this threshold, typically at a level of about 250 ppm. This lower level is not known to have an effect on any individuals and appears to provide a substantial margin of safety while assuring the effectiveness of tin in preserving the food.

Until a decade ago, food cans were typically of three-piece soldered construction. Recent concerns over the lead content of foods, however, resulted in the abandonment of soldering in favor of welded construction or of two-piece (no side seam) fabrication, even though this source of lead was probably a small component in the overall human intake of lead. Both of these newer techniques appear to produce improved can integrity in general, although the soldered tinplate container is capable of many years of safe, stable shelf life. Soldered construction is still used for dry packs, in which the absence of a liquid food component eliminates the migration of lead into the packed product, and of course for nonfood items, because there is no reason to change from a successful time-tested production method.

Can Corrosion Problems. Even with nearly 200 years of experience and some of the strictest quality control programs imaginable, the canning industry is not perfect. Although not all common, failures tend to be serious when they occur, because the economics of efficient food production depend on large, rapid production runs. The slightest misjudgment can result in a problem during long-term storage.

The first consideration in matching a given food product to the appropriate can has always been the thickness of the tin coating, as indicated above. Recent years have seen more extensive use of lacquers to provide an inert barrier against any metal dissolution (see the section "Lacquers" in this article). However, the inevitable defects in lacquer coverage make the tin coating the last defense against corrosion.

Tin is necessary for pale (uncolored or yellow) fruits and many vegetables to preserve the taste and color of the product. Suitable cans are made of plain (unlacquered) tinplate with a coating weight (the usual way of expressing the thickness) of 8.4 to 11.2 g/m^2 (0.8 to 1 g/ft^2). A special grade of tinplate called grade K uses an altered tin-iron intermetallic layer (probably thicker and more continuous over the tin/steel interface) to improve corrosion resistance with these products (Ref 2). Grade K tinplate then allows the use of tin coatings at the lower end of the thickness range.

Parenthetically, it might be mentioned that inorganic tin chemicals have been used as intentionally added preservatives for some food products that have been packed in containers other than tin cans. This fact emphasizes the importance of tin in preserving the organoleptic properties of foodstuffs.

Certain other vegetable packs, such as asparagus, green beans, and tomato-base products, would benefit from tin availability, but are strong detinners. This rapid dissolution of tin may produce an unsightly interior can surface or tin levels above the regulatory limit. The usual remedy is to use lacquer as an inert barrier, but this practice involves the

possibility of even more rapid and concentrated attack at any interior scratch or other defect in coverage. Double lacquering reduces this possibility. Dark fruit packs, such as cherries, behave similarly in that strong detinning may produce undesirable color changes, which can be controlled by double lacquering.

Beer and other beverages cannot tolerate iron or tin dissolution, because of taste degradation or cloudiness, respectively; therefore, these cans are fully lacquered with a two-coat system. Baby foods are similarly treated because of special concerns regarding metal pickup in such cases.

Dairy products can be stored in plain tinplate cans, but it is advisable to use a weak passivation film because dark stains may be produced. Cathodic (only) $Na_2Cr_2O_7$ and a Na_2CO_3 treatment have each proven successful for these packs.

A stronger-than-normal passivation film (or, more precisely, one with a higher metallic chromium content) is used to prevent staining from sulfur, which is a naturally occurring contaminant of some meat products and soups, for example. Tin sulfide stains may be unsightly on the can interior surface or may be protective enough of the tin surface to reverse the tin-iron polarity and cause rapid iron dissolution. Too thick a passivation film may adversely affect lacquerability; therefore, again, correct specification and quality control are needed to produce the required product. An alternative is special lacquers containing zinc compounds that react with the sulfur to form less objectionable, nonstaining sulfides.

Sulfur can also have a deleterious effect if present as an impurity in the base steel, as can copper, phosphorus, and silicon. In these cases, impurity control in steelmaking provides a usable base material. Various tests are used to provide the suitability of the complete tinplate product (see the section "Corrosion Testing of Coatings" in this article).

Still another source of sulfur is as a residual chemical contaminant in the foodstuff. Nitrate contamination is also possible as plant uptake from fertilizers. Nitrates and certain other naturally occurring and additive organic compounds can act as cathode depolarizers, which, by increasing cathodic activity, require an increase in anodic activity, that, is, tin dissolution, probably leading to early pack failure.

The wide variations in natural food products, even the same product produced in different locales, make it impossible to be more specific regarding container-product interactions. Tinplate makers and users always find it necessary to perform pack testing, that is, preparing larger samples of the canned product and observing their performance over several months of storage. Although this testing is expensive, there is no alternative, given the wide variations in product chemistry. A laboratory simulation test has recently been developed that may help in screening variables for subsequent pack testing (Ref 130).

Lacquers, also called enamels, are combinations of various resins modified with various additives (Table 14). These formulations (only the main ingredients are listed in Table 14) must produce an inert, protective film on the tinplate surface at a reasonable cost. To keep costs low, the lacquers must wet well over a surface that has received minimal preparation. In fact, cost is often one of the primary reasons for using lacquers, because they tend to substitute for the use of thicker tin coatings. In covering up so much of the sacrificial anode, however, the integrity of the lacquer film becomes extremely important in determining can performance due to the risk of more concentrated attack at defects.

Table 14 Main types of internal can lacquer

General type of resin and components blended to produce it	Flexibility	Sulfide-stain resistance	Typical uses	Comments
Oleo-resinous (drying oil and natural or synthetic resins)	Good	Poor	Acid fruits	Good general-purpose range at relatively low cost
Sulfur-resistant oleo-resinous (added ZnO)	Good	Good	Vegetables and soups (especially can ends or as topcoat over epoxy phenolic)	Not for use with acid products; possible intense green color with such vegetables as spinach
Phenolic (phenol or substituted phenol with formaldehyde)	Moderate-poor	Very good	Meat, fish, vegetables, and soups	Good at relatively low cost, but film thickness is restricted by flexibility
Epoxy-phenolic (epoxy resins with phenolic resins)	Good	Poor	Meat, fish, vegetables, soups, beer, and beverages (first coat)	Wide range of properties can be obtained by modifications
Epoxy-phenolic with ZnO (ZnO added)	Good	Good	Vegetables and soups (especially can ends)	Not for use with acid products; possible color change with some green vegetables
Aluminized epoxy-phenolic (metallic aluminum powder added)	Good	Very good	Meat products	Clean but rather dull appearance
Vinyl, solution (vinyl chloride-vinyl acetate copolymers)	Excellent	Not applicable	Spray on can bodies, roller coating on ends, as topcoat for beer and beverages	Free from flavor taints; sensitive to soldering heat and not usually suitable for direct application to tinplate
Vinyl, organosol, or plastisol (high molecular weight vinyl resins suspended in a nonsolvent)	Good	Not applicable	Beer and beverage topcoat on ends, bottle closures, drawn cans for sweets, pharmaceuticals, and tobacco	Same as for vinyl solutions, but giving a thicker, tougher layer
Acrylic (acrylic resin, usually pigmented white)	Very good in some ranges	Very good when pigmented	Vegetables, soups, and prepared foods containing sulfide stainers	Attractive, clean appearance of opened cans
Polybutadiene (hydrocarbon resins)	Moderate-poor	Very good if zinc-oxide is added	Beer and beverages first coat; vegetables and soups if with ZnO	Cost and, therefore, popularity depend on country

Difficulties in lacquer application appear as eye holing, which consists of roundish areas of uncovered tinplate surface in the cured coating. These eyeholes may occur singly or as parts of larger affected areas. They may be caused by incompatibility between the lacquer and the surface to be coated, either the oil that must be displaced or the passivation film to which the lacquer must adhere. Dust contamination or improper tinplate surface temperature are other possible causes. Heating the tinplate before lacquer is applied usually alleviates all of these potential problems.

Once successful applied, the lacquer must adhere to the tinplate surface through processing and storage. It must not crack during mechanical deformation, as in a beading process in which circumferential expansions in the sidewall are used for strengthening. The lacquer must also adhere through the heat-processing steps. If the lacquer cracks, there may be rapid attack in the crack. The tin layer under the crack is corroded away (undermining corrosion), causing collapse of the lacquer, widening of the crack, and exposure of the steel. Undermining corrosion may also cause failure after initiation at scratches or other lacquer defects that may occur during processing, transportation or storage. Corrosion proceeds rapidly in such cracks because of their small relative areas. Therefore, lacquers are usually applied as two coats; additional coats are applied to particularly sensitive corrosion areas, such as the side seam in three-piece can technology.

Undermining corrosion becomes more severe with increased tin coating weights because there is more of the readily dissolvable tin under the defect. Therefore, lacquer detachment is a greater possibility, leading to consumer complaints. As outlined above, the use of thinner tin coatings to combat undermining corrosion also increases the possibility of pack failure due to iron dissolution.

External corrosion of tinplate cans follows more closely the classical galvanic behavior described above. The ready availability of oxygen and the lack of complexing agents make the tin coating cathodic, and the unprotected steel will readily rust at plating pores and scratches in the coating that expose the underlying base steel. Coils or sheets of tinplate in transit from tinplate production to canmaking, as well as unfilled cans, are equally susceptible to this kind of deterioration.

A thicker tin coating will provide improved protection by reducing the steel exposure through plating pores. The passivation film also helps to provide corrosion protection. Because both of these factors are usually limited by other considerations, special precautions are taken to minimize moisture and pollution exposure. Where water is an essential part of the processing, as in steam retorting of cans or the subsequent cooling, the water is deoxygenated and treated with corrosion control agents. Minimizing the time of exposure to water is also practiced, as is the use of wetting agents to promote drying of the cans.

The paper to be used for labels and the materials to be used for shipping containers must be carefully selected. The presence of chloride or sulfate compounds in the paper, for example, may create a serious corrosion problem during storage. Wooden shipping cases might release corrosive organic vapors, and these and other materials can promote moisture exposure during transit. Again, it is difficult to be specific, because various foods are packed and then shipped literally all around the world.

A special type of corrosion may occur during transportation or handling of the tinplate. Fretting corrosion results from the intimate contact of two tinned surfaces combined with small relative movements between the two. The rubbing together of the surface asperities produces erosion, and the increased surface area yields more oxidation. Oxide particles are formed, and they act as very effective abrasives to cause additional damage to the surface. Fretting corrosion, therefore, typically features fine spots of dark, embedded tin oxide particles in areas of the tinplate that were subjected to pressure, such as from steel strapping used to secure a bundle of tinplate sheets. The most effective preventive measure is to pack the tinplates so as to minimize the relative movement of the tinplate surfaces. One purpose of the lubricant applied to the tinplate is to reduce fretting corrosion.

Corrosion Testing of Coatings

The preceding sections point out the excellent corrosion resistance of tin and tin alloys and how this property is used to advantage by coatings on stronger structural metals, typically steel or a copper alloy. Because the tin is cathodic to the base metal in normal environments, complete coverage of the base metal is important for preventing rapid attack at any pores in the coating. Therefore, porosity testing is valuable in predicting corrosion performance; however, because porosity tends to decrease with increasing coating thickness, thickness measurements often provide a more convenient indication of suitability.

In fact, most international and national specifications stipulate certain minimum coating thicknesses for anticipated service conditions. For example, ASTM B 545 specifies a minimum tin thickness of 5 μm (0.2 mils) for mild service conditions or where solderability is a primary concern (Ref 131). For exceptionally severe service conditions, such as where abrasion is combined with corrosion, the specification calls for a minimum tin thickness of 30 μm (1.2 mils). Between these extremes, for so-called normal conditions, 20 μm (0.8 mils) on steel or 8 μm (0.3 mils) on copper alloys is the specified minimum (Table 9).

The test methods described below are suited only to the purpose for which they were designed. Corrosion resistance can only be defined relative to a metal and to a particular environment; it is not an absolute property (Ref 2).

Coating Thickness Measurements. Several commercial instruments are available for measuring tin and tin alloy coating thicknesses. They have been developed to satisfy the need for a nondestructive test, and each has advantages and disadvantages.

Perhaps the simplest are the magnetic methods, which require the base metal to be magnetic or ferromagnetic. The tests determine how the coating alters the strength of a magnetic field that is passed through the coating when a magnet is positioned on the coating surface. The force required to remove the magnet is proportional to the tin thickness. The accuracy of the determination is enhanced by the use of accurate standards of known coating thickness to which comparisons can be made. The surface condition of the test sample is obviously very important for accurate measurements because the magnet is brought into contact with that surface.

The β backscatter method directs a beam of electrons (β particles) at the surface to be measured and detects particles scattered back in the direction of the source. This backscatter is in proportion to the coating thickness, and the instrument reads thickness after careful calibration to standards. The accuracy of the method relies on proper alignment of the source, sample, and backscatter collector, and periodic recalibration is important to allow for the gradual depletion of the radioactive source that generates the electron beam. Because the method does not require contact with the surface to be measured, it is particularly useful for high-speed continuous plating operations.

Somewhat similar is the x-ray fluorescence method, which directs x-rays onto the test sample and records secondary emissions that are caused by the excitation of the coating and/or base metal. The secondary emissions are not only in proportion to the coating thickness but are also characteristic of the coating alloy. X-ray fluorescence, therefore, provides a quick alloy analysis in addition to the coating thickness measurement. It also has the advantage of being noncontacting.

Among the destructive tests are the coulometric and microscopic methods. The coulometric test involves essentially a controlled stripping or deplating of the coated surface within an accurately determined area. An electrical current is applied through an electrolyte, resulting in anodic dissolution of the coating. When the coating is removed, a voltage change signals the end of the test. The amount of current passed through this small test cell is proportional to the amount of material removed and therefore implies in coating thickness.

In the microscopic method, the surface to be measured is simply sectioned and then examined optically. A direct measurement of the coating thickness is possible without using plated standards, but there is the potential problem of subjective evaluation. The other metallurgical observations that can be made on a cross section often constitute the reason for using this method.

A few other methods are available for coating thickness measurements. A micrometer check before and after application of the coating can be used for thicker coatings. Gravimetric methods involving weighing parts before and after coating or before and after coating dissolution and then calculating an average thickness based on the weight difference (coating weight) and the surface area from which it was dissolved. A drop test involves a stream of droplets of, for example, trichloroacetic acid solution, applied to a specific spot at a certain rate until the coating is penetrated, with the time to penetration being an indication of the coating thickness. In all test methods, the thinness of the typical tin alloy coating makes it important to perform the test carefully.

Porosity and Rust Resistance Testing. Although thickness testing can be performed quickly to provide process control feedback, common industrial practice includes porosity testing of statistically selected samples. This testing can predict performance more accurately by revealing the extent of variations in coating coverage that might go unobserved in thickness testing, because the latter tends to give an average over an area. The porosity test often uses simulated service conditions, usually with some accelerating factor to provide results more quickly.

Although techniques have been devised for automated test evaluation, most porosity tests rely on a visual assessment of the results. Therefore, the corrosive medium is often selected to give a readily visible corrosion product. This choice facilitates the reporting of both the quantity and distribution of porosity, along with any abnormalities in coverage.

For tin coatings on steel, SO_2, ferricyanide, or ammonium thiocyanate (NH_4CNS) tests have been used, and either of the first two is suitable for testing tin-lead coatings on steel. Tin coatings on copper alloys can be evaluated by using SO_2 or ammonium persulfate ($(NH_4)_2S_2O_8$ tests. Tin-nickel coatings are tested in a manner similar to tin coatings.

The sample of the coated metal is exposed to the corrosive medium for a specified time, perhaps at an elevated temperature to accelerate the corrosive action. After exposure, the test panel is removed and examined for rust or corrosion product. The number of attacked pores per unit area or the percentage of attacked area compared to the total area is the criterion for evaluation.

Solderability. Because tin and tin alloy coatings are so widely used to provide long-term protection to a solderable surface, much effort has recently been devoted to developing solderability tests, including accelerated aging techniques to predict shelf life. Indeed, if the coating is applied molten or if a plated coating is reflowed (also called flow melting), a form of solderability test has already been done in the sense that wetting difficulties will have been revealed during processing.

The simplest solderability test is a vertical dip of the properly fluxed sample into a solder pot. After a typical dwell time of about 3 s, the sample is withdrawn, the coating is allowed to solidify, and the surface is visually inspected for evidence of good wetting.

The other solderability tests tend to be variations of this dip test. In the rotary dip test, the sample is fixed to the end of a rotating arm, which is aligned so that the sample is passed through the upper surface of a solder bath. This test physically simulates the relative motion of surface and bath as it might happen in a wave-soldering operation. By testing a series of samples, a minimum time for complete wetting can be established and compared to the required standards.

Another popular solderability test, the surface tension balance test, is also a variation of the vertical dip test. The most significant difference is that the sample is suspended from an instrumented test rig that accurately records the forces that act on the sample during the dip into the solder pot. If wetting occurs, a force develops that attempts to pull the sample into the bath. The speed with which this force develops and its magnitude are two of the sensitive parameters often specified in standards for this test.

As indicated above, accelerated aging techniques are under investigation. The problem is that the current solderability tests may give a good correlation to actual soldering behavior in the short term, but none can predict soldering performance weeks or months from the time of testing; the latter is almost always more important. Solderability tends to maintain a certain level over the shelf life of the part and then to degrade very quickly to an unacceptable level. Aging the samples in steam for 16 to 24 h seems to give tin or tin-lead coatings the correct temperature and moisture exposure to cause poor sample to degrade. This procedure has won some acceptance for estimating the effects of 6 months to 1 year of normal storage, but only for tin-base coatings.

Special Test for Tinplate. Because of its commercial importance, tinplate is subjected to several special tests. Coating weights (thicknesses) are often determined coulometrically, although some installations use β backscatter or x-ray fluorescence methods to obtain a quick continuous evaluation for process control. Porosity tests may involve the SO_2 or NH_4CNS tests mentioned in the section "Porosity and Rust Resistance Testing" in this article. Other tests determine the presence of tin oxides, the composition of the passivation film, and the coverage of the oil film, all of which are important for good corrosion performance. Several of the special tinplate tests are outlined below.

The Iron Solution Test (Ref 2). The tinplate sample is exposed to a solution containing sulfuric acid (H_2SO_4, H_2O_2, and NH_4CNS under controlled conditions. The amount of iron (in micrograms) dissolved during the fixed test period is termed the iron solution value (ISV). This value reflects to some extent the continuity of the coating; however, it may also be influenced by the quality of the steel, as the test solution was devised as one in which exposed steel is on the threshold of protection by tin.

The Pickle-Lag Test (Ref 2). The steel base of the tinplate is exposed to 6 *M* hydrochloric acid (HCl) under defined conditions, and the time before hydrogen is steadily evolved is measured. This time period (in seconds) is the pickle-lag value; the lower the value, the better. A high value is associated with subsurface oxidation during annealing, and it seems likely that this defect may influence both the continuity of the coating and the continuity of the tin-iron alloy layer.

The Alloy-Tin Couple (ATC) Test (Ref 2). A sample of the tinplate from which the free tin layer has been removed, but with the tin-iron intermetallic layer intact, is coupled to a relatively large electrode of pure tin in deoxygenated grapefruit juice. The current flowing between the test sample and the tin electrode is measured; its value after 23 h is termed the ATC value. The purpose of this test is to assess the restraining effect of the tin-iron compound layer on the cathodic efficiency of the metal exposed when the free tin layer is dissolved from part of the surface. Thus, test results are affected by the continuity of the compound layer and by the characteristics of the steel.

The Tin Grain Size Test (Ref 2). The tin coating is lightly etched, and the size of the crystals revealed is expressed on the ASTM Standard Scale for the grain size of nonferrous metals. Increased grain size is considered beneficial. This is based on experience without, as yet, support from experimental measurements, but the effect of this factor is most likely to be seen in the initial rate of tin dissolution. It has been shown that different crystal faces of tin have differing dissolution and oxidation rates, and perhaps the effects of crystal orientation and crystal size are associated. It is also possible that impurities segregated at the grain boundaries produce a change related to boundary length and thus to grain size.

Other Tests. A cysteine hydrochloride ($C_3H_7O_2NS \cdot HCl$) staining test measures the tendency toward sulfide staining. A heating test simulates stoving (baking) to reveal any tendency toward discoloration during that operation. Finally, a series of tests can be used to evaluate lacquerability and lacquer adhesion to the tinplate. Additional information on these specialized tests is available in Ref 2, 128, and 129.

Corrosion of Lead and Lead Alloys*

Jerome F. Smith, Lead Industries Association, Inc.

Introduction

LEAD has such a successful record of service in exposure to the atmosphere and to water that its resistance to corrosion by these media is often taken for granted. Underground, thousands of kilometers of lead-sheathed cable and lead pipe give reliable long-term performance all over the world. In the chemical industry, lead is used in the corrosion-resistant equipment necessary for handling many chemicals (see the article "Corrosion in the Chemical Processing Industry" in this Volume). For information on the corrosion performance of lead and lead alloys used in lead-acid storage batteries, see the article "Corrosion of Batteries and Fuel-Cell Power Sources" in this Volume. General information on compositions, properties, and applications, can be found in the articles "Lead and Lead Alloys" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Volume 2 of *ASM Handbook.*

Note

* Portions of this article are based on Chapters 5 and 6 in *Lead for Corrosion Resistant Applications--A Guide,* Lead Industries Association, Inc.

The Nature of Lead Corrosion

The corrosion of lead in aqueous electrolytes is an electrochemical process. The metal either enters the solution at anodic sites as metallic cations or is converted anodically to solid compounds. Both corrosion reactions can be represented by the reaction:

$$Pb - 2e^{-} \rightarrow Pb^{2+} \quad \textbf{(Eq 1)}$$

This oxidation reaction, which takes place at anodic sites, is accompanied by a reduction of some constituent in the electrolyte at cathodic sites. In neutral salt solutions, the cathodic reaction is the reduction of dissolved oxygen:

$$\frac{1}{2}O_2 + H_2O + 2e^{-} \rightarrow 2OH^{-} \quad \textbf{(Eq 2)}$$

In acid solutions free of oxygen, the corresponding cathodic reaction is:

$$2H^{+} + 2e^{-} \rightarrow H_2 \quad \textbf{(Eq 3)}$$

The rate of corrosion is a function of the current flowing between the anodes and cathodes of the corrosion cell. Many factors and conditions can initiate or influence this flow of current. In the corrosion of a single metal, such as lead, local anodes and cathodes may be set up as a result of inclusions, inhomogeneities, stress variations, and differences in temperature. In bimetallic (galvanic) corrosion, the anodic and cathodic sites are on different metals, with the less noble metal (anode) corroding in preference to the more noble metal (cathode).

In most environments, lead is cathodic to steel, aluminum, zinc, cadmium, and magnesium and therefore will accelerate the corrosion of these metals. With titanium and passivated stainless steels, lead is the anode of the cell and suffers accelerated attack. In either case, the rate of corrosion is governed by the difference in potential between the two metals, the ratio of their areas, and their polarization characteristics.

The corrosion rate of lead is usually under anodic control, because the most important determinant generally is the solubility and other physical characteristics of the corrosion products formed at anodic sites. Most of these products are relatively insoluble lead salts that are deposited on the lead surface as impervious films, which tend to stifle further attack.

The formation of such insoluble protective films is responsible for the high resistance of lead to corrosion by sulfuric (H_2SO_4), chromic (H_2CrO_4), and phosphoric (H_3PO_4) acids.

In general, anything that damages the protective film increases the corrosion rate. Factors that help create or strengthen the film reduce the corrosion rate. Therefore, the life of the lead-protected equipment can be extended, for example, by washing it with film-forming aqueous solutions containing sulfates, carbonates, or silicates. This procedure is suggested for protecting lead when it will be in contact with corrosives that do not form protective films.

Forms of Corrosion. The corrosion of lead can take many forms. Lead exposed to the usual type of atmospheric attack will corrode uniformly. Pitting will occur under conditions of partial passivity or cavitation, which is the formation and collapse of gas bubbles at a liquid/metal interface.

In some cases, a combination of corrosion and other forms of deterioration, such as erosion, fatigue, and fretting, will cause damage much more severe than that caused by each form of attack working independently. Another type of accelerated corrosion can occur when lead is in contact with a corrosive environment and is subjected to a continuous load exceeding its creep strength. The process of creep will continually expose fresh surface to the corroding environment.

Intergranular corrosion is another form of attack on lead. It occurs at grain boundaries of lead generally in the cast form and can cause a significant loss in strength.

It is evident that the specific rate and form of corrosion that occur in a particular situation depend on many complex variables. However, in each of the four major environments discussed below--water, atmosphere, underground, and chemical--certain factors have a determining influence on what form and rate lead corrosion will have.

Corrosion in Water

Distilled water free of oxygen and carbon dioxide (CO_2) does not attack lead. Distilled water containing CO_2 but not oxygen also has little effect on lead. The corrosion behavior of lead in distilled water containing dissolved CO_2 and dissolved oxygen depends on CO_2 concentration. This dependency, which causes many different reactions to take place in a narrow range of concentration, explains the contradictory nature of much of the corrosion data reported in the literature.

For example, lead steam coils that handle pure water condensate are not severely corroded in systems in which all condensate is returned to the boiler and negligible makeup water is used. However, if makeup water is used, dissolved oxygen can be introduced to the condensate, and corrosion can be severe. Carbon dioxide can also be generated from the breakdown of carbonates and bicarbonates in boiler water, decreasing the severity of corrosion of lead. The oxygen level is the makeup water is usually controlled by adding oxygen scavengers, such as hydrazine or sodium sulfite.

In general, the corrosion rate in natural and domestic waters depends on the degree of water hardness. Water hardness is primarily caused by calcium and magnesium salts in the water. These salts, if present in at least moderate amounts (>125 ppm), form films on lead that adequately protect it against corrosive attack. Silicate salts present in the water increase both the hardness and the protective value of the film. In contrast, nitrate and chloride ions either interfere with the formation of the protective film or penetrate it; thus they increase corrosion.

In soft, aerated natural and domestic waters, the corrosion rate depends on both the hardness and the oxygen content of the water. When water hardness is less than 125 ppm, corrosion rate, like the rate in distilled water, depends on the relative proportions of dissolved CO_2 and dissolved oxygen. Potable waters, in which lead content is not permitted to exceed 0.05 ppm, often have hardnesses below 125 ppm and often contain considerable amounts of CO_2 and oxygen; thus, lead frequently cannot be used for pipe or containers that handle potable waters. This problem of contamination limits the use of lead in such applications, even though from a service point of view, corrosion rate is negligible.

The corrosion rates of chemical lead (99.9% Pb) in several industrial and domestic waters are presented in Table 1. It should be noted that corrosion rate is relatively low, even where water hardness is below 125 ppm. A corrosion rate for a freshwater is also included among the data for seawater in Table 2.

Table 1 Corrosion of chemical lead in industrial and domestic waters

Total immersion

Type of water	Temperature		Aeration	Agitation	Corrosion rate	
	°C	**°F**			**μm/yr**	**mils/yr**
Condensed steam, traces of acid	21-38	70-100	None	Slow	21.59	0.85
Mine water						
pH 8.3, 110-ppm hardness	20	68	Yes	Slow	6.60	0.26
160-ppm hardness	19	67	Yes	Slow	7.11	0.28
110-ppm hardness	22	72	Yes	Slow	6.35	0.25
Cooling tower water, oxygenated, from Lake Erie	16-29	60-85	Complete	None	134.6	5.3
Los Angeles aqueduct water, treated with chlorine and copper sulfate	Ambient		. . .	150 mm/s (0.5 ft/s)	9.65	0.38
Spray cooling water, chromate treated	16	60	Yes	. . .	9.4	0.37

Table 2 Corrosion of lead in natural waters

Location and type of water	Type of test	Agitation	Corrosion rate		Ref
			μm/yr	**mils/yr**	
Bristol Channel; seawater	Immersion about 93% of the time	. . .	12.7	0.50	1
Southhampton Docks; seawater	Half tide level	. . .	2.79	0.11	2
Gatun Lake, CZ; tropical freshwater	Immersion	None	2.03	0.08	3

Fort Amador, CZ; tropical Pacific Ocean	Mean tide level	Flowing[(a)]	5.08	0.20	
San Francisco Harbor; seawater	Mean tide level	Flowing	10.67	0.42	
Port Hueneme Harbor, CA; seawater	Immersion	Flowing[(b)]	5.59	0.22	4
Kure Beach, NC; seawater	Immersion	. . .	15.24	0.60	

(a) At 150 mm/s (0.5 ft/s).

(b) At 60 mm/s (0.2 ft/s)

The corrosion of lead in seawater is relatively slight and may be retarded by incrustations of lead salts. Data on the performance of lead in seawater at several locations are given in Table 2. Comparison of two of the entries in this table shows that at the same tropical location (Panama Canal Zone), the corrosion rate of lead in freshwater is about one-fourth the rate in seawater.

Extensive service experience and laboratory testing have indicated that the corrosion rate of lead is generally quite low in a wide variety of waters. The only major applications in which lead cannot be used are those involving some pure waters containing oxygen and soft natural waters, especially if contamination is of concern. In contrast, as discussed above, addition of calcium and magnesium salts further enhances the resistance of lead to corrosion by water.

Atmospheric Corrosion

In most of its forms, lead exhibits consistent durability in all types of atmospheric exposure, including industrial, rural, and marine (Table 3). These three atmospheric environments are distinct because each involves different factors that promote corrosion. In rural areas, which are relatively free of pollutants, the only important environmental factors influencing corrosion rate are humidity, rainfall, and air flow. However, near or on the sea, chlorides entrained in marine air often exert a strong effect on corrosivity. In industrial environments, sulfur oxide gases and the minerals in solid emissions change the patterns of corrosion behavior considerably. However, the protective films that form on lead and its alloys are so effective that corrosion is insignificant in most natural atmospheres. The extent of this protection is demonstrated by the survival of lead roofing and auxiliary products after hundreds of years of atmospheric exposure. In fact, the metal is preserved permanently if these films are not damaged (Ref 9).

Table 3 Corrosion of lead in various natural outdoor atmospheres

Antimonial lead, such as UNS 52760 (Pb-2.75Sb-0.2Sn-0.18As-0.075Cu), exhibits approximately the same corrosion rate in atmospheric environments as chemical lead (99.9% commercial-purity lead). However, the greater hardness, strength, and resistance to creep of antimonial lead often make it more desirable for use in specific chemical and architectural applications. The ability of some antimonial leads to retain this greater mechanical strength in atmospheric environments has been demonstrated in exposure tests in which sheets containing 4% Sb and smaller amounts of arsenic and tin were placed in semirestricted positions for 3 years. They showed less tendency to buckle than chemical lead, indicating that their greater resistance to creep had been retained.

Painting of lead coatings, especially terne metal (a coating containing 8 to 12% Sn, rem Pb), further raises their resistance to corrosion in outdoor environments. Terne metal has such good paint retention that one coat will far outlast two separate coats on plain steel. The use of terne metal is discussed in the article "Corrosion in the Automotive Industry" in this Volume.

Corrosion in Underground Ducts

Lead is extensively used in the form of sheathing for power and communications cables because of its impermeability to water and its excellent resistance to corrosion in a wide variety of soil conditions (the use of lead-sheathed cables is discussed in the article "Corrosion in Telephone Cable Plants" in this Volume). Cables are either buried directly in the ground or installed in ducts or conduits. In the United States, the preferred method is to lay cable in ducts or conduits made of such materials as cement, vitrified clay, or wood.

Severe corrosion of lead in underground service (in ducts or directly in the soil) is the exception rather than the rule. However, because repair or resplacement of underground components is difficult and expensive, proper corrosion protection is recommended in any underground service. Although the discussion that follows is based on preventive methods used for lead-sheathed cables, it is directly applicable in many ways to the underground behavior of other lead products, such as chemical service pipe.

The environment within ducts is often quite complex (Ref 9). It can include combinations of highly humid manhole and soil atmospheres, free lime leached from concrete, and alkalies formed by the electrolysis of salts in the water that seeps into ducts. Some of the factors involved in the corrosion of lead cable sheathing and how they relate to cable assembly and installation are discussed in Ref 10. Their influence in initiating or accelerating corrosion is described in Ref 10, with simple sketches used for illustration. Two of these factors--galvanic coupling and differential aeration--are discussed below.

Galvanic Coupling. Figure 1 illustrates two typical examples of contact between lead and other metals. In the presence of an electrolyte, such a dissimilar-metal couple forms a galvanic cell in which the more anodic metal is corroded. A difference in potential sufficient to cause corrosion may also arise when the surface of the lead is scratched to expose bright, active metal. In such cases, the exposed metal is the anode and is attacked.

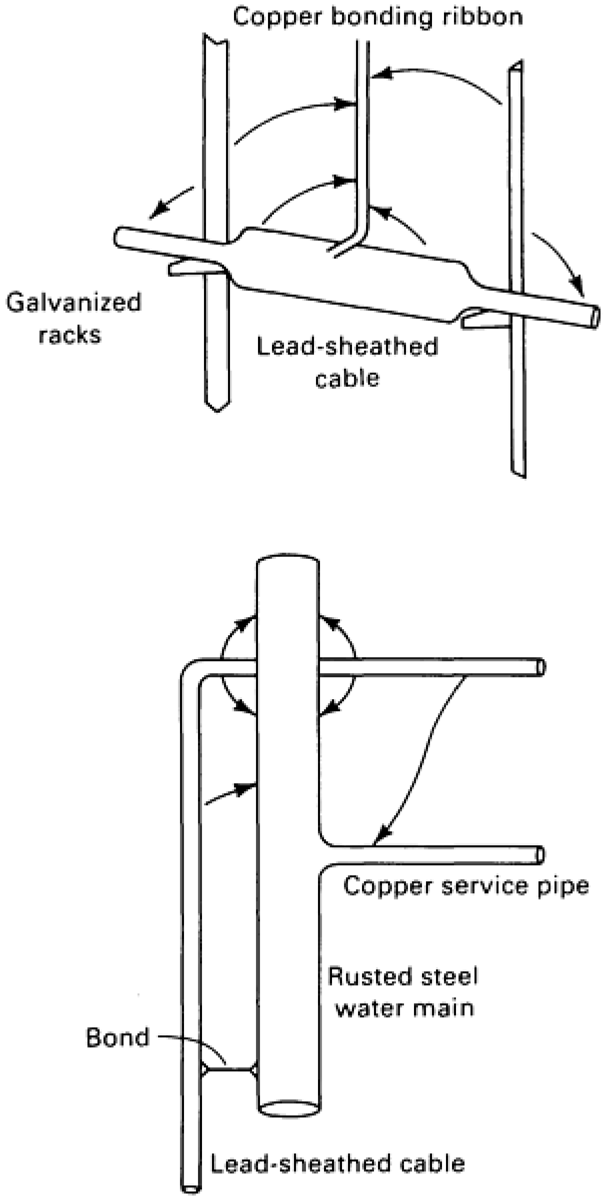

Fig. 1 Corrosion caused by galvanic coupling. Arrows indicate direction of current flow. Source: Ref 2

Differential Aeration. Figure 2 illustrates differential-aeration corrosion. In this type of corrosion cell, areas exposed to low oxygen concentration tend to become anodic to areas exposed to higher oxygen concentrations. As shown, the amount of air able to penetrate the silt and reach the crevice where the cable sheath and the duct meet is less than the amount available at the upper surface of the sheath; this results in corrosion.

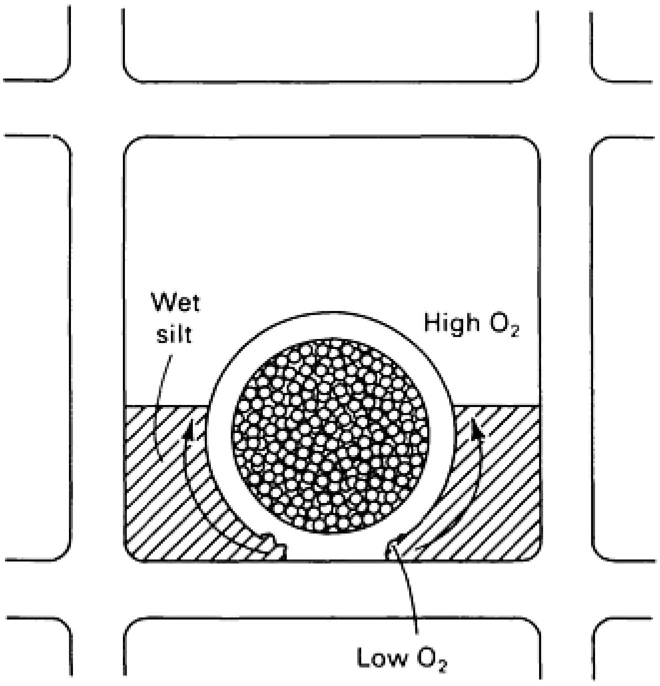

Fig. 2 Corrosion caused by differential aeration in a duct. Arrows indicate direction of current flow. Source: Ref 2

An actual example of differential-aeration corrosion is described in Ref 11. Lead-sheathed cable was pressed tightly against the inner surface of a tile duct, and water formed a meniscus extending from the sheathing surface to the tile. The area that was pressed against the tile did not corrode. However, an adjacent area, where the water was farthest from contact with air, corroded severely. The lead surface in contact with water closer to the air in the duct was the cathode.

Alkalinity is another factor that causes the corrosion of cable sheathing (Ref 12). Sheathing on cable installed in continuous concrete or asbestos cement ducts in concrete tunnels under waterways was found to be severely corroded. Analysis of water samples from these locations revealed that the corrosion had resulted from the presence of up to 1000 ppm of hydroxides. These alkaline water samples (pH 10.9 to 12.2) contained mainly calcium hydroxide. Sodium hydroxide was also found in some tunnels.

The source of the calcium hydroxide was incompletely cured concrete. Electrolysis of solutions of deicing salts that had seeped into the tunnels was believed to be the source of sodium hydroxide. The buildup in concentration occurred because seepage water was not being removed (the ducts had been designed to function without removal of seepage water). Proper drainage and use of completely cured, impervious concrete were suggested as corrective measures.

Stray currents can cause severe corrosion of lead pipe or lead cable sheathing. Stray currents are those that follow paths outside intended circuits. They may also be minor earth currents. Stray currents cause corrosion at the point where they leave the metal. Sources of stray currents include electric railway systems, grounded electric dc power, electric welders, cathodic protection systems, and electroplating plants. Stray alternating currents are much less damaging than stray direct currents.

It has also been found that corrosion of lead cable sheathing in manhole water depends more on the magnitude and polarity of the potential between the ground and the lead sheathing than it does on the natural dissolved salts in the water. Corrosion is at a minimum when the sheathing is cathodic to the ground (Ref 13, 14). Grounding prevents this type of corrosion.

Other factors that can initiate the corrosion of lead sheathing include contact with acetic acid (in wooden ducts), microorganisms, and corroded steel-tape armor. Bacterial corrosion usually occurs when aeration is poor and mud, water, or organic matter is present. Bacteria capable of reducing sulfates to sulfides are the principal cause of attack. Microbial

decomposition of the hydrocarbons present in cable coatings may also produce organic acids corrosive to lead. Corrosion of lead by corroded steel-tape armor can occur when the oxide coating formed on the steel is cathodic to lead.

Corrosion in Soil

Soils vary widely in physical and chemical characteristics and, consequently, in corrosive effect. More than 200 varieties of soil in the U.S. have been classified according to texture, color, and natural drainage. The physical properties of soils that most influence the corrosion of lead in underground service are those that affect the permeability of the soil to air and water, because good drainage tends to minimize corrosion. Soils with coarse textures, such as sands and gravels, permit free circulation of air. Corrosion in such soils is approximately the same as in the atmosphere. Clays and silty soils generally exhibit fine texture and high water-holding capacity and therefore poor aeration and drainage.

Numerous chemical compounds are present in soils, but only those soluble in water play important roles in the corrosion of metals. For example, the calcareous nature of some Indiana soils influences corrosion through alkaline attack or the promotion of bacterial activity.

Considerable corrosion testing of lead and lead alloys in numerous soils has indicated that corrosion rate decreases with increasing particle size and that the distribution of anodic and cathodic areas depends on soil particle size, water activation value of the soil, soil pH, and duration of exposure. Test results also show that lead tends to become passive in soils regardless of water content; however, addition of sodium bicarbonate reactivates it.

The data in Table 4 show that in most soils the average corrosion rate of lead is low--from less than 2.5 to 10 μm (0.1 to 0.4 mil) per year. It should be noted, however, that the depth of pitting is often a more important measure of underground corrosion behavior than corrosion rate.

Table 4 Corrosion of lead alloys in various soils

Maximum exposure time: 11 years

The most comprehensive investigation of corrosion of metals buried in soils was conducted by the National Bureau of Standards from 1910 to 1955 (Ref 15). This investigation included lead alloy pipe of three different compositions buried in 14 soils. Specimens were removed periodically; maximum exposure time was 11 years (Table 4).

Analysis of the data in Table 4 indicates that, in general, weight lost and maximum pit depth decrease with increasing aeration of the soil. For example, poor aeration caused severely deep pitting of the lead buried in Sharkey clay, in Lake Charles clay, and in cinders, but pitting of pipe buried in the well-aerated Cecil clay loam was shallow.

Resistance to Chemicals

The excellent resistance of lead and lead alloys to corrosion by a wide variety of chemicals is attributed to the polarization of local anodes caused by the formation of a relatively insoluble surface film of lead corrosion products (Ref 16). The extent of protection depends on the compactness, adherence, and solubility of these films.

Solubilities of various lead compounds in water at room temperature are given in Table 5. These data are general indicators of the behavior of lead in solutions that promote the formation of these compounds. The solubility of a lead corrosion product, however, depends on the solution in which the lead is immersed. Therefore, the solubility of that corrosion product in water is not always an adequate indicator of its behavior in another solution. This fact is illustrated by the variation in solubility of lead sulfate ($PbSO_4$) in H_2SO_4 as acid concentration and temperature change (Fig. 3). The $PbSO_4$ film is less soluble in H_2SO_4 solutions than it is in water. Solubility drops to a minimum value at acid concentrations of 30 to 60% and then increases at higher concentrations. At intermediate concentrations, the sulfate film is so insoluble that corrosion is negligible.

Table 5 Solubility of lead compounds

Lead compound	Formula	Temperature		Solubility [a], Kg/m^3
		°C	**°F**	
Acetate	$Pb(C_2H_3O_2)_2$	20	68	433

Fig. 3 Solubility of lead sulfate in sulfuric acid

Another example of the importance of the solubility relationship of the lead film to its environment is shown in Fig. 4. Lead nitrate ($Pb(NO_3)_2$) is quite soluble in dilute and intermediate-strength solutions of nitric acid (HNO_3) at room temperature. Lead is not resistant to corrosion under such conditions. However, above an HNO_3 concentration of 50%, $Pb(NO_3)_2$ is only slightly soluble, and lead is quite resistant to attack.

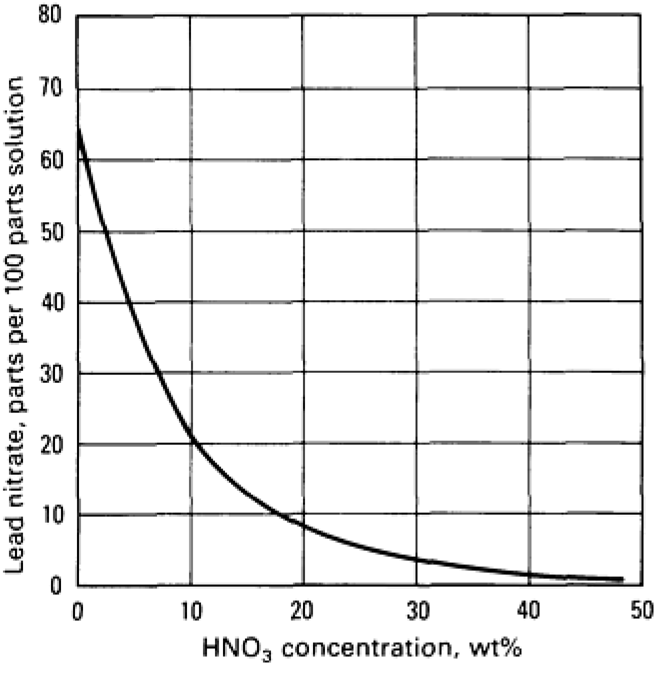

Fig. 4 Solubility of lead nitrate in nitric acid

Increases in temperature generally increase corrosion rate (Fig. 3). This effect is primarily due to increases in film solubility.

Galvanic Corrosion. When lead is anodic to a metal to which it is coupled and a firm film develops on the lead, galvanic corrosion of the lead will be negligible. For example, when lead is galvanically connected to a copper or a copper alloy in an H_2SO_4, H_2CrO_4, or H_3PO_4 solution, the lead is protected by a firm film even though it is the anode in the galvanic cell. However, when the other metal is the anode, galvanic corrosion of the lead may occur, and it is sometimes severe. Aluminum or magnesium will be severely corroded if coupled with lead in the presence of an electrolyte. If lead is coupled with Monel in a 6% H_2SO_4 solution, corrosion of the Monel will be accelerated.

A factor to be kept in mind is that environmental changes can reverse the galvanic positions of the two metals. For example, iron is anodic to lead in acids and cathodic to it in alkalies.

In general, galvanic corrosion of lead is significant only when the lead is coupled with a metal to which it is anodic, when an electrolyte is present, and when a firm film cannot be maintained; corrosion of metals anodic to lead seldom occurs. When galvanic corrosion of either lead or the dissimilar metal does occur, it is unlikely to be severe, because lead occupies a central position in the galvanic series.

Physical variables also influence the corrosion rate of lead in many situations. For example, if the flow velocity of a solution is above a critical point, it can completely erode the protective film, leaving only a clean lead surface exposed for continued attack. This is demonstrated by the rapid increase in corrosion of lead in 20% H_2SO_4 at velocities greater than 1.5 m/s (300 ft/min). The presence of foreign insoluble matter further aggravates this condition.

Fatigue stresses may also break the protective film on lead, repeatedly exposing lead to environmental attack. However, applied fatigue stresses no greater than the creep strength of lead do not significantly affect corrosion properties.

Quantitative Corrosion Data. It is important to remember when evaluating quantitative corrosion data that lead weighs more per unit of volume and is normally used in greater thicknesses than most other metals. The effects of these two factors should be considered in evaluating the data presented in this section.

Lead has high corrosion resistance to H_2CrO_4, H_3PO_4, H_2SO_4, and sulfurous (H_2SO_3) acids and is widely used in their manufacture and handling. Lead satisfactorily resists all but the most dilute solutions of H_2SO_4. It performs well at acid concentrations up to 95% at ambient temperatures, up to 85% at 220 °C (428 °F), and up to 93% at 150 °C (302 °F) (Fig. 5). Below a concentration of 5%, the corrosion rate increases, but it is still relatively low. In the lower range of concentration, antimonial lead is recommended.

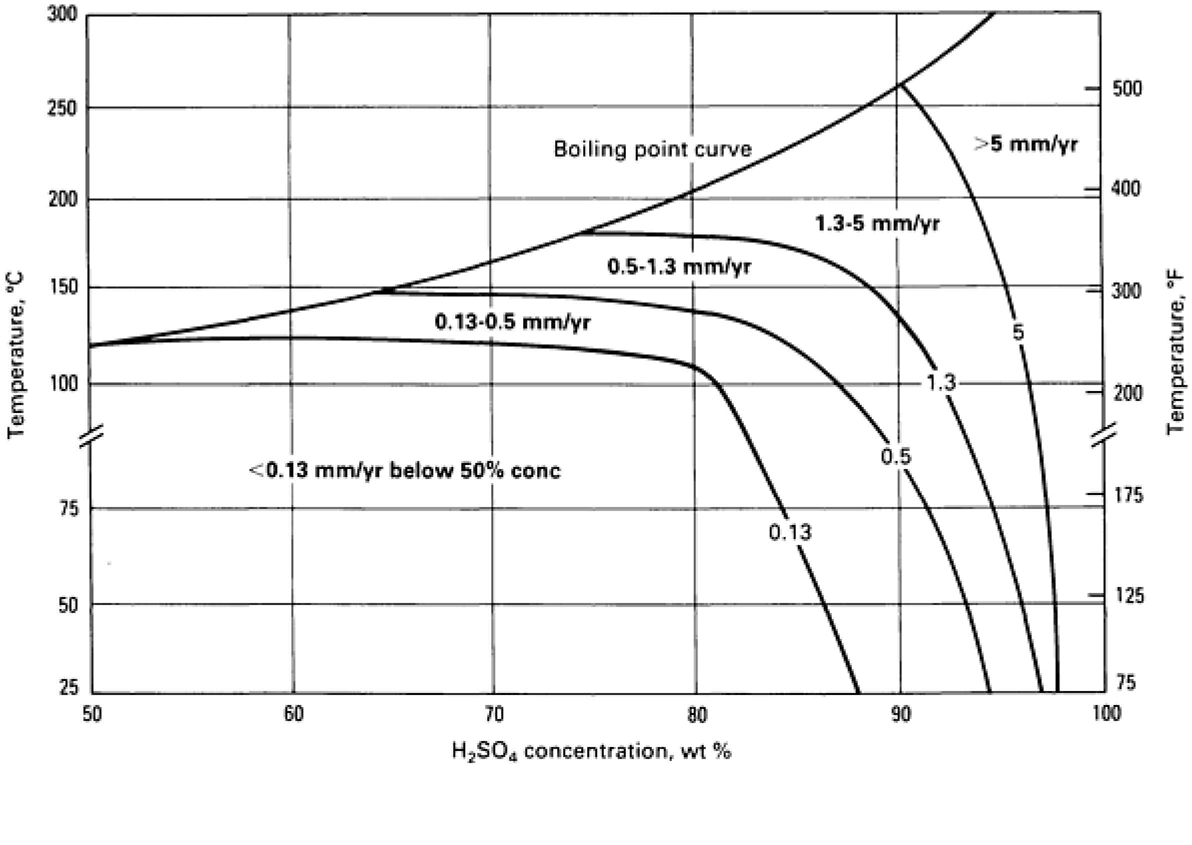

Fig. 5 Corrosion rate of lead in H_2SO_4. Source: Ref 18

Lead exhibits the same excellent corrosion resistance to higher concentrations of H_2CrO_4, H_2SO_3, and H_3PO_4 at elevated temperatures. Lead is also generally resistant to solutions of salts formed by each of these salts. However, the reaction to mixtures of these salts is much more complex.

Lead finds especially wide application in the manufacture of H_3PO_4 from phosphate rock when H_2SO_4 is used in the process. Corrosion rates are low for all acid concentrations up to 85% (Table 6). The corrosion rate of 6% antimonial lead has been reported to be lower than that of chemical lead in a plant test using a solution containing 32% H_3PO_4, 0.4% H_2SO_4, and 1% chlorides at 88 °C (190 °F). In pure acid manufactured from elemental phosphor, lead corrodes at a higher rate because of the absence of sulfates.

Table 6 Corrosion of chemical lead in commercial phosphoric acid at 21 °C (70 °F)

Solution	Corrosion rate	
	μm/yr	**mils/yr**
20% H_3PO_4	86.4	3.4
30% H_3PO_4	124.5	4.9
40% H_3PO_4	144.8	5.7
50% H_3PO_4	162.6	6.4
85% H_3PO_4	40.6	1.6
80% H_3PO_4[(a)]	325.1	12.8

(a) Pure grade

Lead has fair corrosion resistance to dilute hydrochloric acid (HCl) (up to 15%) at 24 °C (75 °F); the corrosion rate increases at higher concentrations and at higher temperatures (Table 7). The presence of 5% ferric chlorides also accelerates corrosion (Table 8).

Table 7 Corrosion of lead in hydrochloric acid at 24 °C (75 °F)

5% HCl + 5% $FeCl_3$	711	28	940	37
10% HCl + 5% $FeCl_3$	1041	41	1930	76
15% HCl + 5% $FeCl_3$	2235	88	4064	160
20% HCl + 5% $FeCl_3$	3810	150	4826	190

The resistance of lead to corrosion by hydrofluoric acid (HF) is only fair. However, lead is used to handle HF because it is the only low-priced metal that has adequate corrosion resistance. The corrosion rate in this acid (if it is free of air) is less than 510 μm/yr (20 mils/yr) for a wide range of temperatures and concentrations (Fig. 6).

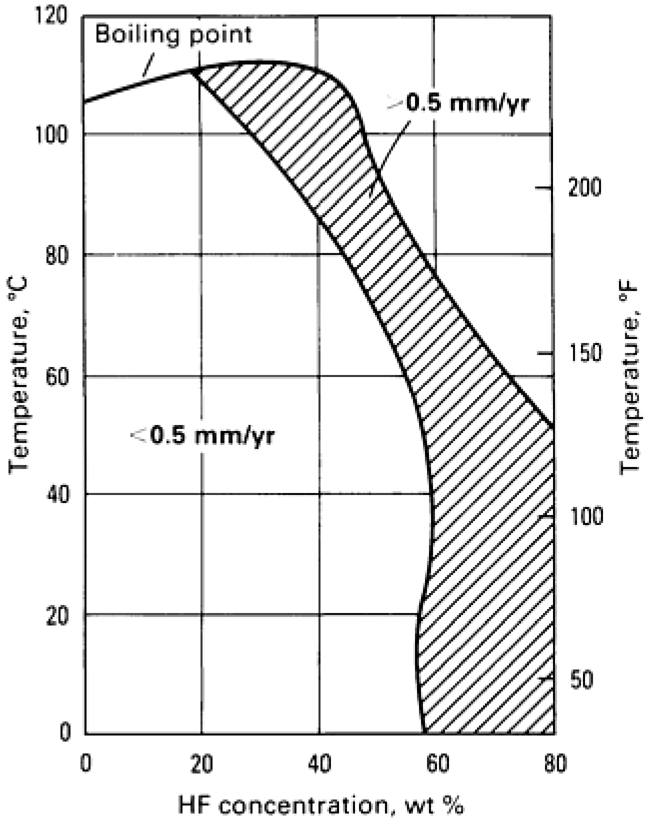

Fig. 6 Resistance of lead to corrosion in air-free hydrofluoric acid

Nitric, acetic, and formic acids in most concentrations corrode lead at rates high enough to preclude its use in these acids. However, although HNO_3 rapidly attacks lead when dilute, it has little effect at strengths of 52 to 70%. The same is true of HF, acetic acid, and acid sodium sulfate.

Addition of H_2SO_4 to acids corrosive to lead often lowers the corrosion rate. For example, although HNO_3 in concentrations less than 50% is quite corrosive to lead (Table 9), in the presence of 54% H_2SO_4 the corrosion rate in 1% and 5% HNO_3 is quite low even at 118 °C (245 °F) (Table 10). Other concentrations of H_2SO_4 also lower the corrosion rate in HNO_3 (Table 11). The composition range of mixed H_2SO_4 and HNO_3 solutions for which chemical lead has a corrosion rate of less than 500 μm (20 mils) per year is shown in Fig. 7. Chemical lead is preferred over 6% antimonial lead for handling these mixtures of acids.

Qualitative corrosion data serve to provide guidelines for screening suitable metals for chemical equipment. Laboratory test environments may not always simulate actual plant conditions, and there may be significant variations among plants manufacturing the same product. Therefore, it is often more helpful to be less specific when categorizing the corrosion rates of lead in various chemicals. Table 15 presents such less specific information and should be used only as a guide for determining whether further tests are warranted. Most of the data in Table 15 are for chemical lead. The corrosion rates of different grades of lead in the same chemical all normally fall within the same category. Therefore, no mention is made of variations in corrosion rate for other grades of lead.

Table 15 Corrosion rate of lead in chemical environments

For corrosion rate information on lead in other chemical environments, see the more extensive tables contained in Lead for Corrosion Resistant Applications--A Guide, Lead Industries Association, Inc.

Stannous chloride	24	75	10-50	D
Zinc sulfate	35	95	. . .	B
Zinc chloride	79	175	25	B

(a) The four categories of the Table are: A, <50 μm/yr (<2 mils/yr): negligible corrosion--lead recommended for use. B, <500 μm/yr (<20 mils/yr): practically resistant--lead recommended for use. (When the only information available is that "lead is resistant" to a certain chemical, that chemical was arbitrarily placed in this category.) C, 500-1270 μm/yr (20-50 mils/yr): lead may be used where this effect on life can be tolerated. D, >1270 μm/yr (>50 mils/yr): corrosion rate too high to merit any consideration of lead.

Tin-Lead Solder Alloys

Solders in the tin-lead system are the most widely used of all joining materials. Industrial solder alloys are in use that contain a combination of materials from 100% Pb to 100% Sn, as demanded by the particular application. Each alloy has unique characteristics. In general, properties are influenced by the melting characteristics of the alloys, which in some measure are related to their load-carrying and temperature capabilities. Table 16 gives the melting temperatures of some tin-lead compositions and their respective applications. More detailed information on the compositions and melting characteristics of tin-lead solders can be found in *Welding, Brazing, and Soldering,* Volume 6 of the *ASM Handbook.* Corrosion-related data of these alloys are also presented in the article "Corrosion in Tin and Tin Alloys" in this Volume.

Table 16 Melting characteristics and applications of tin-lead solders

Composition, %		Temperature				Uses
		Solidus		**Liquidus**		
Tin	**Lead**	**°C**	**°F**	**°C**	**°F**	
2	98	270	518	312	594	Side seams for can manufacturing
5	95	270	518	312	594	Coating and joining metals
10	90	268	514	299	570	
15	85	226	440	288	550	
20	80	183	361	277	531	Coating and joining metals, or filling dents or seams in automobile bodies

25	75	183	361	266	511	Machine and torch soldering
30	70	183	361	255	491	
35	65	183	361	247	477	General purpose and wiping solder
40	60	183	361	238	460	Wiping solder for joining lead pipes and cable sheaths. For automobile radiator cores and heating units
45	55	183	361	227	441	Automobile radiator cores and roofing seams
50	50	183	361	216	421	General purpose. Most popular of all
60	40	183	361	190	374	Primarily used in electronic soldering applications in which low soldering temperatures are required
63	37	183	361	183	361	Lowest-melting (eutectic) solder for electronic applications

Applications. Solder alloys containing less than 5% Sn are used for joining tin-plated containers and for automobile radiator manufacture. For automobiles, a small additional amount of silver is usually added to provide extra joint strength at automobile radiator operating temperatures. Solder alloys of 10Sn-90Pb and 20Sn-80Pb are also used in radiator joints. With compositions between 10Sn-90Pb and 25Sn-75Pb, care must be taken to avoid any kind of movement during the solidification phase to prevent hot tearing in solders with a wide freezing range.

Higher tin content solders at the 25Sn-75Pb and 30Sn-70Pb compositions have lower liquids temperatures and can be used for joining materials with sensitivity to high temperature or where the wetting characteristics of the tin are important to providing sound soldering joints. Solder alloys in the composition range described above are usually applicable to industrial products and generally are used in conjunction with inorganic fluxing materials.

The widely used general-purpose solder alloys contain 40 to 50% Sn. These solders are used for plumbing applications, electrical connections, and general soldering of domestic items. The 60Sn-40Pb and 63Sn-37Pb alloys are used most extensively in the electronic industries for both hand soldering and wave or dip applications. Sometimes silver additions are made to alloys used in the electronics industries to reduce dissolution of silver-based coatings. The corrosion performance of tin-lead solders for electronic applications is discussed in the article "Corrosion in the Electronics Industry" in this Volume.

Corrosion of the Noble Metals

Gaylord D. Smith, Inco Alloys International, Inc.; Edward Zysk, Englehard Corporation

Introduction

THIS ARTICLE seeks to characterize the corrosion resistance of the eight noble metals: ruthenium, rhodium, palladium, silver, osmium, iridium, platinum, and gold. The elements are listed in order of their atomic number as found in periods 5 and 6 (Group VIII and Ib) of the periodic table. These metals are unique in their nobility and for the most part offer industry corrosion resistance that is unmatched in base metals and their alloys. The available information on the corrosion resistance of each element varies widely. Generally, more data are available for the more abundant, more easily fabricated elements. Silver and platinum have been evaluated in more environments than the other elements. Conversely, very little data are available for the intractable elements, osmium and ruthenium.

The information is presented on an element by element basis. For each element, the general fabricability of the metal is briefly defined. More detailed information on fabricability is available in Ref 1, 2, and 3 and *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Volume 2, *ASM Handbook.* This will aid in assessing the relevance of any particular noble metal to the immediate problem at hand. Atomic, structural, and physical properties can also play an important role in the use of any element or alloy in a given environment. Table 1 lists selected physical properties for all of the noble metals. Similarly, where data exist, typical properties and the effect of working are given for each element. Corrosion data are divided into several categories, including high-temperature oxidation. These data follow a general summary of the performance of each element. For comparative purposes, certain tables have common corrosive environments in each table for each element. This should aid the reader in finding the optimal element or alloy for any given type of common corrosive environment. Much of these data, as found in the literature, were originally presented in a myriad of different corrosion units. This information has been standardized in units of millimeters per year (mils per year). Similarly, virtually all the corrosion results are based on short-duration tests, and as is true of virtually all corrosion data, the information is intended to serve principally as a guide of expected results, because short-term results do not always reliably predict longer-term corrosion rates. Relatively little data are available on alloying effects. Most alloying,

however, is done to vary mechanical and physical properties. Therefore, the corrosion resistance of the principal elements of most noble metal alloys is still relevant to the performance of many of their available commercial alloys.

Table 1 Selected properties of the noble metals

Property	Metal							
	Platinum	**Palladium**	**Iridium**	**Rhodium**	**Osmium**	**Ruthenium**	**Gold**	**Silver**

(d) Annealed.

Corrosion data for the noble metals have been summarized for the various elements in the past (Ref 1, 3, 4, 5, 6, 7, 8, 9, 10). Some of these data are in conflict and some are in question. A best effort has been made to present the likely corrosion rate. Data have been taken from many sources, and it is impossible to reference each data point. However, the references cited will frequently contain additional detail in specific incidences.

Because of the high cost of the noble metals, a corrosion rate of approximately 0.05 mm/yr (2 mils/yr) was selected as an arbitrary practical upper limit of acceptable corrosion. Negligible corrosion is defined as a corrosion rate of less than 0.25 mm/yr (10 mils/yr) but generally greater than 0.05 mm/yr (2 mils/yr). Most of the corrosion data are presented as falling in one of these classifications. For some applications, more rigorous limits and knowledge of the actual corrosion rate are required as a result of product purity or economics. For these applications, a more rigorous search of the literature or actual laboratory/field testing may be warranted.

Silver

Fabrication. Next to gold, silver is the most easily fabricated metal in the periodic table. It is very soft and ductile in the annealed condition. Silver is available in a large variety of product forms, including sheet, strip, foil, bar, wire, and shaped extrusions. Although silver work hardens, it is easily annealed in air above about 300 °C (570 °F). Silver is readily fusion welded--preferably by argon arc welding, because an oxyhydrogen flame can embrittle silver through gas absorption. Silver can be soldered by a number of silver-or tin-base solders. It can also be hammer peened to form strong joints.

Silver is commonly clad to copper, nickel, and steel alloys by either brazing or solid-phase bonding. Silver-lined tubing can be fabricated by expanding silver tubing inside the base metal tubing.

Atomic, Structural, and Physical Properties. There are a number of interesting features about silver that are defined in Table 1. For example:

- Silver has the lowest density of the noble metal group of elements
- Silver has the lowest melting point of all the noble metals
- The thermal conductivity of silver is the highest of all the elements near room temperature
- The room-temperature electrical resistance of silver is the lowest of all the elements

Mechanical Properties. Annealed silver has relatively low yield and tensile strengths, but appreciable strength can be induced through cold working. Tensile strength can be increased from 124 to 186 MPa (18 to 27 ksi) for annealed material to approximately 310 MPa (45 ksi) following 50 to 80% cold work. Silver loses strength rapidly above room temperature and, accordingly, is used with caution if high-temperature service is contemplated. Silver cladding is being successfully used to extend the useful temperature range of silver and its alloys.

Corrosion Resistance. Extensive reviews of the corrosion resistance of silver are available in the literature (Ref 1, 4, 5, 6, 8). The principal objectives of this article are to draw a comparison between silver and the other noble metals with respect to corrosion resistance and to highlight some of the commercial corrosive environments in which silver can or cannot be used.

The corrosion resistance of silver depends on purity; much of the data presented here is for 999 fine silver (the fineness of silver is the silver content in parts per thousand). Silver can be used in hydrochloric acid (HCl), but results can be unsatisfactory under strongly aerating conditions when the concentration of acid and the temperature are increased (Table 2). The halide acids, with the exception of hydrofluoric acid (HF), passivate silver under favorable conditions by forming a stable protective film. Silver-lined vessels are used for the bromination of organic materials, but hydrobromic acid (HBr) exposure is limited to room temperature and a maximum of 14% acid. Similarly, silver is restricted to room-temperature exposure in dilute hydroiodic acid (HI). Nitric acid (HNO_3) that contains traces of nitrous acid attacks silver vigorously. Hot, concentrated (60%) sulfuric acid (H_2SO_4) also attacks silver rapidly, as does 95% acid at room temperature. Phosphoric acid (H_3PO_4) can be handled at all concentrations and temperatures of 160 to 200 °C (320 to 390 °F). The corrosion resistance of silver in acids is given in Table 3. The Pourbaix diagram for silver is given in Ref 11. Silver is not attacked by water or steam to 600 °C (1110 °F).

Table 2 Corrosion of silver in hydrochloric acid

Sulfurous, all concentrations	90 (195)	<0.05	2
Tartaric, all concentrations[b]	100 (212)	<0.05	2

(a) Attack will occur whenever silver chloride film is ruptured.

(b) Oxygen increases attack in dilute tartaric acid at room temperature.

Silver is resistant to dry and moist chlorine and dry bromine, but is not resistant to iodine and fluorine unless it is cathodically protected (Table 4). Silver is resistant to many hydroxide, sulfate, carbonate, nitrate-bisulfate, and halide salt solutions, but is attacked by others (Table 5).

Table 4 Corrosion of silver in halogens

Halogen	Temperature, °C (°F)	Corrosion rate, mm/yr (mils/yr)
Chlorine, dry[a]	100 (212)	Slight >0.05 (2)
Chlorine, moist or in solution	100 (212)	<0.05 (2)
Saturated chlorine in water	Room	<0.05 (2)
Bromine, dry[a]	Room	<0.05 (2)

Bromine, in methanol	Room	>0.05, <0.5 (2, 20)
Bromine, in glacial acetic acid	50 (120)	<0.05 (2)
Iodine, dry	Room	Dissolution
Iodine, moist or in solution	Room	Dissolution
Fluorine, dry[(b)]	Room	Very slight attack

(a) Halogen attack accelerates with increasing temperature, especially with moisture present.

(b) Can be used as cathode to 250 °C (480 °F) for electrolysis of potassium fluoride plus HF to produce fluorine

Zinc chloride, all concentrations	Boiling	<0.05	2

(a) Provided oxidizing agents are not present.

(b) Air must be excluded.

(c) Attacked upon heating.

(d) Causes deterioration of potassium perborate.

(e) Mass transfer possible above 600 °C (1110 °F)

Table 6 lists corrosion rate data for silver in nearly 100 organic compound environments. Silver is satisfactory for use in nearly 90% of these environments. This is an impressive account, given the myriad of environments presented. Several of the organics for which silver is not recommended did not attack silver; rather, silver affected the organic compound, such as certain fats and the essential oils. This is also true for hydrogen peroxide and hydrazine. Silver is attacked by organic amines and by ammoniacal solutions of copper acetate. The inertness of silver in many organic environments makes it the material of choice, especially where high product purity is essential.

Table 6 Corrosion resistance of silver in organic compounds

Vinyl chloride, pure	200 (390)	<0.05	2

(a) Silver may taint the flavor of fats.

(b) Solutions must be free of air and ammonia.

(c) Silver may impart metallic taste

Silver is attacked by most fused bisulfates, cyanides, halides, phosphates, and peroxides, but is not attacked at temperatures below 500 °C (930 °F) by sodium hydroxide and at slightly lower temperatures by potassium, cesium, and rubidium hydroxides. All the low-melting molten metals attack silver, including mercury, sodium, potassium, lead, tin, bismuth, and indium. The corrosion resistance of silver in various gases is given in Table 7. The standard electrode potential for silver ($Ag \rightleftharpoons Ag^+ + e^-$) is +0.79 V and is exceeded only by gold and the platinum group metals.

Table 7 Corrosion of silver in gases

Gas	Temperature, °C (°F)	Corrosion rate	
		mm/yr	**mils/yr**
Acetylene, dry	Room	Risk of explosion	
Ammonia, pure	190 (375)	<0.05	2
Ammonium chloride, vapor	200 (390)	Attacked	
Carbon dioxide, pure	Room	<0.05	2
Carbon monoxide, pure	300 (570)	<0.05	2

Hydrogen, pure	700 (1290)	<0.05	2
Hydrogen chloride, dry[(a)]	430 (805)	<0.05	2
Nitric oxide, pure	Room	Attacked	
Nitric tetroxide, pure	Room	<0.05	2
Nitrogen, pure	500 (930)	<0.05	2
Oxygen, pure [(b)]	100 (212)	<0.05	2
Ozone, with 98% oxygen	Room	<0.05	2
Steam, pure[(c)]	600 (1110)	<0.05	2
Sulfur dioxide, pure	Red heat	Attacked	
Sulfur trioxide, pure	Red heat	<0.05	2

(a) Silver is protected by a layer of silver chloride that forms rapidly on the surface.

(b) Attack becomes appreciable at 200 °C (390 °F).

(c) Without pressure

Oxidation. Silver is resistant to dry and moist air at ordinary temperatures. At slightly elevated temperatures, silver may form a thin film of silver oxide. Above about 455 °C (850 °F), any silver oxide present will dissociate at atmospheric pressure, leaving the surface clean once again. However, molten silver dissolves appreciable quantities of oxygen, which can result in considerable internal porosity upon resolidification as the oxygen is rejected from the lattice. Oxygen diffuses more freely through solid silver than through any metal. This fact has made it feasible to internally oxidize certain alloying elements, such as magnesium, in order to dispersion strengthen silver in, for example, the Ag-10MgO alloy used for electrical contacts. The information on oxygen in silver is reviewed in Ref 12. Similarly, the causes and characteristics of sulfur-induced tarnish on silver and silver-rich alloys are reviewed in Ref 6. Surprisingly, the extensive research aimed at improving the tarnish resistance of silver by alloying has been largely unsuccessful.

Silver is blackened by ozone, with the maximum rate of attack at 220 to 250 °C (430 to 480 °F); the black tarnish disappears above about 455 °C (850 °F). Silver can be exposed to carbon monoxide to 300 °C (570 °F), to hydrogen to 700 °C (1290 °F), and to nitrogen to 500 °C (930 °F). At red heat, sulfur dioxide and sulfur trioxide rapidly attack silver. This attack becomes progressively worse with temperatures beginning at or near room temperature (Table 7).

The relatively poor strength of silver at elevated temperatures has minimized its use at high temperatures. However, cladding has extended the useful temperatures at which silver can be used.

Alloying of Silver for Corrosion Applications. Sterling silver, by definition, must contain a minimum of 92.5% Ag. Although the remainder is unrestricted, it is usually copper. Because copper is soluble in silver to the extent of about 4%, sterling silver is commonly a duplex alloy. The copper in solid solution has little effect on corrosion resistance, but the duplex microstructure may be a source of galvanic attack in strong electrolytes, such as seawater. However, this effect is rare in most environments. At slightly elevated temperatures, the copper is selectively oxidized. In this regard, copper does adversely affect the tarnish resistance of silver. However, copper additions to silver improve the strength of the metal, an attribute that is exploited in making cooling coils for beer and other foodstuff manufacturers. In general, base metal alloying does little to improve the corrosion resistance of silver. Most alloying of silver with base metals is done to change mechanical properties and melting point.

Some electrical contacts have been made with a 60 to 70% Ag alloy containing up to 30% Au. A ternary Au-24Ag-6Pt alloy is extensively used in telephone equipment. Silver-gold binary alloys are used for jewelry and dental applications as well (see the article "Tarnish and Corrosion of Dental Alloys" in this Volume). Alloys of silver containing 3 to 10% Pd are also used for electrical contact materials. It should be noted that the alloy Pd-23Ag, because of its dimensional stability and high hydrogen permeability, has found acceptance as a diffusion membrane for the production of ultrapure hydrogen. Alloys in the silver-gold-palladium ternary field possess excellent high-temperature oxidation resistance, favorable brazing characteristics, and a wide range of fusion temperatures from the melting point of silver (961.9 °C, or 1763.4 °F) to that of palladium (1554 °C, or 2829 °F).

Corrosion Applications of Silver. The use of silver and silver-rich alloys in jewelry, coinage, and sterling ware is well known and documented. Also of commercial significance are the uses of silver in manufacturing and processing equipment within the food, chemical, and pharmaceutical industries. Silver has been used for decades within the food industry to maintain purity and freedom from metallic taste. Silver is resistant to many organic acids, salts, compounds, and foodstuffs and is used to manufacture, concentrate, and evaporate these products. Silver equipment has been used for handling syrups, fruit juices, beer, cider, white vinegar, jellies, gelatin, fatty acids, and essential oils, as well as autoclaves, mixing vessels, boiling pans, storage vats, and transfer equipment. Similarly, in the pharmaceutical industry, silver equipment is used to produce certain fine chemical, hormones, and vitamins (see the article "Corrosion in the Pharmaceutical Industry" in this Volume).

The chemical industry frequently uses silver-lined process equipment to minimize corrosion. Silver is used in apparatus to synthesize urea from ammonia and carbon dioxide. Dye manufacturers use silver to handle aniline, ethyl chloride, boric acid, iodine, formaldehyde, magnesium chloride, magnesium sulfate, and zinc oxide. Silver-lined equipment is used to dehydrate glacial acetic acid and to process and store acetic anhydride in the rayon industry and phenol in the synthetic coatings industry. Highly refined acid products, such as phthalic acid made from hardwood distillation, can be processed in silver-lined stills. Silver vessels are often used to produce highly corrosive writing inks. Silver condensers are used to produce high-purity methyl acetone. High-purity sodium and potassium hydroxide are concentrated to the anhydrous melt in silver pans and commercial grades of these products are also concentrated in silver-lined continuous vacuum evaporators operating at over 315 °C (600 °F). Silver-tubed condensers are used for condensing 70% HF from the hot hydrogen fluoride vapors formed during the hydrofluorination of uranium. Silver metering equipment is employed is disperse wet chlorine gas in water purification installations. The chemical industry uses equipment made from silver to produce fluorophosphoric acid and salts. Rupture disks for emergency relief of pressure in chemical-processing equipment are frequently made of silver.

The use of silver to produce mirrors is based on the relative inertness of silver in air as well as its high and uniform reflectivity in the visible light range. Silver-containing electrical contacts and batteries derive their utility from the chemical nobility and stability of silver, although in relay contacts the formation of silver sulfide, whose resistance increases as the current decreases, imposes restraints on the use of silver and its alloys in this field.

Gold

Fabrication. Gold is a highly malleable element that does not work harden significantly at room temperature. It is available for industrial use in all product forms, including thin strip and leaf, tubing, and fine wire. It is readily fabricated into finished-product forms and claddings. Gold is easily fusion or hammer welded. Soft soldering is not recommended.

The common unit of gold content in an alloy is the karat. This is the proportion of gold in alloy in twenty-fourths. Karat weight K is calculated on the following basis:

$$K = \frac{\text{wt\% Au} \times 24}{100}$$

In jewelry, gold-clad stock is designated by the ratio of weight of gold to the total weight of the material.

Some atomic, structural, and physical properties of gold are given in Table 1.

Mechanical Properties. Annealed gold is extremely soft (25 to 27 HV) at room temperature and is relatively low in tensile strength (125 to 138 MPa, or 18 to 20 ksi). Cold-worked wire cannot be strengthened much above 207 MPa (30 ksi). Because of the low strength of gold, the use of gold cladding on stronger base metals is common. Gold cannot be used as a structural material at elevated temperatures because of creep of the metal. Gold rupture disks usually are not used above 80 °C (175 °F).

Corrosion Resistance. Pure gold essentially owes its corrosion resistance to the low chemical affinity of the element. Passive film protection, such as occurs for silver in halide environments, is rare.

Table 8 gives the corrosion resistance of gold in acids. Gold is very resistant to H_2SO_4 to 250 °C (480 °F), and attack above this temperature may be primarily dependent on available oxygen. Gold is also resistant to concentrated HCl to its boiling point and to HNO_3 concentrations of up to 50% at the boiling point. However, hot mixtures of HNO_3 and H_2SO_4 will rapidly attack gold, as will aqua regia and hydrogen cyanide (with oxygen present). Mixtures of HCl, HBr, and HI with HNO_3 are extremely corrosive to gold. Mixtures of HF and HNO_3 are not corrosive to gold. Gold is resistant to most other acids.

Table 8 Corrosion of gold in acids

Acid	Temperature, °C (°F)	Corrosion rate	
		mm/yr	**mils/yr**
Acetic, glacial	100 (212)	<0.05	2
Aqua regia	Room	Rapid dissolution	
Arsenic, all concentrations	Room	<0.05	2

Gold is generally attacked by the gaseous halogens, wet or dry. Only dry fluorine and wet or dry iodine can be handled by gold and then only within limitations (Table 9). Gold, second only to platinum, is resistant to dry hydrogen chloride to 870 °C (1600 °F), to oxygen to its melting point, to ozone to 100 °C (212 °F), to phosgene at room temperature, and to sulfur dioxide, dry and wet, to 600 °C (1110 °F) (Table 10).

Table 9 Corrosion of gold in halogens

Halogen	Temperature, °C (°F)	Corrosion rate	
		mm/yr	**mils/yr**
Bromine, all concentrations, dry and wet	Room	Attacked	
Chlorine, dry	Room	0.3	12
	120 (250)	0.7	27.6
	150 (300)	1.5	60
	175 (345)	3.0	120
	205 (400)	30.5	1200

Fluorine, dry	<500 (930)	<0.05	2
Iodine, dry and wet	Room	<0.05	2
Iodine, dry and wet	>50 (120)	Attacked	
Iodine, 5% in alcohol	Room	Attacked	

Table 10 Corrosion of gold in various gases

Gas	Temperature		Corrosion rate,	
	°C	**°F**	**mm/yr**	**mils/yr**
Hydrogen chloride, dry	870	1600	<0.05	2
Ozone, with 98% oxygen	100	212	<0.05	2
Phosgene	Room		<0.05	2
Steam	800	1470	<0.05	2
Sulfur dioxide, dry and wet	600	1110	<0.05	2

Gold is not attacked by most inorganic salts in solution for their typical conditions of use (Table 11). Exceptions are the solutions of alkali cyanide and peroxide. Most alkali and alkaline melts as nitrates, hydroxides, and bisulfates will eventually attack gold, but only at elevated temperatures. The corrosion resistance of gold in over 40 organic compounds is given in Table 12. In all cases, gold was found to be resistant enough for commercial use.

Table 11 Corrosion of gold in salts

Salt	Temperature, °C (°F)	Corrosion rate	
		mm/yr	**mils/yr**

Vinyl chloride, pure	500 (930)	<0.05	2

Gold is attacked by all low-melting alloys, including mercury, sodium, potassium, lead, tin, bismuth, and iridium. The standard electrode potential for gold ($Au \rightleftharpoons Au^+ + e^-$) is + 1.68 V.

Oxidation Resistance. Gold does not oxidize at any temperature up to its melting point, but may possess an absorbed layer of oxygen on the surface. Gold and its alloys greater than 14 karat are not susceptible to tarnish by hydrogen sulfide, sulfur, or other nonoxidized sulfur compounds. However, because gold does not support its own mass at elevated temperatures, high-temperature applications are minimal.

Corrosion Applications. Gold is primarily used for its decorative appearance in jewelry, coinage, dentistry, and gold leaf. Because of its softness and lack of resistance to halogens, its use in chemical applications, even as gold-lined

apparatus, is somewhat limited. Gold is resistant to nonoxidizing H_3PO_4 and phosphates; therefore, it is used for lining autoclaves handling phosphate mixtures to 500 °C (930 °F). In the production of zirconium by the iodide process, gold closure gaskets are used to handle dry iodine vapors at 500 °C (930 °F). The use of gold-lined equipment to perform hydrochlorinations and hydrofluorinations of organic compounds in the chemical industry has been established. Laboratory ware fabricated from an AU-10Pt alloy is frequently used in place of platinum.

The stability of gold, coupled with its ability to reflect infrared radiation, has made it a popular glass window coating for energy conservation in tall buildings. Gold-base brazing alloys are used in critical aerospace and chemical equipment applications. Electroplated gold is used for its stability in electrical applications, such as connectors, relay switches, and contacts. Gold-silver-copper alloys are used for pen nibs and for slip rings and brushes in electrical instruments. Gold-palladium-iron alloys are used for potentiometer wire. A gold-palladium-iron alloy having a high resistivity and a negative temperature coefficient of resistance has been used as a resistor and potentiometer wire.

Platinum

Fabrication. Platinum is a soft, ductile, white metal, and like other face-centered cubic (fcc) metals, it can be readily hot or cold worked. Hot working is typically begun at 1000 °C (1830 °F), with reductions per pass as great as 50% being possible. Cold work is usually performed with reductions of 10% per pass and intermediate annealing after 75% reduction in thickness. Wire processing is similarly performed. Platinum can be processed bare into leaf and wire as small as 2.5 μm (0.1 mil). Pure platinum can be annealed in a short time at 600 to 700 °C (1110 to 1290 °F). Alloys require higher temperatures. Platinum can be annealed in air, but other atmospheres, such as nitrogen, argon, and helium, can also be used without damage. Platinum is readily fusion or resistance welded. Platinum can be electro-deposited on base metals.

The principal atomic, structural, and physical properties of platinum are listed in Table 1.

Mechanical Properties. Platinum work hardens at about the same rate as copper or silver; the mechanical properties obtained are strongly influenced by the purity of the platinum. The hardness and tensile strength are in the range of 37 to 42 HV and 124 to 165 MPa (18 to 24 ksi) for annealed material. After a 50% cold reduction, these values increase to 90 to 95 HV and 207 to 241 MPa (30 to 35 ksi). Elongation decreases from 30 to 40% to about 3%. The tensile strength of annealed platinum wire versus temperature is given in Table 13. The 100-h stress rupture life of annealed platinum at 925 °C (1700 °F) is with a stress of 14 MPa (2000 psi) and at 1300 °C (2370 °F) is with a stress of 1.7 MPa (245 psi).

Table 13 Effect of temperature on the tensile strength of annealed platinum wire

1.3-mm (0.05-in.) diam wire annealed at 1100 °C (2010 °F) for 5 min

Test temperature		Tensile strength	
°C	**°F**	**MPa**	**ksi**
20	70	138	20
200	390	117	17
400	750	90	13
600	1110	76	11
800	1470	55	8
1000	1830	28	4

Corrosion Resistance. The exceptional corrosion resistance of platinum, one of the more familiar of its characteristics, is widely acknowledged and is extensively covered in the literature (Ref 1, 7, 9, 10). Platinum is one of the few metals that is unaffected by atmospheric exposure, even in sulfur-bearing industrial atmospheres.

Platinum is resistant to corrosion by single acids (Table 14), alkalies, aqueous solutions of common salts (Table 15), and organic materials (Table 16). The potential-pH diagram for platinum as defined by Pourbaix shows that platinum at 25 °C (75 °F) is immune to attack at all but the lowest pH levels and high redox potentials (Ref 11). Even at elevated temperatures, platinum is resistant to dry hydrogen chloride and sulfurous gases (Table 17). Platinum is resistant to most halogen gases at room temperature, with dry and moist bromine being the exception (Table 18). Platinum is also essentially inert to many molten salts, and it resists the action of fused glasses if oxidizing conditions are maintained.

Table 14 Corrosion of platinum in acids

Acid	Temperature, °C (°F)	Corrosion rate	
		mm/yr	**mils/yr**
Acetic, all concentrations	Boiling	<0.05	2

Aqua regia and mixtures of HCl and oxidizing agents will attack platinum, as will free halogens and selenic acid to some degree at elevated temperatures. A number of low-melting metals, including lead, tin, antimony, zinc, and arsenic, will readily alloy with and attack platinum at their melting temperatures. Low-melting phases are formed with silicon, phosphorus, bismuth, and boron, and salts or compounds of these metals can be detrimental at high temperatures under reducing conditions.

As an anode, platinum will resist attack in a wide variety of alkaline, neutral, and mild acid solutions. There is attack in strong HCl. If an alternating current is applied to platinum electrodes, attack will occur in cyanide and in some acid solutions. The standard electrode potential ($Pt \rightleftharpoons Pt^{+} + 2e^{-}$) is approximately +1.2 V at 25 °C (75 °F).

Effect of Alloying on Corrosion Resistance. Alloys containing up to 25% Pd have essentially the same corrosion resistance as platinum and are not discolored by heating in air. The addition of palladium up to 25% raises the annealed hardness and tensile strength of platinum.

The corrosion resistance of the entire binary series of rhodium-platinum alloys is excellent, with corrosion resistance tending to improve with higher rhodium contents. For example, a 10% addition of rhodium to platinum reduces the corrosion rate in 36% HCl at 100 °C (212 °F) from 0.2 mm/yr (50 mils/yr) to 0 and the attack of 100 g/L ferric chloride ($FeCl_3$) at 100 °C (212 °F) from 16.7 to 0.2 mm/yr (660 to 50 mils/yr). Alloys containing less than about 20% Rh can be hot or cold worked, while those containing between 20 to 40% Rh must be hot worked prior to cold working. The practical limit for workability is about 40% Rh.

Iridium and ruthenium additions to platinum result in corrosion resistance similar to that obtained through rhodium additions. However, the ranges for working are slightly more restrictive for iridium and much more limiting for ruthenium. All the alloys of the gold-platinum binary system remain quite corrosion resistant. Alloys containing more than 60% Ag are rapidly attacked by HNO_3 and $FeCl_3$ and are tarnished by exposures to industrial atmospheres.

Nickel additions rapidly harden platinum and gradually reduce the nobility of platinum. Up to 50% Cu can be added to platinum while still retaining its resistance to HNO_3.

Platinum can be used as a minor alloying element in the base metals titanium and chromium. Platinum additions as small as 0.1% greatly increase the resistance of these base metals to HCl and H_2SO_4.

Oxidation Resistance. Platinum is outstanding in its resistance to oxidation, remaining untarnished upon heating in air at all temperatures and retaining its metallic luster up to the melting point. At temperatures above about 750 °C (1380 °F), an extremely small but measurable weight loss occurs because of the formation of a volatile oxide, probably PtO_2, and because of volatilization of the metal. The loss due to oxide formation is the greater of the two effects as higher temperatures are reached, and it is influenced by such factors as oxygen pressure, atmosphere flow rate, degree of saturation of the atmosphere with the oxide, and the geometry of the system (Ref 13, 14). A comparison of the oxidation resistance of platinum with that of a number of other high-melting metals is given in Fig. 1.

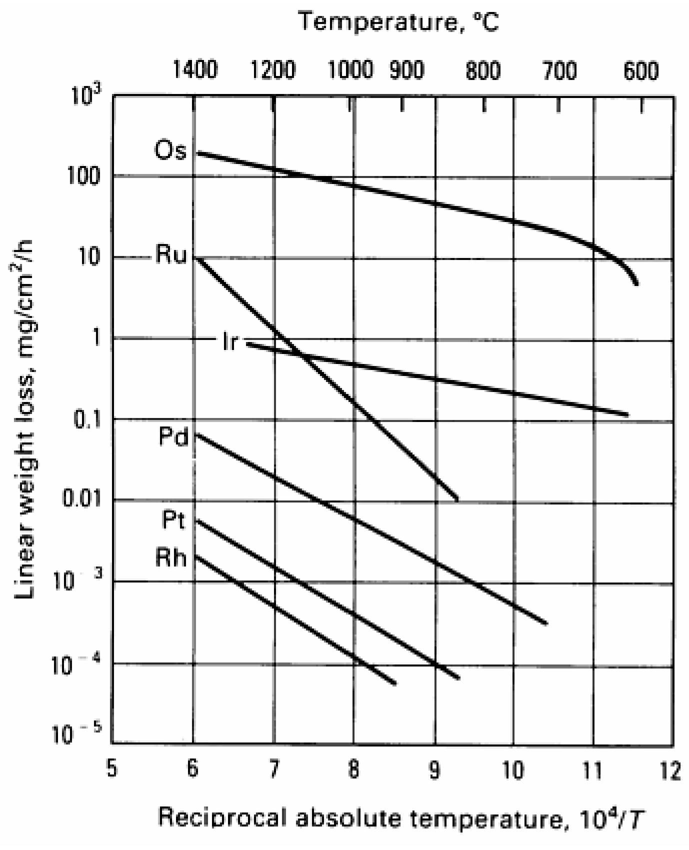

Fig. 1 Weight losses of platinum-group metals oxidized in air

Alloys with more than 5% Rh or Ir are slowly oxidized in air at temperatures between 750 °C (1380 °F) for rhodium, 900 °C (1650 °F) for iridium, and 1150 °C (2100 °F) with the formation of a superficial blue-black film. At higher temperatures, the film decomposes, and the alloy becomes bright again. Above about 800 to 900 °C (1470 to 1650 °F), both alloy systems lose mass because of the volatilization of oxides formed on the surface and the preferential volatilization of the alloying element. Iridium-containing alloys have greater volatilization rates at a given temperature than rhodium-containing platinum alloys. When heated in air, ruthenium is selectively oxidized from ruthenium-platinum alloys, although less vigorously than osmium.

Corrosion Applications. Pure platinum, as well as platinum containing small amounts of rhodium, gold (5%), or iridium, is used for crucibles and other laboratory ware. The first major use of platinum was in laboratory ware and, to a certain extent, in chemical equipment, particularly for stills and condensers in the concentration of H_2SO_4. Today, laboratory apparatus and ware made from platinum and other noble metals are extensively used in analytical control work (fusions, ignitions, ashing) and research demanding corrosion resistance at room and elevated temperatures. Platinum

crucibles are used for the production of large synthetic crystals. The chemical industry uses platinum for constructing heating and cooling coils, evaporation apparatus, stills, and autoclaves. Corrosion-resistant platinum rupture disks are used for the protection of pressure vessels handling corrosive materials. Platinum electrodes are used for the electrolytic production of hydrogen peroxide and per-salts, such as perchlorates, because they have a high oxygen overvoltage and do not corrode or effect the purity of the product. In addition, platinum electrodes can be used for cathodic protection in seawater and in chlorine production.

Platinum and, preferably, Pt-5Rh or Pt-10Rh are used in woven screen form to catalytically oxidize ammonia to HNO_3. Platinum, platinum-rhodium, and other platinum-base alloys are used in large quantities by the glass industry for molds, nozzles, and spinnerets.

The platinum resistance thermometer and the 90%Pt-Pt thermocouple are used to define the International Practical Temperature Scale between 13.81 K and 630.74 °C and between 630.74 °C and 1064.43 °C (freezing point of gold), respectively. In commercial practice, the rhodium platinum-platinum thermocouple is regularly used to 1400 °C (2370 °F) and under special conditions to as high as 1600 °C (2910 °F).

Because of its tarnish resistance, platinum is used in the jewelry, dental, medical implant, and electrical contact fields.

Palladium

Fabrication. In many respects, the fabricability of palladium resembles that of platinum and gold, which are closely associated with palladium in the periodic table. Like other fcc metals, palladium is ductile and can be readily hot or cold worked. Palladium can withstand drastic working and forming operations and, like gold, can be processed into leaf as thin as 0.1 m (4 in.). Many wrought and fabricated forms of palladium and its commercial alloys are readily available, including sheet and strip, bar and wire, and shaped extrusions. Palladium and some alloys are easily electroplated.

Physical Properties. Palladium, with a density of 12.02 g/cm^3 (0.434 lb/in.^{3}), is the lightest of the platinum-group metals. It also has the lowest melting point of the platinum metal group (1554 °C, or 2829 °F). The principal physical properties of palladium are listed in Table 1.

Mechanical Properties. Palladium work hardens at about the same rate as platinum; the annealed hardness increases from 40 HV to about 105 HV after a 50% reduction in thickness. Similarly, the tensile strength increases from 207 MPa (30 ksi) annealed to about 379 MPa (55 ksi) after a 50% reduction in thickness to 448 MPa (65 ksi) following a 75% reduction. The tensile strength of annealed palladium wire decreases progressively with increasing temperature, as shown in Table 19. The 100-h stress rupture life of palladium at 925 °C (1700 °F) is with a stress of 4.1 MPa (595 psi) and at 1300 °C (2370 °F) is with a stress of 1.7 MPa (247 psi) (Ref 15, 16).

Table 19 Effect of temperature on the tensile strength of annealed palladium wire

1.3-mm (0.05-in.) diam wire annealed at 1100 °C (2010 °F) for 5 min

400	750	125	18
600	1110	88	13
800	1470	57	8
1000	1830	26	4

Corrosion Resistance. Palladium is generally resistant to corrosion by most single acids, alkalies, and aqueous solutions of many common salts (Tables 20 and 21). It is not attacked at room temperature by H_2SO_4, HCl, HF, acetic, or oxalic acids, but may be attacked at 100 °C (212 °F) or when air is present. Nitric and hot H_2SO_4 attack palladium, as do $FeCl_3$ and hypochlorite solutions, chlorine, bromine, and, to a negligible extent, iodine. Table 22 lists the resistance of palladium to halogens at room temperature. The Pourbaix diagram for palladium, although not complete, can be found in Ref 11. Palladium is readily corroded anodically in HCl or acid chloride solutions. As an electrode for cathodic protection use in seawater, palladium corrodes at a rate of 8.6 g/A · yr at a current density of 540 A/m^2 (50 A/ft^2). The current efficiency is 0.05%. In binary palladium-platinum alloys, the corrosion rate in this application becomes equal to that of platinum if the palladium content is less than 20%. Cyanide solutions containing an oxidizing agent are useful for metallographic etching.

At high temperatures, molten salts such as sodium peroxide, hydroxide, and carbonate attack palladium, but the molten nitrate does not. Hydrogen sulfide at temperatures above 600 °C (1110 °F) attacks the metal and produces a low-melting phase. The standard electrode potential (Pd   Pd + $2e^-$) is approximately +0.83 V at 25 °C (75 °F).

Effect of Alloying Elements on Corrosion Resistance. The additions of 2% Pt to palladium makes the alloy resistant to the jewelers' HNO_3 drop test used to determine equivalency with gold alloys, and the addition of 10% Pt to palladium makes it completely resistant to HNO_3. In $FeCl_3$ solution (100 g/L), 10% Pt decreases the room-temperature corrosion rate of palladium from 11.9 to 8.6 mm/yr (469 to 339 mils/yr). A 30% Pt addition further decreases the corrosion rate to 1.8 mm/yr (71 mils/yr).

Both iridium and rhodium are quite effective in improving the corrosion and tarnish resistance of palladium. Palladium alloys with 2% Ir or Rh are resistant to the HNO_3 drop test, and alloys with 10% of either element are untarnished by industrial sulfur-bearing atmospheres. The addition of up to 10% Ru only slightly improves the corrosion resistance of palladium. Alloys containing more than 10% Au are resistant to tarnish by industrial sulfur-bearing environments, and those with more than 20% Au are resistant to HNO_3 and HCl.

The corrosion resistance of binary palladium-nickel or cobalt alloys is intermediate between that of the component metals and can be raised to levels above those of gold alloys by the addition of platinum, rhodium, or iridium in quantities of from 5 to 20%. Small additions of palladium (0.15 to 0.20%) to titanium may have been found to be effective in improving its corrosion resistance. In such corrosive media as boiling HCl, an almost hundredfold increase in corrosion resistance is obtained. Similar effects in chromium have also been observed.

Oxidation Resistance. Palladium is not tarnished by dry or moist air at ordinary temperatures. At temperatures in the range of 400 to 790 °C (750 to 1450 °F), a thin oxide film forms in air. At higher temperatures, the superficial oxide decomposes to give off oxygen, leaving a clean metal surface.

At temperatures above about 1000 °C (1830 °F), the behavior of palladium in air or oxygen is complicated by the interplay of two phenomena: the solution of oxygen in palladium (which increases the weight) and the loss of metal by volatilization (which decreases the weight). The mass change data for palladium oxidized in air over the temperature range 700 to 1400 °C (1290 to 2550 °F) is given in Fig. 1. The oxidation of palladium (thin oxide film formation) can be eliminated by alloying with 75% Pt (Ref 17, 18). Because palladium lacks an oxide film above 1000 °C (1832 °F), the volatilization losses will depend on rate of flow of the gas stream over the surface of the metal (Ref 19, 20).

Corrosion Applications. Pure wrought or electroplated palladium is used for electrical contacts, and large quantities are currently in use in relays for telephone service. Palladium and palladium-rich alloys, because of their freedom from tarnish, perform with high reliability and low electrical noise even with low contact forces. Many alloys containing palladium have been developed to meet specific contact requirements. A list of some of these alloys is given in Table 23. The palladium content provides the noble metal characteristics; other metals are added for improved hardness, electrical resistance, or economy.

Table 23 Properties and applications of typical palladium electrical contact materials

Material	Melting point		Electrical conductivity, %IACS[(a)]	Hardness, HR15-T		Density		Typical applications

(a) International Annealed Copper Standard

Palladium does not stain or discolor porcelain that is fired on it, and palladium-rich alloys are used as supports in porcelain overlay dental restorations. In the jewelry field, palladium hardened with a few percent of ruthenium or rhodium provides a light, white, tarnish-free ally suitable for such articles as watch cases, brooches, and settings for gems. Palladium is an exceptionally effective whitener for gold; the addition of as little as 15% produces as satisfactory white color. In contrast to the great increase in hardness and working difficulties encountered when gold is whitened by other metals, the white gold-palladium alloys are ductile and readily worked.

Palladium alloys are well suited for the construction of fine wire precision resistors because of their ductility, corrosion resistance, and the range of electrical resistivities available. Alloys with exceptionally low-temperature coefficients of electrical resistivity have been developed for applications as potentiometer resistor wire. An alloy that is widely used for this is Pd-40Ag, which has a resistivity of 42 Ω·cm in the as-worked condition and a temperature coefficient of only 0.00003/°C (0.00005/°F) in the temperature range 0 to 100 °C (32 to 212 °F).

Metallic films fired on glass or ceramic substrates are of interest for thin film resistors. For this application, palladium-gold resistance films can be produced by the thermal decomposition of resinate mixtures. In another process, a mixture of finely ground low-melting glass and palladium and silver powders is fired on the substrate. Thin film resistors made in this manner do not exhibit a critical resistance/composition dependence.

A palladium-alloy, noble metal thermocouple combination has been developed that approximates the high electromotive force (emf) developed by one of the commonly used base metal thermocouples. Designed to operate at temperatures up to about 1300 °C (2375 °F), the Platinel thermocouple also exhibits a superior stability and life over the base metal thermocouples. Consisting of a gold-palladium negative leg and a palladium-platinum-gold positive leg, the thermocouple produces an emf approximating that of base metal thermocouples over a wide temperature range. Because of the close match of emf, the palladium alloy thermocouple can be substituted for the base metal thermocouple in many instances without the need to modify the existing instrument.

In general, brazing alloys containing palladium exhibit exceptional wettability, good flow and gap-filling characteristics, freedom from the tendency to attack and erode base metals, good ductility, and other desirable brazing qualities. The palladium-containing brazing alloys have proved useful for dissimilar-metal or metal-to-ceramic joints, for extremely thin sheet metal assemblies, and for assemblies that must withstand extreme service temperatures. The alloys can be used to braze a wide range of base metals, including low-alloy and stainless steels; nickel-, cobalt-, and copper-base alloys; and refractory metals such as tungsten and molybdenum. They are consequently gaining a significant place in the gas turbine, jet engine, air frame, missile, nuclear, and electronic industries.

Gold-palladium alloys are used for thermal fuses to prevent temperature override in furnaces. The range of melting temperatures possible with the different gold-palladium combinations (1063 to 1552 °C, or 1954 to 2825 °F), the narrow melting range of the alloys, and their corrosion and oxidation resistance make them well suited for this service.

Rhodium

Fabrication. Rhodium powder can be consolidated either by powder metallurgy techniques or by melting. Powder compacts are sintered by air, inert atmospheres, hydrogen, or vacuum at about 1200 °C (2190 °F).

The melting of rhodium requires careful control of atmospheric conditions because liquid rhodium will dissolve a large quantity of oxygen, which is rejected upon solidification. If conditions are reducing, the rhodium may become contaminated through reduction of the refractory crucibles. A satisfactory technique for the production of small rhodium ingots is electron beam or argon arc melting on a water-cooled copper hearth.

Sintered or cast rhodium ingots can be worked down to thin strip or fine wire. The fabrication of these wrought forms requires an initial hot working at a temperature of 1200 °C (2190 °F) or higher, but subsequently, the temperature can be dropped. At thinner gages, the metal can be cold worked. During cold work, the rhodium should be given stress-relief

anneals at 600 to 800 °C (1110 to 1470 °F), but complete annealing should be avoided because recrystallized metal is less ductile than metal with a fibrous structure. Moderate amounts of cold work (up to 40 to 50%) can be given between stress-relief anneals.

The principal atomic, structural, and physical properties for rhodium are listed in Table 1. Rhodium is characterized by:

- High specular reflectivity
- The highest electrical conductivity of all the platinum-group metals
- The highest thermal conductivity of all the platinum-group metals
- A high melting point: 1963 °C (3565 °F)
- A density of 12.41 g/cm^3 (0.448 lb/in.^{3}), approximately 58% that of platinum

Mechanical Properties. The hardness of wrought rhodium in the annealed condition averages about 130 HV. Therefore, rhodium is harder than platinum or palladium (each about 40 HV).

Rhodium work hardens rapidly. A 15% reduction by cold rolling increases hardness to 300 HV. The hardness of annealed rhodium decreases progressively with increasing temperature; hardness falls from about 120 HV at room temperature to 80 HV at 600 °C (1110 °F) and to less than 50 HV at 1100 °C (2010 °F). The tensile strength of annealed rhodium is 827 to 896 MPa (120 to 130 ksi), while a tensile strength of 1379 to 1517 Mpa (200 to 220 ksi) is obtainable in cold-drawn wire.

Corrosion Resistance. Rhodium is resistant to corrosion by nearly all aqueous solutions at room temperature, including concentrated acids, but it is slowly attacked by solutions of sodium hypochlorite. In wrought or cast form, it is unattacked at 100 °C (212 °F) by concentrated HCl, HNO_3, and aqua regia, but it is attacked slowly by concentrated H_2SO_4 and by HBr (Table 24). Table 25 lists corrosion rates of rhodium in other environments. Rhodium can be used for insoluble anodes in electrolytic processes in which evolution of oxygen and chlorine occurs. When alternating current is used, however, rhodium is dissolved fairly readily in a number of electrolytes.

Table 24 Corrosion of rhodium in acids

Acid	Temperature		Corrosion rate

Aluminum sulfate, 100 g/L	100	212	nil	

Rhodium is unattacked by chlorine at room temperature, but it may be attacked at elevated temperatures. It is generally more resistant to the halogens than platinum, although it is less resistant than iridium (Table 26). In the massive form, it is attacked slowly by molten sulfur, but finely divided metal may react violently. Rhodium is resistant to wet or dry gaseous sulfur dioxide vapors to 1000 °C (1830 °F) if elemental sulfur is not present.

Table 26 Corrosion of rhodium in halogens at room temperature

Halogen	Corrosion rate, mm/yr (mils/yr)
Chlorine, dry	nil
Chlorine, moist	nil
Saturated chlorine in water	nil

Bromine, moist	nil
Saturated bromine in water	nil
Iodine, dry	nil
Iodine, moist	<0.25 (10)
Iodine in alcohol, 50 g/L	<0.25 (10)

Rhodium is resistant to attack by some molten salts. Rhodium crucibles have been used at 1620 °C (2950 °F) for growing calcium tungstate single crystals by the Czochralski technique.

Rhodium is attacked to varying extents by fused alkalies under oxidizing conditions; the rate of corrosion is comparable to that of platinum. It is corroded fairly rapidly by alkali cyanides and fused sodium bisulfate.

At temperatures 200 °C (360 °F) above their melting points, gold, silver, mercury, cesium, potassium, sodium, and gallium have negligible corrosive action on rhodium, but unlike iridium and ruthenium, rhodium is rapidly dissolved by lead and bismuth. The standard electrode potential of rhodium (Rh $Rh^{2+} + 2e^-$) is about +0.6 V at 25 °C (75 °F).

Oxidation Resistance. Rhodium does not tarnish in air at room temperature, even in the most severe atmospheric conditions, but heating in air at temperatures above about 600 °C (1110 °F) will produce a thin oxide film that is visible as a dark discoloration. The weight change due to oxidation at these temperatures is negligible even after prolonged heating.

The oxide decomposes at about 1100 °C (2010 °F) in air at normal pressure and at slightly higher temperatures in oxygen. At higher temperatures, rhodium dissolves some oxygen and simultaneously reacts with it to form a volatile oxide. The volatile oxide is formula rhodium dioxide (Ref 21).

The vapor pressure of rhodium dioxide is directly proportional to the partial pressure of oxygen in the atmosphere. It is slightly less than that of the corresponding platinum oxide at temperatures below 1200 °C (2190 °F), but at higher temperatures the reverse is true.

Corrosion Applications. Rhodium is principally used as an alloying element in conjunction with platinum and palladium. Rhodium-containing platinum alloys are used for crucibles, furnace windings, thermocouple elements, linings for glass extrusion nozzles and spinnerets, and woven screen oxidation catalysts for production of HNO_3 from ammonia.

Rhodium is used to harden palladium is jewelry applications. It also increases the corrosion resistance. Similarly, rhodium increases the hardness and corrosion resistance of nickel.

As the element, rhodium is electroplated for a number of decorative and nontarnishing uses, including jewelry, reflective mirrors, and electrical contacts. Rhodium is also vacuum deposited on glass to produce mirrors with high reflectivity and chemical stability. Thin coatings of rhodium on glass make an excellent gray filter.

Iridium

Fabrication. Pure iridium is not readily amenable to conventional fabrication and is generally used as an alloying element. However, iridium powder can be consolidated by conventional powder metallurgy techniques or by melting. Powder compacts are preferably sintered in vacuum at 1500 °C (2730 °F) before forging, rolling, swaging, or other hot-working operations for consolidation. Melting can be carried out in an argon arc furnace on a water-cooled copper hearth or by induction heating in a zirconia crucible, again in an argon atmosphere. In both cases, iridium powder is the raw material, which is preferably first briquetted and vacuum sintered into a partially consolidated material.

Sintered or cast iridium has working characteristics that are similar to those of tungsten and therefore requires considerable care in the early stages of processing. Initial breakdown of cast or sintered shapes is done in the temperature range of 1200 to 1500 °C (2190 to 2730 °F).

Subsequent drawing to wire is performed by warm working at 600 to 750 °C (1110 to 1380 °F), which is below the recrystallization temperature. Such wire has a fibrous structure, a hardness of 600 to 700 HV, and useful tensile strength and ductility. Drawing at lower temperatures leads to a rapid increase in hardness and splitting of the wire. Drawing of material that has been fully recrystallized by annealing results in frequent breakage.

Iridium can also be rolled at 600 to 750 °C (1110 to 1380 °F) into strip with the fibrous structure characteristic of drawn wire. In addition, iridium can be rolled at higher temperatures (1200 to 1500 °C, or 2200 to 2730 °F) to yield a product with an equiaxed structure and hardness of about 400 HV. In general, worked material that has a fibrous structure is preferred because it has better ductility and strength.

Warmed-worked iridium does not exhibit a sharp recrystallization temperature. Some softening occurs upon heat treatment at 700 °C (1290 °F), but it is necessary to heat to a minimum of 1000 °C (1830 °F) or higher temperatures before full recrystallization occurs.

Atomic, Structural, and Physical Properties. A number of interesting features of the atomic, structural, and physical property data for iridium are listed in Table 1. For example:

- Iridium has the distinction of being the heaviest element known, with a density of 22.65 g/cm^3 (0.818 lb/in.^{3})
- Next to osmium, iridium has the highest melting point of the platinum-group metals, 2447 °C (4437 °F)
- The modulus of elasticity of iridium is one of the highest for an element, 517 GPa (75,000 ksi)

Mechanical Properties. Iridium shows a high degree of work hardening compared with other fcc metals. The hardness of annealed iridium increased by 250 HV with 20% cold reduction as compared to an increase of 30 HV for pure platinum worked to a similar degree. The very small amounts of the impurities segregated at the grain boundaries may be the cause of the rapid work-hardening behavior. The excellent high-temperature strength properties of iridium place it in the category of the refractory metals.

Corrosion Resistance. Iridium is the most corrosion-resistant metal known. It is completely unattacked by the common mineral acids at normal and high temperatures and by cold and boiling aqua regia (Table 27). It is the most resistant of the platinum metals to the halogens, as shown in Table 28. It is slightly attacked by fused sodium and potassium hydroxides and by fused sodium bicarbonate. Iridium is resistant to anodic corrosion in aqueous electrolytes, but may be attacked in aqueous potassium cyanide, HCl, and ammonium carbonate solutions under the action of an alternating current. The corrosion resistance of iridium in other environments is shown in Table 29. Iridium can be dissolved by aqua regia under pressure by heating to 250 to 300 °C (480 to 570 °F). Iridium is resistant to wet or dry gaseous sulfur dioxide to 1000 °C (1830 °F) if elemental sulfur is not present.

Iridium shows excellent resistance to attack by a wide range of molten metals. Iridium is unattacked by gallium, lithium, potassium, sodium, indium, mercury, and bismuth at temperatures up to 200 °C (360 °F) above their respective melting points under an atmosphere of argon. It is only slowly attacked by molten lead, tellurium, cadmium, antimony, tin, calcium, silver, and gold. On the other hand, the metal is readily attacked by molten copper, aluminum, zinc, and magnesium. The standard electrode potential of iridiumr ($Ir \rightleftharpoons Ir^{3+} + 3e^-$) is about + 1.0 V at 25 °C (75 °F).

Oxidation Resistance. Iridium does not tarnish at room temperature, but heating in air at temperatures above about 600 °C (1110 °F) will produce a thin oxide tarnish. At temperatures of 1000 °C (1830 °F) and higher, iridium loses weight through the formation of a volatile oxide, which is reported to be either iridium sesquioxide, iridium trioxide, or iridium dioxide (Ref 21, 22, 23, 24). The weight loss as a function of time is linear because base metal is continually exposed to the attacking air. The linear mass change for all the platinum metals is plotted in Fig. 1. Although the weight loss in air is much greater for iridium than for platinum, iridium is the only metal with a sufficiently high melting point that can be used unprotected in air at temperatures up to 2300 °C (4170 °F) without catastrophic failure.

Corrosion Applications. Except for the use of pure iridium as high-performance sparkplug electrodes and for very high-temperature crucibles used in the preparation of single crystals of certain optical and electronic glasses, iridium is largely used for hardening and increasing the corrosion resistance of platinum and palladium. In platinum, which in the fully annealed state has a tensile strength of 131 MPa (19 ksi), a 10% Ir addition increases tensile strength to 414 MPa (60 ksi); a 35% iridium addition increases tensile strength to 965 MPa (140 ksi). Additional hardening can be obtained in platinum alloys containing 10 to 30% Ir by heat treating in the temperature range of 500 to 800 °C (930 to 1470 °F). As a rather less potent hardener than ruthenium, iridium can be added to platinum in significantly higher concentration than ruthenium without impairing ductility and workability.

Iridium is unattacked by lithium, sodium, potassium, bismuth, gallium, lead, silver, and gold at up to 200 °C (360 °F) above the respective melting points of these metals (Ref 25). It is also unattacked by mercury up to 550 °C (1020 °F). Iridium is not wetted by the lithium, sodium, potassium, bismuth, gallium, and lead at these test temperatures, although at 400 °C (720 °F) above its melting point gallium does wet iridium and there is some surface attack. Gold and silver wet iridium and form continuous films over both inside and outside the sintered crucible.

Tellurium, cadmium, and tin attack iridium at all temperatures above their melting points, along with the formation of intermediate compounds at the interface. These compounds have some protective value for the iridium, although they are brittle and do not adhere well to the iridium. Antimony also reacts with iridium to form an intermetallic compound, but this compound does not seem to adhere to the iridium and has no protective action.

Molten copper, calcium, and zinc at all temperatures penetrate iridium intergranularly; this is followed by the dissolution of iridium in these liquid metals. Copper, in particular, penetrates very rapidly into the iridium. Magnesium and aluminum attack iridium very rapidly by uniform diffusion at the interface; the solid solution so formed then dissolves in the liquid metal.

In addition to hardening platinum, iridium greatly enhances its corrosion resistance, particularly in environments involving nascent chlorine, aqua regia, and similar corrosives. Because of their exceptional resistance to corrosion and tarnish, platinum-iridium alloys containing up to 30% Ir have been used in:

- Chemical plants handling extremely corrosive materials
- Electrical contacts exposed to severe environments and where extreme reliability of chlorine is required
- Jewelry, surgical tools, and implants (catheters, microelectrodes, and pacemaker components)
- Primary standards of length and weight

Iridium is also an effective hardener for palladium, and it imparts corrosion resistance. Although not so widely applied as their platinum counterparts, the palladium alloys have been used for jewelry and electrical contacts.

Iridium alloys containing up to 60% Rh have been proposed for high-temperature thermocouples. The couple iridium versus Ir-40Rh is regarded as one of the most satisfactory for use in oxidizing atmospheres at temperatures as high as 2100 °C (3810 °F).

The naturally occurring alloy osmiridium (30 to 65% Os balance iridium) has been widely used for the tipping of fountain pen nibs, for instrument pivots, and for similar applications requiring high hardness and extreme resistance to wear and corrosion. Recently, osmiridium has been replaced by a wide variety of complex synthetic alloys containing, among others, the refractory metals, together with iridium, ruthenium, osmium, rhodium, and platinum.

Iridium-tungsten alloys have been principally developed for springs required to operate at high temperatures. These springs have excellent relaxation properties at temperatures up to 800 °C (1470 °F).

Small additions of iridium are very effective in improving the corrosion resistance of titanium. As with the other platinum-group metals, addition of as little as 0.1% Ir increases the corrosion resistance of titanium to nonoxidizing acids a hundredfold. Similar improvements have been reported for chromium containing 0.5% Ir.

Ruthenium

Fabrication. Wrought forms of ruthenium are limited. Those products that are available are generally fabricated by powder metallurgy techniques. The ruthenium powder is obtained from the refining process. Hot working can be accomplished at 1150 to 1500 °C (2100 to 2730 °F), although rolling of bar to strip can be performed in the range of 1050 to 1250 °C (1920 to 2280 °F) to minimize grain growth and edge cracking due to large grain size. Cold rolling of ruthenium is very limited because of the low ductility of the metal. The metal work hardens rapidly and requires frequent intermediate anneals.

Single-crystal ruthenium, prepared by electron beam zone refining, shows a relatively high degree of ductility when compared to polycrystalline material. However, the material work hardens rapidly, and upon annealing, it reverts to a polycrystalline state and exhibits low ductility.

Atomic, Structural, and Physical Properties. A high melting point (2310 °C, or 4190 °F), a moderate density of 12.45 g/cm^3 (0.45 lb/in.^{3}) and a Young's Modulus of 414 GPa (60,000 ksi) characterize ruthenium. In relation to other metals of the platinum group, ruthenium bears closest resemblance to osmium and, like it, has a hexagonal close-packed (hcp) structure. The principal atomic, structural, and physical properties of the metal are given in Table 1. Some of these properties will vary according to the degree of preferred orientation present in the material.

Mechanical Properties. The hardness of ruthenium varies considerably according to the orientation of the hexagonal lattice. The hardness of sintered bar, swaged at 1500 °C (2730 °F) with a 45% reduction in area and subsequently annealed at the same temperature, is in the range 400 to 450 HV on longitudinal sections and 250 to 300 HV on transverse sections.

The tensile strength of a polycrystalline sintered bar, swaged with a 45% reduction in area at 1500 °C (2730 °F) and subsequently annealed at the same temperature, in 496 MPa (72 ksi), and the elongation is 3%. High-temperature tensile tests carried out in air indicate a steady decrease in strength with increasing temperature and a maximum in elongation and reduction of area in the temperature range of 750 to 900 °C (1380 to 1650 °F).

Corrosion Resistance. Ruthenium is resistant to attack by cold and hot acid solutions, including aqua regia, and in this respect, is superior to platinum (Table 30). However, its resistance to attack under certain oxidizing conditions is not as high as that of platinum. Therefore, it is attacked fairly rapidly by sodium hypochlorite. Saturated aqueous solutions of chlorine and bromine and alcoholic solutions of iodine attack the metal slowly (Table 31). It is dissolved fairly rapidly as an anode in a large number of electrolytes and more rapidly by alternating current electrolysis. Ruthenium is attacked by fused alkaline hydroxides, carbonates, and cyanides and is attacked very rapidly by fused sodium peroxide. The corrosion resistance of ruthenium in other environments is given in Table 32.

Table 30 Corrosion of ruthenium in acids

Aluminum sulfate, 100 g/L	nil

Ruthenium exhibits good resistance to attack by molten lithium, sodium, potassium, copper, silver, and gold when it is heated in an atmosphere of argon. No solution attack by these metals occurs up to 100 °C (180 °F) above their melting points, although grain-boundary penetration is observed with sintered and unworked ruthenium. It is also resistant to attack by molten lead, and up to 700 °C (1290 °F), attack by liquid bismuth is extremely slight. The solubility of ruthenium in bismuth at this temperature is 0.029%, and at 1200 °C (2190 °F), it is 0.016%.

Oxidation Resistance. Ruthenium does not tarnish at room temperature even in heavily polluted atmospheres, but when heated in air or oxygen to temperatures approaching 800 °C (1470 °F), it oxidizes to form a surface film of ruthenium dioxide. Between this temperature and 1150 °C (2100 °F), there is simultaneous formation of a volatile oxide, probably ruthenium monoxide and ruthenium dioxide. At higher temperatures, only ruthenium monoxide is formed. The vapor pressure of the monoxide when formed on heating ruthenium in pure oxygen at temperatures in the range of 1200 to 1400 °C (2190 to 2555 °F) has been found to follow the approximate relationship:

$$\log_{10} P = \frac{11\,100}{T} + 4.83$$

where T is the absolute temperature, and P is the pressure in atmospheres (Ref 21). The actual rate of weight loss upon heating the metal in air will depend on a number of factors, including the geometric form of the sample under test and the degree of movement of the surrounding atmosphere. The mass change of ruthenium in air in comparison with the other platinum metals is given in Fig. 1

Corrosion Applications. Because of the lack of wrought forms of ruthenium that can be readily fabricated, the applications of ruthenium in corrosive environments are limited. High-ruthenium alloys containing other platinum metals or base metals have been used for electrical contacts and for severe wear resistance applications, such as tips for fountain pen nibs and for nonmagnetic instrument pivots. High hardness and excellent resistance to corrosion are the prime virtues of these alloys. Ruthenium dioxide coated titanium is an effective anode in chlorine-manufacturing cells.

Ruthenium is commercially added to platinum and palladium as a hardener. A 5% addition of ruthenium to annealed platinum will increase the hardness from 40 to 130 HV; similarly, the hardness of annealed palladium can be increased from 40 to 90 HV. The work-hardening rate of these metals is also increased by the addition of ruthenium.

Small additions of ruthenium have also been found to be effective in improving the corrosion resistance of titanium. As with other platinum metals, addition of as little as 0.01% Ru results in a hundredfold increase in resistance to corrosion in reducing acids.

Ruthenium is unattacked by lithium, sodium, potassium, gold, silver, copper, lead, bismuth, tin, tellurium, indium, cadmium, calcium, and gallium at temperatures up to 200 °C (360 °F) above the melting points of the respective metals (Ref 25). Gold, silver, and copper flow readily over the surface of ruthenium, but do not wet it. Ruthenium is also unattacked by mercury at temperatures to 550 °C (1020 °F). Ruthenium is apparently unattacked at lower temperatures by gallium, but there is some attack at temperatures 400 °C (720 °F) above the melting point of gallium. Similarly, bismuth dissolves ruthenium very slowly at 700 °C (1290 °F), with the dissolution occurring uniformly at the ruthenium surface.

Ruthenium is attacked by molten aluminum or zinc at all temperatures above their melting points. This attack appears to consist of uniform dissolution of the surface and does not result in the formation of intermetallic compounds or grain-boundary penetration. On the other hand, attack by magnesium and antimony occurs with the formation of an intermetallic compound at the interface, which appears to have some protective value.

Osmium

Fabrication. Osmium is an element that is essentially impossible to fabricate except by powder metallurgy, and-even with powder metallurgy techniques, extreme care must be used. Arc melting must be done under vacuum or inert atmospheres.

Atomic, Structural, and Physical Properties. Osmium has the highest melting point (about 3045 °C, or 5513 °F) and the second-highest density (22.57 g/cm^3, or 0.815 lb/in.^{3}) of the platinum-group metals. Osmium is similar in many properties to ruthenium and, like ruthenium, has an hcp crystal structure. The principal physical properties of the element are given in Table 1. Some of these properties will vary according to the degree of preferred orientation present in the test specimen.

Mechanical property data on osmium are scarce. The annealed hardness of osmium is 300 to 670 HV (Ref 26). This makes osmium the hardest of the platinum-group metals.

Corrosion Resistance. Compared to other elements in the platinum-group metals, osmium has relatively modest corrosion resistance. The element is attacked by aqua regia and the oxidizing acids, but is resistant to HCl and H_2SO_4 (Table 33). Osmium is attacked by the halogens at room temperature (Table 34), and the attack becomes progressively worse upon heating. Osmium is dissolved fairly rapidly in sodium hypochlorite at room temperature and in $FeCl_3$ at 100 °C (212 °F) (Table 35). Osmium burns in the vapor of sulfur and phosphorus and is attacked by molten alkali hydrosulfates, potassium hydroxide, and oxidizing agents. Osmium powder readily absorbs considerable amounts of hydrogen.

Table 33 Corrosion of osmium in acids

Acid	Temperature		Corrosion rate, mm/yr (mils/yr)

Hydrogen sulfide, moist	Room	<0.25	10
Sodium hypochlorite + sodium chloride, saturated solution	Room	Rapid dissolution	
Ferric chloride, 100 g/l	100 (212)	3.0	120

Oxidation Resistance. Osmium powder will slowly oxidize even at room temperature to form osmium tetroxide. Osmium tetroxide boils at 130 °C (265 °F) and is extremely toxic.

Corrosion Applications. Osmium is the rarest of the platinum-group metals; annual worldwide production amounts to only a few thousand ounces. Much of this production is for medical applications. A principal use of osmium is in the manufacture of hard, nonrusting pivots for instruments, phonograph needles, tipping the nibs of fountain pens, and certain types of electrical contacts. Alloys containing at least 60% Os or osmium plus ruthenium in conjunction with another platinum-group metal are usually used in these applications.

Anodic Behavior of the Noble Metals

Under anodic conditions in nitrate and cyanide solutions, silver is readily dissolved. This behavior is the basis of numerous silver electroplating baths. Silver becomes passive in most halide and hydroxide solutions because of the formation of a silver halide layer and a silver oxide layer, respectively. In sulfate solution, silver first forms a passive film of sulfate, but upon application of a higher potential, the sulfate becomes an oxide that can be reduced again to silver sulfate at a potential even lower than that required for the initial sulfate film formation.

Gold dissolves readily when it is made anodic in chloride solution containing an oxidizing agent. Only under conditions of low acid concentration or high current densities will the surface gradually become passivated by an absorbed layer of oxygen. In H_2SO_4, gold initially dissolves as Au^+, but the surface gradually becomes passivated by a layer of gold hydroxide.

Platinum and iridium are capable of carrying high current densities in certain acidic and alkaline solutions, but can become passivated with difficulty by absorbed oxygen. This film formation is accelerated by the superimposition of an alternating current on the direct current. The low solubility of platinum has made it a valuable commercial anode material for the electrolytic production of persulfates and perchlorates, electroplating anodes, and cathodic protection. Platinum loses less than 0.6 mg/A · yr over a current density range of 540 to 5400 A/m^2 (50 to 500 A/ft^2) in flowing seawater, and less than 1 g per ton of chlorine produced in the electrolysis of brine. In strong HCl solutions, platinum may be attacked, particularly if the temperature is raised. Rhodium becomes anodically passive in HCl. Conversely, palladium is readily dissolved anodically in acid chloride solutions and under certain neutral chloride conditions. Ruthenium metal is dissolved anodically in both HCl and H_2SO_4.

Small additions of the noble metals, particularly palladium and platinum, can substantially lower the corrosion rate of such metals as titanium, stainless steel, and chromium. This is achieved through the noble metal additions by their cathodic reduction of dissolved oxygen or hydrogen ions, permitting larger current densities and higher positive potentials in the anodic regions of the surface. To be effective, this higher potential must move the metal into a passive condition; otherwise, the corrosion rate will be accelerated. The technique works well for many base metal alloys in H_2SO_4.

Anodic Behavior of the Noble Metals

Under anodic conditions in nitrate and cyanide solutions, silver is readily dissolved. This behavior is the basis of numerous silver electroplating baths. Silver becomes passive in most halide and hydroxide solutions because of the formation of a silver halide layer and a silver oxide layer, respectively. In sulfate solution, silver first forms a passive film of sulfate, but upon application of a higher potential, the sulfate becomes an oxide that can be reduced again to silver sulfate at a potential even lower than that required for the initial sulfate film formation.

Gold dissolves readily when it is made anodic in chloride solution containing an oxidizing agent. Only under conditions of low acid concentration or high current densities will the surface gradually become passivated by an absorbed layer of oxygen. In H_2SO_4, gold initially dissolves as Au^+, but the surface gradually becomes passivated by a layer of gold hydroxide.

Platinum and iridium are capable of carrying high current densities in certain acidic and alkaline solutions, but can become passivated with difficulty by absorbed oxygen. This film formation is accelerated by the superimposition of an alternating current on the direct current. The low solubility of platinum has made it a valuable commercial anode material for the electrolytic production of persulfates and perchlorates, electroplating anodes, and cathodic protection. Platinum loses less than 0.6 mg/A · yr over a current density range of 540 to 5400 A/m^2 (50 to 500 A/ft^2) in flowing seawater, and less than 1 g per ton of chlorine produced in the electrolysis of brine. In strong HCl solutions, platinum may be attacked, particularly if the temperature is raised. Rhodium becomes anodically passive in HCl. Conversely, palladium is readily dissolved anodically in acid chloride solutions and under certain neutral chloride conditions. Ruthenium metal is dissolved anodically in both HCl and H_2SO_4.

Small additions of the noble metals, particularly palladium and platinum, can substantially lower the corrosion rate of such metals as titanium, stainless steel, and chromium. This is achieved through the noble metal additions by their cathodic reduction of dissolved oxygen or hydrogen ions, permitting larger current densities and higher positive potentials in the anodic regions of the surface. To be effective, this higher potential must move the metal into a passive condition; otherwise, the corrosion rate will be accelerated. The technique works well for many base metal alloys in H_2SO_4.

Corrosion of Beryllium*

John J. Mueller, Battelle Columbus Laboratories; Donald R. Adolphson, Sandia Laboratories

Introduction

THE CORROSION BEHAVIOR OF BERYLLIUM in aqueous and elevated-temperature oxidizing environments has been extensively studied for early-intended use of beryllium in nuclear reactors and in jet and rocket propulsion systems. Since that time, beryllium has been used as a structural material in less corrosive environments. Its primary applications include gyro systems, mirror reentry vehicle structures, and aircraft brackes. Only a small amount of information has been published that is directly related to the evaluation of beryllium for service in the less severe or normal atmospheric environments associated with these applications.

Despite the lack of published data on the corrosion of beryllium in atmospheric environments, much can be deduced about its corrosion behavior from studies of aqueous corrosion and the experiences of fabricators and users in applying, handling, processing, storing, and shipping beryllium components. The methods of corrosion protection implemented to resist water and high-temperature gaseous environments provide useful information on methods that can be applied to protect beryllium for service in future long-term structural applications.

Numerous grades of beryllium are commercially available, and these grades provide a wide range of compositional variations. The grades of material included under the name beryllium contain other elements at low concentrations, all of which are considered impurities and are generally not introduced as alloying elements. The major controls applied in producing beryllium are the minimization of impurities and control of the ratio of certain impurities, that is, maintenance of a prescribed ratio of about 2:1 for iron and aluminum in some grades. The impurities in normal commercial grades vary

from 1 to 4.5% and include oxygen, carbon, iron, chromium, nickel, silicon, aluminum, and copper (Ref 1). The impurities may be present in solid solution, as separate phases or compounds, or as particulate inclusions.

Reported corrosion results for beryllium often do not seem consistent or reproducible. This is perhaps because the investigators have used widely different grades of beryllium without properly characterizing the material involved or because a given has widely different compositions or distribution of impurities. Table 1 lists compositions of various grades of vacuum hot-pressed beryllium.

Table 1 Compositions of four grades of vacuum hot-pressed beryllium

S, structural grade; I, instrument grade

Chemical composition	S-65B	S-200F	I-220A	I-400
Be, % (min)	99.0	98.5	98.0	94.0
BeO, % (max)	1.0	1.5	2.2	4.2[(a)]
Al, ppm (max)	600	1000	1000	1600
C, ppm (max)	1000	1500	1500	2500
Fe, ppm (max)	800	1300	1500	2500
Mg, ppm (max)	600	800	800	800
Si, ppm (max)	600	600	800	800
Other, ppm (max)	400	400	400	1000

(a) BeO specified is minimum in this instance.

Corrosion of Beryllium in Air

Beryllium is commonly referred to as being self-protective against atmospheric oxidation; it resembles aluminum, titanium, and zirconium in this respect. Beryllium is unique among the alkaline earth metals in providing this characteristic. The protective nature of its oxide is partially due to the fact that temperature poses no reported corrosion problems for beryllium (Ref 2). On the other hand, air that contains water at a level at which condensation can occur with temperature cycling can cause beryllium to corrode under certain conditions. Because the atmospheric-corrosion problem can be regarded as an extension of the aqueous corrosion of beryllium, the corrosion behavior of beryllium in water and aqueous environments is important in understanding corrosion in air environments. The condensable water vapor in normal air environments provides the basis for this relationship.

Causes of Corrosion in Air. There are two primary situations in which beryllium has been found to be susceptible to corrosion in a water-bearing air atmosphere. One cause of corrosion in air is when the beryllium contains beryllium carbide (Be_2C) particles exposed at its surface by a machining operation. The water available from the surrounding air will slowly react with the carbides to form a flowery white buildup of beryllium oxide (BeO) according to the reaction:

$$Be_2C + 2H_2O = 2BeO + CH_4$$

with methane as a gaseous product. The reaction:

$$Be_2C + 4H_2O = 2Be(OH)_2 + CH_4$$

has been suggested as an intermediate step in arriving at the final BeO product (Ref 3). This is consistent with the observed formation of a white gelatinous product from the reaction of Be_2C in an aqueous environment (Ref 4).

This type of corrosion is commonly manifested by the bursting out of the beryllium at the edges of the carbide particles or by the formation of blisters as a result of the localized volume expansion during reaction.

The reactivity of carbides in an air atmosphere was first reported in 1955 (Ref 5). In work performed at Oak Ridge National Laboratory in 1947, white corrosion products and blisters were observed to form on the surface of extruded beryllium that had been exposed for about 6 months to the local humid air. The corrosion products were caused by carbide inclusions that were parallel to the extrusion axis. Similar corrosion attack was discovered during the shelf storage of finished precision-machined components (Ref 4, 6). The components were scarpped because of the disruption of the finely machined, unetched surfaces.

In one case, an instrument grade material corroded in service in a controlled gas environment containing a fixed value of relative humidity (Ref 3). The corrosion, which was in the form of spotty white buildup and disruption of the surface, occurred at carbide sites. The type of corrosion observed was experimentally duplicated with carbide-seeded beryllium subjected to the same type of environment. In addition, beryllium that exhibits flowery corrosion spots during extended air storage was also found to yield a similar pattern of corrosion attack within hours of immersion in an aqueous bath (Ref 4).

The carbon present in commercial beryllium may be distributed uniformly as fine carbide particles or randomly as a smaller number of bulk particles. Such a difference in distribution can lead to differing corrosion results. For example, one study investigated the effect of a large atypical carbide inclusion corroding in an air environment during storage (Ref 7). The carbide inclusion was disk shaped, about 13 mm ($\frac{1}{2}$ in.) in diameter, in an approximately 76-mm (3-in.) diam beryllium component. The inclusion was exposed to the atmosphere at the machined surface. The volume expansion resulting from reaction with water in the air caused a large piece of beryllium to break out of the component. The volume expansion that occurred in this case from reaction with water vapor also causes the blistering and disruption of beryllium at the edges of smaller Be_2C inclusions.

In another study, during preparation of beryllium specimens with artificially added graphite inclusions, the formation in air of the typical white corrosion products was observed at particles exposed at the machined surfaces and fracture surfaces of tensile specimens (Ref 8). Metallographic examination of sections through graphites inclusions disclosed the presence of a shell of Be_2C around each graphite particle that formed during hot pressing of the beryllium.

The second major cause of corrosion in a humid air environment occurs when the beryllium surface contains contaminants in the form of chlorides and sulfates that remain on the beryllium after a final drying operation or are introduced after proper rinsing and drying. The use of tap water or a chloride-contaminated water bath without adequate cascade rinsing in deionized water prior to drying has been frequently reported as a cause of corrosion during subsequent processing or storage (Ref 9, 10, 11, 12). The residual surface contaminants become concentrated upon drying and require very little water or condensation derived from temperature and humidity changes to provide a condition for corrosion at active sites. In one case, plastic piping, which is used to avoid metallic contamination of the rinse system, was found to be a source of chloride ions (Cl^- that resulted in corrosion of components during storage (Ref 12).

Fingerprinting of clean, dried beryllium components is one of the most commonly encountered sources of surface contamination which can result in subsequent etching and corrosion of beryllium. The corrosive nature of fingerprints is

apparent from the need to abrade and renew the affected surface mechanically before most chemical treatments (Ref 1, 13). All producers and users of beryllium strongly specify the avoidance of hand contact with semifished and finished beryllium components.

The final cleaning treatment can be very important, particularly in view of the present-day trend of avoiding the chlorinated solvents that had often been used to remove oily surface contamination. Solvent and/or chemical cleaning extremely important when the final machined surface will not be given a final acid-etching treatment to remove mechanically produced surface imperfections.

In one laboratory, a step has been taken toward developing cleaning procedures that are effective in removing surface contamination while avoiding the use of chlorinated solvents (Ref 14). An alkaline detergent-type bath with superimposed ultrasonic treatment has been found to be effective in removing all types of normal soils, with the exception of silicone greases. A suitable solvent for the silicone grease, followed by an alkaline detergent cleaning, should be an effective procedure in this instance.

A comparison was made of the results of cleaning in an alkaline detergent and by means of other solvents, including chlorinated solvents. The evaluation involved scanning electron microscopy of the cleaned surfaces and surface-outgrassing measurements. The results showed that the alkaline detergent cleaning produced a surface that was cleaner than that obtained with the other cleaning methods. Surprisingly, the detergent-cleaned surface yielded a smaller amount of water in the outgassing experiments than the surface cleaned with chlorinated solvent. The higher yield from thte chlorinated solvent cleaned surface was attributed to water held by surface contaminants that were not removed by this cleaning procedure.

An acid-etching treatment is commonly used on machined beryllium components to remove machining-damaged surface material. The material removed by etching may contain microcracks, which are open defects into which contaminants can penetrate and cause corrosion. Precision components that cannot be acid etched but are lapped to final size are susceptible to corrosion as a result of the unremoved microcracks (Ref 7). In the removal of only a few tenths of a mil of stock by lapping with an improper lapping agent, the microcracks can be smeared over with adjacent material. This results in entrapment of contaminants and corrosion of the component at a later time. A free-cutting diamond paste was recommended as the lapping agent.

Contamination From the Atmosphere. Rainwater has been recognized as a potential source of corrosive agents that can be inadvertently transported into a protective environment and cause deterioration of susceptible materials. Table 2 lists the corrosive agents commonly found in rainwater.

Table 2 Corrosive agents in rainwater

Agent and source	Location	Concentration, ppm
Chloride (Cl^-) ions, major source is sea spray	Over sea or near coastlines	Average 2-20; with extreme winds, may increase up to 100
	500 miles or more inland	Average 0.1-0.2, but sometimes higher than 1.0
Sulfate (SO_4^{2-}) ions; major sources in industrial areas	Large cities, industrial areas	Average 10-50; higher under extreme conditions such as smog
	Other areas	1-5
Nitrate (NO_3^-) ions	Over land	0.5-5

Hydrogen ions (pH)	Over land	Average approximately 5; may decrease to 3 near industrial centers

Inadvertent admission of atmospheric moisture into silos and launch control centers of missile systems has been cited as the cause of most of the general corrosion problems associated with the various metals contained in these structures (Ref 15). Despite the fact that corrosion problems have been encountered in missile silos, the maintenance of a humidity-controlled environment has generally been effective in protective most components from corrosion. For example, one manufacturer has not found a single case of corrosion of beryllium components in rocket thrusters during periodic examination of all operational units through years of continued service (Ref 16). These components were maintained under humidity-controlled conditions.

The open atmosphere above the ocean provides a site of unusually high salt content. Storms at sea and the mist generated by a moving vessel have been found to produce severe corrosion of beryllium brake shoe pads on military carrier bombers (Ref 17, 18). The brake shoes were typical of those that have performed well for years on the C5A military transport in less corrosive environments. The salt-laden environment of the aircraft carrier caused the brake pads to pit and to become covered with corrosion products.

One study demonstrated the noncorroding nature of pure water vapor when the beryllium surface is uncontaminated and free of exposed Be_2C inclusions (Ref 19). Polished, bare specimen coupons were subjected to an atmosphere of 95% relative humidity at 40 °C (100 °F) for 30 days with a result of no apparent corrosive attack. Neither microscopic examination nor weight gain measurements indicated corrosive attack on any of the specimens.

Aqueous Corrosion of Beryllium

Beryllium that is clean and free of surface impurities has very good resistance to attack in low-temperature high-purity water. The corrosion rate in good-quality water is typically less than 0.025 mm/yr (1 mil/yr) (Ref 20). Beryllium has been reported to perform without problems for 10 years in slightly acidified demineralized water in a nuclear test reactor (Ref 7, 21). This high-purity water environment also produced no evidence of accelerated corrosion with the beryllium galvanically coupled with stainless steel or aluminum.

Beryllium of normal commercial purity, however, is susceptible to attack, primarily in the form of localized pitting, when exposed to impure water (Ref 22). Chloride and sulfate ions (SO_4^{2-}) are the most critical contaminants in aqueous corrosion. Because these contaminants are present in tap water, most processing specifications warn against its use. In cases where tap water can be used, the final rinses are done in deionized water to ensure taht the Cl^- or SO_4^{2-} impurities are not retained on the subsequently dried metal surface.

The pitting of beryllium in aqueous baths containing Cl^- or SO_4^{2-} ions has generally been attributed to attack in areas anodic to the bulk of the metal (Ref 23). In an investigation consisting of 12-month corrosion tests in water 85 °C (185 °F), the pitting attack was attributed to a lack of metal purity (Ref 24). Years later, in a study prompted by rejection of beryllium components for the presence of hard inclusions, pitting corrosion was shown to be associated with points of silicon and aluminum segregation (Ref 25). In subsequent studies, an aqueous corrosive agent containing 200 ppm Cl^- ion, 400 ppm SO_4^{2-} ion, and approximately 50 ppm carbonate ion (CO_3^{2-}) was used to produce rapid pitting attack of the beryllium. Electron microprobe analysis showed that the localized pitting occurred at sites rich in either silicon or aluminum.

On the basis of the examination of pitted specimen surfaces by microprobe analysis, the following general conclusions were drawn (Ref 26):

- Pitting corrosion is determined by the distribution of alloy impurities
- Sites that have high concentrations of iron, aluminum, or silicon (probably in solid solution) tend to form corrosion pits
- The corrosion sites are often characterized by the presence of alloy-rich particles, which are probably beryllides; however, the particles themselves do not appear to be corrosion active

- Pitting density is believed to be related to the number of segregated regions in the matrix containing concentrations of iron, aluminum, or silicon higher than concentrations present in the surrounding areas

Segregated impurities, such as Be_2C particles, intermetallic compounds, or alloy-rich zones, can contribute to localized attack when present in an exposed beryllium surface (Ref 7, 25). As previously noted, Be_2C forms a gelatinous corrosion product in an aqueous environment. As the purity of beryllium has improved during the years of its commercialization, the problem of localized corrosion at segregated particles and inclusions has significantly decreased (Ref 6, 27).

The effects of the surface finish of beryllium on aqueous corrosion were investigated in one study (Ref 28). The specimen conditions included (1) as-machined, (2) pickled in chromic-phosphoric (H_2CrO_4-H_3PO_4) acid after machining, and (3) machined, annealed beryllium reannealed in vacuum for 1 h at 825 °C (1515 °F). The results of long-term tests in demineralized water at 85 °C (185 °F) showed that the pickled specimens corroded at a higher rate than the others during the first 60 days of testing. The machined and annealed specimens initially corroded faster than the as-machined specimens. It was found, however, that with extended exposure times the magnitude of attack for all the types of surfaces reached about the same value: 0.0025 to 0.005 mm/yr (0.1 to 0.2 mil/yr).

Extensive information on the behavior of beryllium under the combined effects of stress and chemical environment is not readily available. The first reported work involved the use of extruded material in water containing 0.005 *M* hydrogen peroxide (H_2O_2) at pH 6 to 6.5 at 90 °C (195 °F) (Ref 29). No evidence of cracking was noted even though stresses up to 90% of the yield strength were used. Stress corrosion has been reported on cross-rolled sheet when synthetic seawater was used as the test medium (Ref 30). Studies of time to failure versus applied stress revealed that the time decreased from 2340 to 40 h as the applied stress was increased from 8.4 to 276 MPa (1220 to 40,000 psi, or 70% of yield strength). Failure appeared to be closely associated with random pitting attack. Certain pits appeared to remain active, which promoted severe localized attack.

In-Process Corrosion Problems and Handling and Storage Procedures

Many of the specified practices used by manufacturers and users result from knowledge of the problems experienced in processing and handling of components. One example of this is the common specification to avoid contact of beryllium by tap water. Early processors encountered serious problems of pitting or surface corrosion in beryllium that was allowed to stand in tap water, or was rinsed off with tap water and, after drying, was allowed to stand in a damp atmosphere where water condensation could easily occur on the contaminated surfaces. Improper handling, inadequate control of chemical and rinse baths, and improper storage or packaging procedures are the primary causes of in-process corrosion problems.

In-Process Problems

Inadvertent contact with water can be a damaging factor for beryllium. An airframe manufacturer experienced a major production problem when water vapor condensing on overhead piping dripped onto structures in the processing line (Ref 31).

Chloride ions from sources other than tap water can also lead to pitting attack in aqueous baths. Chlorinated solvents used to remove oils and greases have been found to be sources of Cl^- ions when the solvent is carried into a cleaning bath by an as-machined surface (Ref 14). As mentioned earlier, plastic piping, which is used to avoid metallic contamination in a chemical cleaning facility, provided a source of Cl^- ions (Ref 6).

Fingerprinting of in-process parts has been a commonly cited problem (Ref 9, 10, 11). Under certain atmospheric conditions, the salt in a fingerprint may seriously etch a beryllium surface. Such etching of a finished, critically size component can cause rejection of the component (Ref 11, 12). Etching on a semifinished surface, if not seen and properly prepared, can lead to localized corrosion of a chemically treated surface.

Corrosion problems are often discovered well after their occurrence (Ref 12). One example of this is the use of a dye penetrant solution for nondestructive testing. If it is merely wiped off a surface, the dye penetrant solution can later seep out of crevices and cause localized attack. A second example is when localized galvanic attack is found on beryllium parts. The cause was traced back to a cutoff operation in which the beryllium contacted steel while wetted by the coolant.

Contact with apparently dry materials has also been found to be the cause of corrosion of beryllium. In one case, beryllium became etched when it was placed on an inspection bench on which a rubberized mes was used to prevent nicking and scratching of finished parts (Ref 9). In another instance, a molded styrofoam support used for shipment of a complex satellite boom caused severe localized etching of the beryllium at points of pressure contact (Ref 9). The beryllium part was not shipped in direct contact with the styrofoam, but the part had been laid on the foam after being removed from its polyethylene bag for inspection. It can only be surmised that the etching resulted from attack by chemical compounds contained in the contacting materials. Lastly, small beryllium components that had been inserted into plastic shop-routing folders were attacked by the photocopied routing sheets, which directly contacted the components (Ref 12).

Handling and Storage Procedures

In handling and packaging beryllium components for shipment or storage, it is important to maintain an initially clean surface and to avoid unduly moist environments. The various practices employed by industry are discussed below.

Handling of beryllium parts with bare hands is often done and is not harmful when the part is in a rough or semifinished stage. In general, a finish-machined surface, even if it is to be acid etched to remove machine-damaged surface material, should not be handled with bare hands. A fingerprint left on the surface for some time, during which it may etch the beryllium, may retard the beneficial aspects of the acid-etching treatment or at least may provide a questionable artifact after etching. Fingerprints that have etched the beryllium adversely affect conversion or passivation coatings, disrupting the continuity of the coating and thus its effectiveness (Ref 11, 12, 13).

The common practice in handling finished and semifinished parts (or when handprinting is unacceptable) is to use protective gloves. White cotton, nylon, polyethylene, or rubber gloves are usually used.

Packaging for Shipment. Polyethylene bags are extensively used by industry as protective containment and/or barriers to contact between beryllium and its surrounding (Ref 10, 11, 27). A permeable container with a desiccant is often used inside the polyethylene bag to remove undesirable moisture (Ref 11, 27). An argon gas purge of the interior of the bag has been used as a means of displacing the moisture initially present (Ref 9). Because of the desire to minimize the availability of moisture to the beryllium, an attempt is generally made to provide an effective seal at the bag opening. An integrally molded interlocking seal or the practice of overlapping and taping provides an effective seal against free moisture access to the interior.

Molded foam, formed styrofoam, and contoured fiber-type insulation materials are typical means of supporting and protecting large beryllium structures or components against mechanical damage inside a shipping container (Ref 9, 10, 27). In some cases, when support is desired in all directions (if the container is overturned), a molded upper closure is used to encase the structure totally with supporting material. In almost every case, however, a polyethylene bag provides an effective separator between the beryllium and the contacting support material.

Storage of beryllium components while awaiting assembly or use can be safely accomplished under the conditions used for shipment, that is, in a compatible container made of metal or polyethylene with a desiccant to maintain a dry storage atmosphere. Heating a cabinet with a light bulb to keep the interior about 50 °C (120 °F) has been found to be effective for long-term storage of gyro components (Ref 6). A room or chamber with humidity control, as well as a humidity-controlled missile silo, can be effective in preventing corrosion of beryllium rocket motor components during storage periods of several years (Ref 6, 11, 32). The following points should be considered in safely storing components for extended period of time:

- Ensure that the component entering storage is free of corrosion-causing contaminants
- Maintain a moderately dry and noncondensing environmental atmosphere
- Ensure against contact with materials of nonproven compatibility

Corrosion-Protection Surface Treatments and Coatings

Extensive development and study of surface treatments and coatings for beryllium have been done to provide protection against many potentially severe environments. The status of these activities is summarized in Ref 7, 33, and 34. In addition to the treatment designed to provide normal storage and handling protection, many of the coatings and treatments developed for more severe applications are useful for less demanding applications. For example, those treatments

designed to provide protection against seawater are effective in protecting against corrosion of beryllium during processing or use in air environments.

Chromate-type coatings are applied by a simple dip treatment. The coatings thus produced provide reasonable protection for beryllium during handling and storage and against attack by salt-containing environments for moderately long time periods. Some coatings are extremely thin, being virtually immeasurable by conventional techniques. One investigation demonstrated the ability of a chromate-type coating on S-100 beryllium to hold up well under a 100% relative humidity test involving 50 6-h cycles at 75 °C (170 °F) and under a 5% salt spray test for a period of 120 h (Ref 35).

Another study found that a passivation chromate tretment applied to a type of beryllium that showed susceptibility to white spot formation in moist air was very effective in improving resistance to such attack (Ref 36). The treatment involved a 30-min dip in a solution consisting of 25% H_3PO_4, 25% saturated solution of pottassium chromate (K_2CrO_4), and 50% deionized water. Specimen life in 100% relative humidity at 70 °C (160 °F) increased from 1 day to 10 to 14 days because of the passivation treatment.

As further evidence of the protection afforded by a patented passivation treatment, an accelerated water immersion test consisting of 30 days in distilled water at 95 °C (205 °F) was used to evaluate the effectiveness of the treatment (Ref 13). The results showed a reduction in corrosion rate by a factor of 50. The protective chromate coating was less than 0.01 μm (0.0004) mil thick. Also, another study found that a conversion coating on instrument grade beryllium containing Be_4C markedly reduced the corrosive attack by moisture in the service atmosphere (Ref 3).

In one case, a beryllium mirror that had been given a chromate passivation coating and had been stored on the roof of a California facility, unprotected except for a roof shelter, did not exhibit significant surface degradation after more than 6 months of exposure (Ref 32). The mirror surface appeared darker, but had retained 97 to 98% of its reflectivity and had lost only about 0.5% of its reflectivity to the 10-μm wave-length.

Commercial manufacturers of beryllium components are often required by drawing specifications to provide passivation-type coatings on finished parts. These coatings are effective in providing protection during shipment and short periods of storage under less-than-ideal conditions.

Fluoride coatings are produced by treating beryllium in fluorine above 520 °C (970 °F), which produces a glassy-appearing water-insoluble coating. The structure of the coating is of the rhombic tridymite type. This type of coating was shown to be very effective in resisting corrosion in chloride-containing water and in distilled water (Ref 37). Coatings 0.2 and 1.2 μm (0.008 and 0.05 mil) thick were unchanged after 3000 h in distilled water at room temperature. A 0.2 μm (0.008-mil) thick coating provided effective protection in water containing a 150-ppm concentration of Cl^- ion.

Anodic coatings that are similar in character to the well-known anodizing on aluminum have been shown to improve the resistance of beryllium to corrosion in normally corrosive aqueous solutions and to air oxidation at elevated temperature. There are a variety of formulations for anodizing solution compositions that provide differing qualities and results in various test environments. Nitric acid (HNO_3), H_2CrO_4, sodium dichromate ($Na_2Cr_2O_7$), and sodium hydroxide (NaOH) are common ingredients in many anodizing bath formations.

Anodized films vary in thickness from 2.5 μm (0.1 mil) to several mils, depending on solution type, applied voltage, current density, bath temperature, and time of treatment. The film qualities vary in accordance with descriptive terms, such as color, thickness, adherence uniformity, density, and electrical characteristics. It was concluded from a survey of many anodizing procedures that the following simple formulations produced the most uniform and adherent coatings (Ref 38):

- Solution of 50% HNO_3 with current density of 2.15 A/m^2 (0.20 A/ft^2) for 5 min
- Solution of 7.5% NaOH with a current density of 108 A/m^2 10 A/ft^2 for 20 min

The following experimental corrosion results on anodized coatings show the effectiveness of anodized coatings in resisting water and salt-containing environments. The results attest to the potential of anodized coatings in providing protection for beryllium in structural applications in which normal air environments are encountered.

Brush-produced anodic coatings were found to protect beryllium effectively for the following indicated times in the associated environments (Ref 3):

- 2400 h in a humidity cabinet
- 3 months at 40 °C (100 °F) in tap water
- 2000 h in ASTM salt spray test

In one study, approximately 5-μm (0.2-mil) thick anodic coatings produced in a 1% H_2CrO_4 solution and sealed in boiling water evaluated (Ref 19). No corrosion was detected after exposure to 5% salt fog spray at 40 °C (100 °F) for 30 days.

Anodized coatings prepared in two distinctly different baths were evaluated as protection for beryllium experimentally seeded with Be_4C (Ref 3). When microanalysis techniques were used to determine gas generation in humid gaseous environment, it was shown that the anodized coatings markedly reduced the corrosion rate.

The results of an evaluation of anodized coatings showed favorable performance in 5% salt spray tests at room temperature, but indicated poor performance at 50 °C (120 °F) (Ref 39). Only one specimen among five tested at room temperature showed attack after 24 h. Five similar specimens exposed at 50 °C (120 °F), however, were noticeably corroded within 24 h. In synthetic seawater, unprotected beryllium corroded at a rate 21 times that of the anodized beryllium. Pitting of the anodized material was first observed after 30 days in test. The performance of the coatings at 50 °C (120 °F) was much poorer than in other reference cases, but the results showed a definite improvement over uncoated material of similar quality. The difference in performance observed may reflect a difference in the quality of the coatings evaluated or of the beryllium used.

One prominent application of anodized coatings is in the mirror industry, in which beryllium is used for its light weight, high modulus of elasticity, and high specific heat and thermal conductivity. In this application, anodizing is used in conjunction with the good thermal properties of beryllium. The anodic coatings is favored for its high thermal emissivity and absorptivity values. Its corrosion resistance is an added benefit. An anodic coating applied before lapping the spherical mirror surface has beenfound to provide corrosion protection against pitting corrosion at the unlapped edge of the mirror (Ref 27). The lapping compound tends to move to the rim of the lens structure, where it will readily attack bare beryllium if allowed to stand even for relatively short periods of time.

Plated Coatings. Beryllium is rarely plated to provide general corrosion protection but rather to comply with specific requirements, Plated coatings, whether applied by electroless or electrolytic plating techniques, are commonly used on beryllium to provide areas for electrical contact, to improve wear resistance, or to improve polishing characteristics in the case of mirrors.

Organic paint coatings are used when an electrically insulating barrier is required between the beryllium component and another metallic structure. Coatings used for this purpose provide protection against galvanic attack in the event of an electrolyte gaining access to the joint.

In one case, an electrodeposited paint coating added over a passivation coating was found to provide suitable protection for beryllium structures requiring long-term storage capability (Ref 31). A previously used black anodizing treatment yielded a coating that became troublesome because of its ease of scratching and chipping and the need for additionally protecting the uncoated sites of the electrical contact.

In one study, a polyvinyl butyrol phosphating primer was evaluated for the Navy for atmospheric protection of several metals, including beryllium (Ref 40). A two-coating system was recommended for storage for periods of 8 to 10 months in open exposure to the atmosphere.

An epoxy primer has been found to be effective for general protection of sheet and tubular components in communications satellite platform structures (Ref 12). The primer is used on all exposed surfaces, and all of the individually coated components are joined by adhesive bonding or mechanical fasteners. The primer is applied immediately after a flash etching of the surfaces to be coated and is cured by baking. The primer system of protection was selected to satisfy the requirement of years-duration storage capability for the fabricated structures.

Corrosion of Uranium and Uranium Alloys

Lawrence J. Weirick, Sandia National Laboratories

Introduction

THE CORROSION of uranium and uranium alloys will be reviewed in this article. Included are sections on the oxidation of unalloyed uranium, the effect of alloying elements on oxidation response, the corrosion behavior of uranium alloys in aqueous solutions, the influence of microstructure on corrosion properties of the alloys, galvanic behavior, the stress-corrosion cracking (SCC) of uranium alloys, and protective coatings for uranium and uranium alloys, particularly metallic coatings of electroplated nickel and ion-plated aluminum. This article is not intended as a complete review of all the areas mentioned; additional information on a particular section is available in the cited references.

Oxidation of Unalloyed Uranium

The oxidation and corrosion of unalloyed uranium has been of interest to metallurgists and engineers since the early 1940s. However, only recently has there been agreement among researchers on reaction rates and mechanisms, particularly in environments containing both water vapor and oxygen.

Oxygen. Uranium reacts with oxygen according to:

$$U + \left(\frac{2 + x}{2}\right)O_2 \rightarrow UO_{2+x} \qquad \textbf{(Eq 1)}$$

where x is between 0.2 to 0.4 at temperatures to 200 °C (390 °F). The oxide thus formed is hyperstoichiometric uranium dioxide (UO_2). The most recent review of the literature on the reaction of uranium with oxygen or dry air at temperatures up to 300 °C (570 °F) is provided in Ref 1. The best estimate of the uranium-oxygen reaction rate constant (expressed in units of $mg/cm^2/h$) for the temperature range of 40 to 300 °C (105 to 570 °F) is:

$$K = 9.4 \times 10^7 \exp\left(\frac{-18\ 000}{RT}\right) \quad \textbf{(Eq 2)}$$

where the weight gain (in milligrams per square centimeter) with time (in hours) is due to the quantity of oxygen consumed, *R* is a constant, and *T* is temperature. Thus, the reaction rates were found to be linear and independent of oxygen pressure above 133 Pa (1 torr). The reaction product was determined by x-ray diffraction analysis to be nominally $UO_{2.2}$, which has a face-centered cubic (fcc) crystal structure. The reaction product is very compact and adherent.

One of the most extensive studies of the oxidation of uranium covered the temperature range of 300 to 625 °C (570 to 1155 °F) and oxygen pressures from 133 to 667 kPa (100 to 500 torr) (Ref 2). No influence of oxygen pressure was observed in this range. The data were fitted to an equation of the form $w^n = kt$, where *w* is the quantity of oxygen consumed (in milligrams per square centimeter) in time *t* (in minutes), and *k* and *n* are constants. Values for *n* and *k* were functions of temperature *T,* and three rate equations were proposed:

$$w^{4/5} = 1.0 \times 10^5 t \exp\left(\frac{-16\ 800}{RT}\right) \quad \textbf{(Eq 3)}$$

$$w = 0.840 \quad \textbf{(Eq 4)}$$

$$w^{6/5} = 1.8 \times 10^4 t \exp\left(\frac{-14\ 300}{RT}\right) \quad \textbf{(Eq 5)}$$

Equation 3 is for 300 °C < *T* < 450 °C (570 °F < *T* < 840 °F), Eq 4 is for *T* = 450 °C (840 °F), and Eq 5 is for *T* > 450 °C (840 °F). The rate of oxidation accelerates with time up to 450 °C (840 °F), is constant at *T* = 450 °C (840 °F), and decreases with time at temperatures above 450 °C (840 °F). The data in Ref 2, along with those of several other investigators, are summarized in Fig. 1. The deviation in the curve from linearity at 450 °C (840 °F) was attributed to a change in the character of the oxide from a highly porous and nonprotective layer to a more compact scale, although all of these oxides were identified as nominally UO_2.

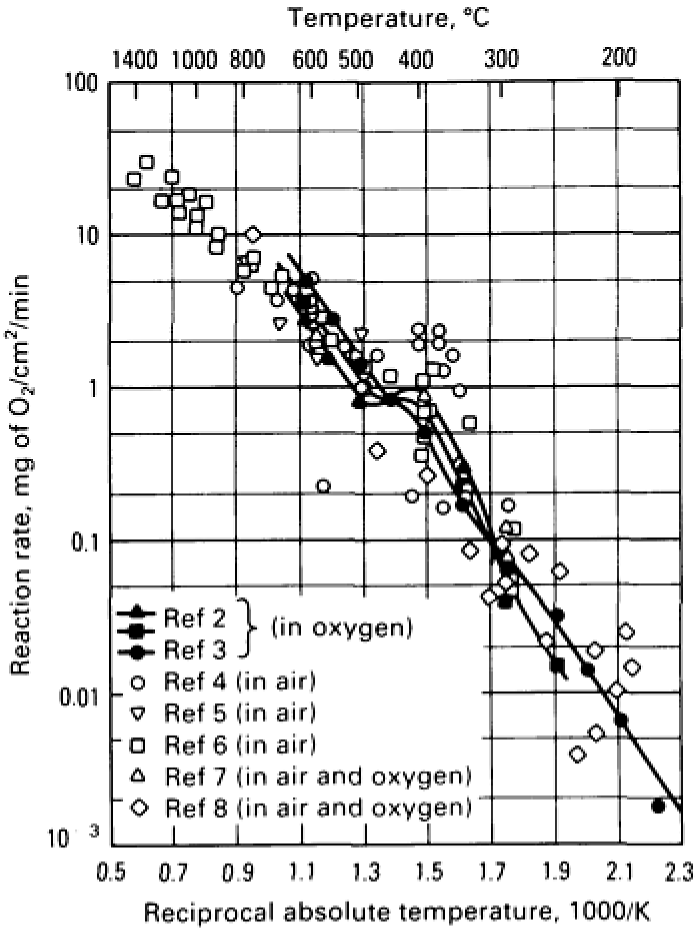

Fig. 1 Oxidation rates of uranium in air and in oxygen

Water Vapor. Uranium reacts with water vapor according to:

$$U + (2 + x)H_2O \rightarrow UO_{2+x} + (2 + x)H_2 \quad \textbf{(Eq 6)}$$

where x is between 0 and 0.1 in the absence of oxygen. In the most recent investigation of the uranium-water vapor reaction, Equation 6 was found to the linear between 30 and 80 °C (85 and 175 °F) (Ref 9). The reaction rate is proportional to the square root of the humidity and obeys Eq 7:

$$K = 4.1 \times 10^8 r^{1/2} \exp\left(\frac{-15\,500}{RT}\right) \quad \textbf{(Eq 7)}$$

where r is the fractional relative humidity. These data and Eq 7 agree very well with the results in Ref 10 and 11 (Fig. 2). Both investigators found a water vapor pressure dependency of 1:2.1. The crystal structure of the UO_2 is fcc. The reaction product forms loose flakes that readily spall from the base metal. The quantity of hydrogen produced is typically from 1 to 12% less than the 2 mol predicted for every mole of oxide produced.

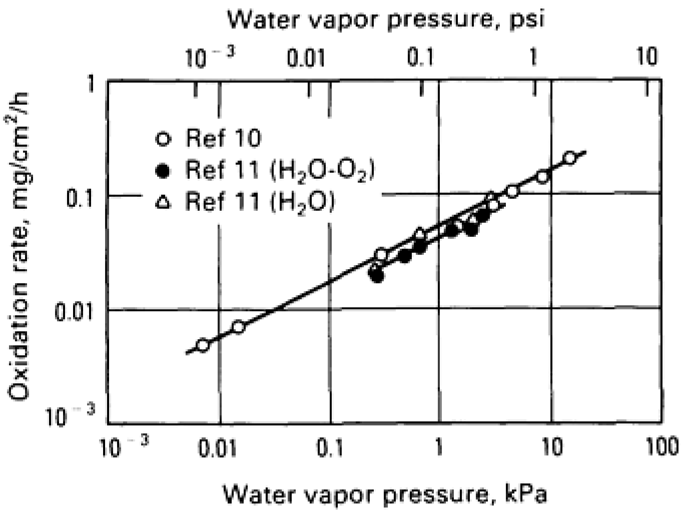

Fig. 2 Oxidation rate of uranium at 100 °C (212 °F) versus water vapor pressure

Water Vapor-Oxygen Mixtures. Until the work done in the early 1980s, which is discussed in Ref 11, it was thought that uranium in a water vapor-oxygen mixture reacted with water vapor, forming UO_2 and releasing hydrogen that combined with the free oxygen to form more water vapor. This work, combining both thermogravimetric and gas spectrometric techniques, showed that uranium reacts with oxygen directly in a water vapor-oxygen mixture. The water vapor affects the uranium oxide structure formed, producing a more defective, or nonstoichiometric, oxide than that formed in the absence of water vapor. Thus, uranium reacts with oxygen in the water vapor-oxygen mixture according to:

$$4U + 9/2\ O_2 \quad U_4O_9 \qquad \textbf{(Eq 8)}$$

The most recent and extensive investigation of th uranium-oxygen-water vapor system measured the kinetics between 40 and 100 °C (105 and 212 °F), and between 11 and 75% relative humidity (Ref 12). The reaction rate is given by:

$$K = 7.6 \times 10^{13} \exp\left(\frac{-26\ 400}{RT}\right) \qquad \textbf{(Eq 9)}$$

Equation 9 is linear and not proportional to either the water vapor pressure (relative humidity) or the oxygen pressure. However, at oxygen concentrations from 100 to 10 ppm, the reaction reverts to the uranium-water vapor reaction shown in Fig. 3. The reaction product, identified by x-ray diffraction analysis (Ref 11) as U_4O_9 or $UO_{2.25}$, is fcc and is compact and adherent. No hydrogen is produced.

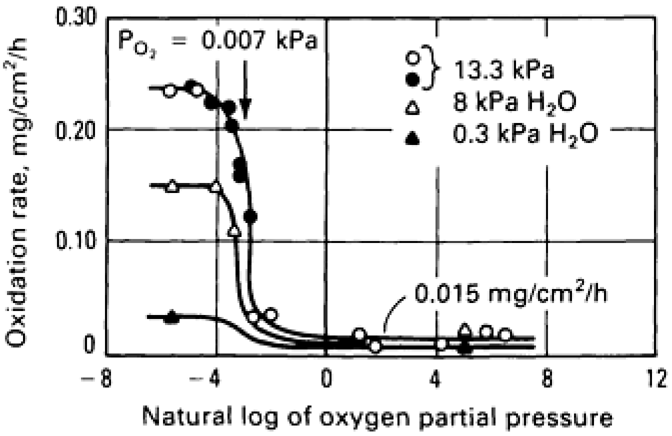

Fig. 3 Oxidation rate of uranium versus oxygen pressure in water vapor at 100 °C (212 °F). Source: Ref 10

Water. Although numerous papers and review articles have been written concerning the reactivity of uranium in water, that is, the corrosion of uranium, most of this work is decades old. The consensus from these investigations is that the rate of corrosion of uranium in water at 25 °C (75 °F) equals the rate of oxidation of uranium in water vapor at 100 °C (212 °F) as the relative humidity approaches 100%, that rate being 0.57 mg/cm^2/h (Ref 13). The reaction product has been identified as $UO_3 \cdot 0.8H_2O$ (Ref 13).

Aqueous Solutions. The corrosion properties of uranium in aqueous solutions are highly dependent on the pH of the medium, owing to the participation of hydrogen ion (H^+) in the redox reactions involved in corrosion. General corrosion in caustic aqueous solutions in the presence of oxygen normally proceeds by coupling the anodic dissolution reaction to the oxygen to hydroxl ion (OH^-) cathodic reaction. The H^+ ion to hydrogen gas reaction does not seem to become significant until a low pH is reached. Factors in the specific corrosion mechanism that lead to the accumulation of hydrogen in the region of the surface film and film/metal interface cause increased general corrosion rates.

Effect of Alloying Elements on Oxidation Response

Most of the uranium alloys under study and in use have come from binary and higher combinations of the γ-miscible elements titanium, molybdenum, niobium, and zirconium. Addition of these elements stabilizes the γ phase and increases corrosion resistance.

Titanium. The most recent and extensive study involving the oxidation of a uranium-titanium alloy investigated the oxidation of a U-0.75Ti alloy in environments containing oxygen and/or water vapor at 140 and 100 °C (285 and 212 °F) (Ref 14). The reaction rate of U-0.75Ti with water vapor at 140 °C (285 °F) was found to be linear and proportional to the water vapor pressure ($K \propto P_{H_2O}^{1:2.1}$) for water vapor pressures between 267 and 2670 Pa (2 and 20 torr) (Fig. 4). Hydrogen was produced by the reaction at a rate of approximately 2 mol for every 1 mol of UO_2 formed. A pressure dependency of one-half suggests that a dissociative/adsorption equilibrium exists at the reaction interface.

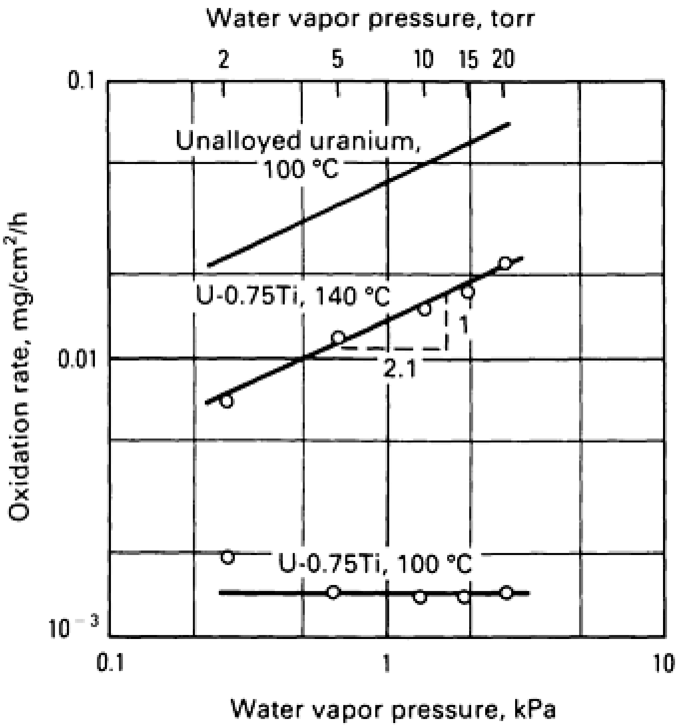

Fig. 4 Oxidation rate of U-0.75Ti versus water vapor pressure. Source Ref 14

In contrast, the behavior exhibited by U-0.75Ti when tested at 100 °C (212 °F) in water vapor showed no pressure dependency on water vapor after approximately 50 h of exposure (Fig. 4). The rate measured was 1.4×10^{-3} mg/cm^2/h. This occurrence was believed to be due to the reaction rate being controlled by a solid-state diffusion process rather than a dissociative adsorption process.

The reaction rate of U-0.75Ti with oxygen was also linear and independent of the oxygen pressure for oxygen pressures between 67 Pa and 133 kPa (0.5 and 1000 torr) at both temperatures. The reaction rates at 140 and 100 °C (285 and 212 °F) were approximately 3.2×10^{-3} and 1.2×10^{-4} mg/cm^2/h, respectively. The reaction rate was thought to be controlled by the reaction of the metal with oxygen ions (O^{2-}) at the metal/oxide interface.

The reaction rate of U-0.75Ti in environments containing both water vapor and oxygen was found to be linear and not dependent on either water vapor or oxygen pressure for the ranges investigated at both temperatures. The oxidation rates were 3.7×10^{-3} and 1.5×10^{-4} mg/cm^2/h at 140 and 100 °C (285 and 212 °F), respectively. Thus, the addition of water vapor to a pure oxygen environment had only a small effect on the oxidation kinetics. Also, the mechanism for oxidation in the mixed environment was thought to be the same as that in oxygen, that is, the reaction of metal with O^{2-} ions at the metal/oxide interface.

The reaction products were identified as oxygen-rich variants of the form UO_{2+x}, where x is greater than 0 but less than 0.25. X-ray diffraction analyses of samples from each of the three environments showed that the crystal structure of the oxides was fcc.

The oxidation rates for this alloy were one to two orders of magnitude lower than the rates for uranium in equivalent environments. Otherwise, the alloy behaved similarly to unalloyed uranium in all three environments. In general, the oxidation resistance of uranium increases with increasing additions of titanium up to an addition level of 2 wt% (Ref 15).

Molybdenum. The published literature on the atmospheric corrosion of uranium-molybdenum alloys is very limited. The available literature on the corrosion of all uranium-molybdenum alloys in both moist air and moist nitrogen has been reviewed. The only conclusions that can be made are that these alloys have a corrosion resistance comparable to uranium-titanium alloys of the same atomic percentage and that the corrosion resistance increases with molybdenum content.

Niobium. Although a number of investigations of the oxidation of uranium-niobium binary alloys have been reported in recent years, the two studies that included the most alloys and controlled conditions are discussed in Ref 16 and 17. In the first study, the alloys were tested in water-saturated nitrogen or oxygen at 75 °C (165 °F), and in the second, specimens were exposed to pure water, water vapor plus oxygen, or water vapor plus air at 125 °C (255 °F). In both experiments, the alloys showed considerably reduced reaction rates compared to unalloyed uranium, with the resistance of the alloy to reaction with the moisture increasing with niobium content, and the presence of oxygen in the test environment reduced the rate of hydrogen evolution. In all cases, more hydrogen was absorbed by the alloy than was released into the atmosphere. The amount of hydrogen released into the atmosphere decreased significantly with increasing niobium content, but all of the alloys absorbed roughly the same amount of hydrogen.

The most recent investigation of a uranium-niobium alloy involved the atmospheric corrosion of the U-6Nb alloy (Ref 18). The temperature range investigated was between 50 and 110 °C (120 and 230 °F), and the corresponding relative humidity ranged from 75 to 17%. The oxidation rate of U-6Nb in water vapor was so slow that it was not possible to derive an equation for the corrosion rate, even at 110 °C (230 °F). In moist air, the reaction was slightly faster than had been measured in moist nitrogen, but was still about 1/500 of the rate for unalloyed uranium.

Niobium-Zirconium. The uranium-niobium-zirconium alloy of the most interest is a U-7.5Nb-2.5Zr alloy designated as mulberry, which was given the label of a "stainless" uranium alloy. In humid environments, mulberry reacts similarly to the binary U-6Nb alloy. Oxidation data for mulberry in humid environments are provided in Ref 19.

Corrosion Behavior of Uranium Alloys

The factors that control metallic corrosion can be categorized as thermodynamic or kinetic. The electrochemical principles of thermodynamics are those of reversible cells and standard potential; kinetics is governed by polarization techniques.

Humid Air. Figure 5 illustrates the relationship between the percent of alloying additions and corrosion response in hot, humid air. The data show the rate of hydrogen generation of selected uranium alloys exposed to 100% relative humidity in oxygen at 75 °C (165 °F). This relationship is shown as approximately linear. Thus, increasing the total amount of alloying additions, irrespective of the alloying element, increases the resistance to corrosion.

Water. In addition to work at Argonne National Laboratory, Battelle Columbus Laboratories, and the Army Materials and Mechanics Research Center (AMMRC), a series of Russian articles (Ref 20) discusses the relative resistance of numerous uranium alloys to boiling water at 100 °C (212 °F). It has been shown that the corrosion resistance of uranium alloys to boiling water is inversely proportional to the percentage of α-uranium present in the particular compositions. An increase in the corrosion resistance with alloying is due to the formation of the γ phase. The most promising alloying additives--molybdenum, niobium, and zirconium--have been extensively studied.

Dilute Salt Solutions. Because the corrosion resistance of uranium alloys in hot, moist air and in boiling water has been found to be proportional to the total alloying content, it is expected that this proportionality also holds true for corrosion in dilute salt solutions. Electrochemical measurements have indicated that this should be the case. In one study, standard or corrosion potentials of various uranium alloys were measured in a 0.001 *M* potassium chloride (KCl) solution against a standard calomel electrode (Ref 21). Figure 6 shows these measured potentials versus the total alloying content of the alloys. Although the relationship is not strictly linear between potential and alloy content, it is directly related. Kinetic data on the corrosion rates of uranium alloys in dilute salt solutions are scarce, but those that have been published confirm this relationship.

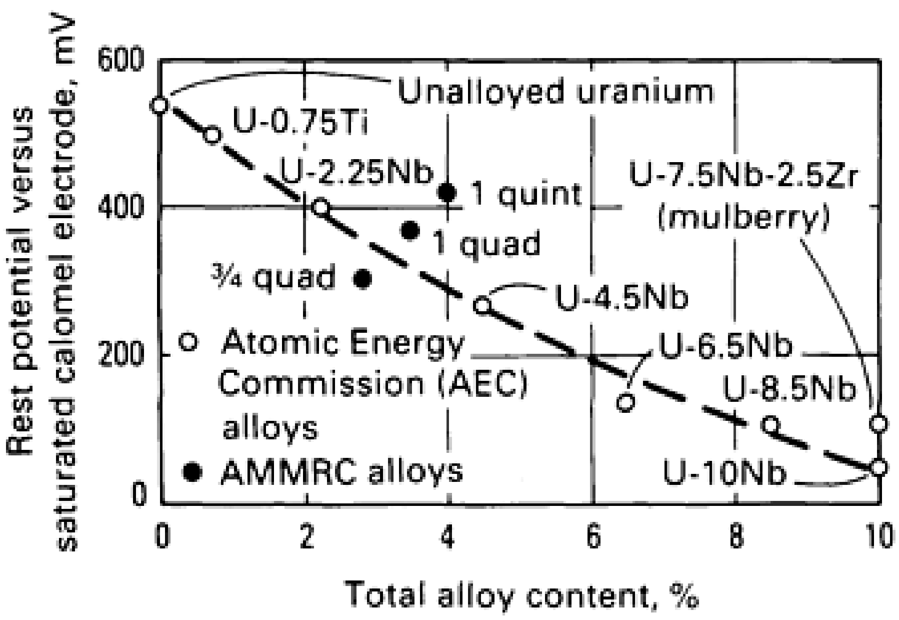

Fig. 6 Rest potential versus total alloy content for uranium alloys in 0.001 *M* KCl at 25 °C (75 °F). $\frac{1}{2}$ quad, U-0.5Nb-0.5Mo-0.5Zr-0.5Ti; $\frac{3}{4}$ quad, U-0.75Nb-0.75Mo-0.75Zr-0.5Ti; 1 quad, U-1Nb-1Mo-1Zr-0.5Ti; 1 quint, U-1Nb-1Mo-1Zr-0.5Ti-0.5V

Ocean Water. As with the preceding corrosion environments, the corrosion susceptibility of uranium alloys in ocean water is expected to decrease with increasing alloy content. In one investigation, the corrosion potentials of a number of uranium alloys were measured in artificial seawater (Fig. 7). The observed trend of decreasing corrosion potential with increasing alloying content is very similar to that discussed previously for the dilute salt solution test. Thermodynamics again predicts a decreasing corrosion rate with increased alloy content. The kinetics of the uranium alloy-ocean water reaction were measured gravimetrically, the results showed a logarithmic relationship between the corrosion rate and the total alloy content (Fig. 8).

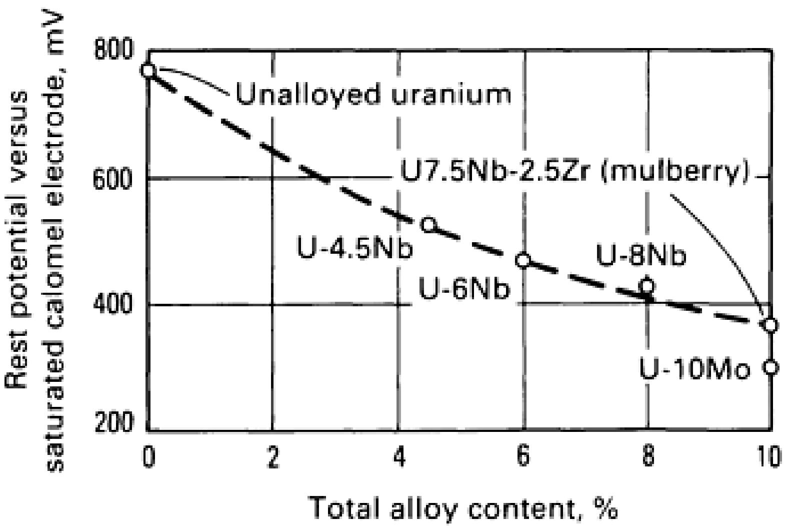

Fig. 7 Rest potential versus total alloy content for uranium alloys in ocean water at 20 °C (70 °F). Source: Ref 22

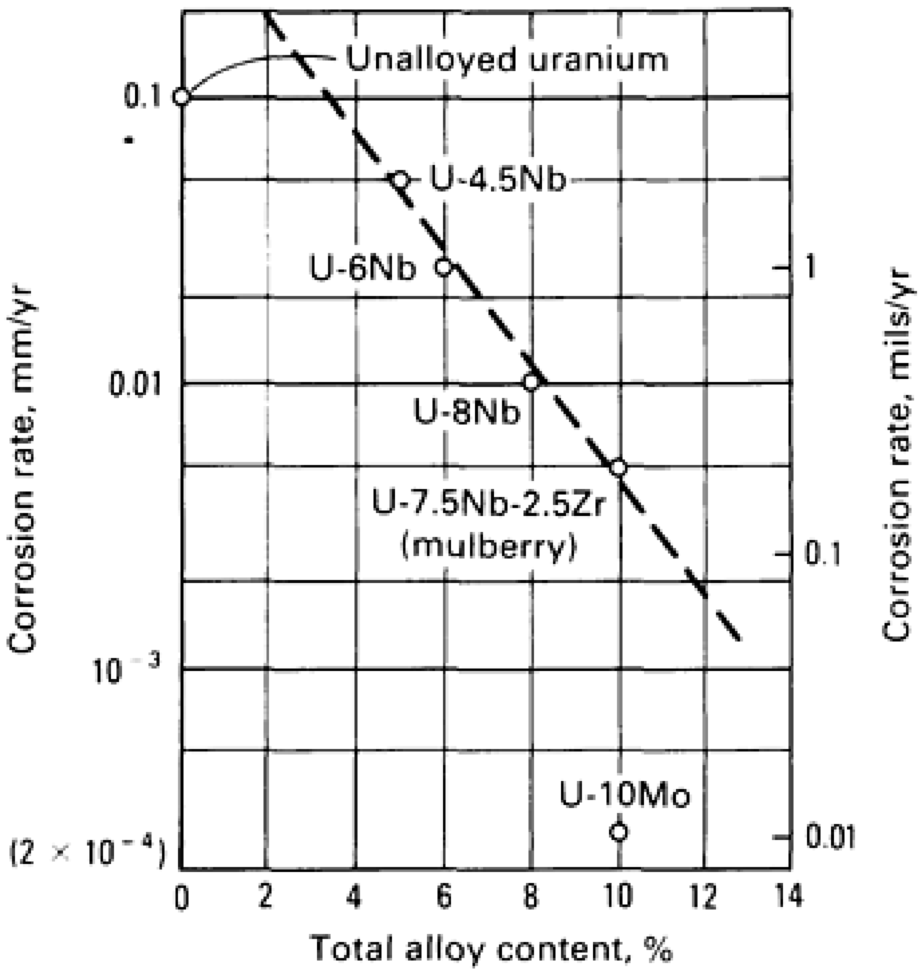

Fig. 8 Corrosion rate versus total alloy content for uranium alloys in ocean water at 20 °C (70 °F). Source: Ref 23

Acids and Bases. An indication of the possible anodic reactions can be obtained by examining the Pourbaix diagram for uranium shown in Fig. 9. In the potential range from -1.8 to 1.2 V at low pHs (0 to 2.0), uranium forms primarily soluble species. The uranium ion U^{3+} forms in the active region near the corrosion potential, and the uranyl ion (UO_2^{2+})forms in the transpassive region. In the passive region, UO_2 undoubtedly forms. Anodic polarization techniques can be used to study the ease of transition from the active to the passive state as well as the dissolution behavior of the metal and its alloys. The transition from the active to the passive state is accompanied by a decrease in corrosion rate of the order of 10^4 to 10^6, which is extremely significant for many applications.

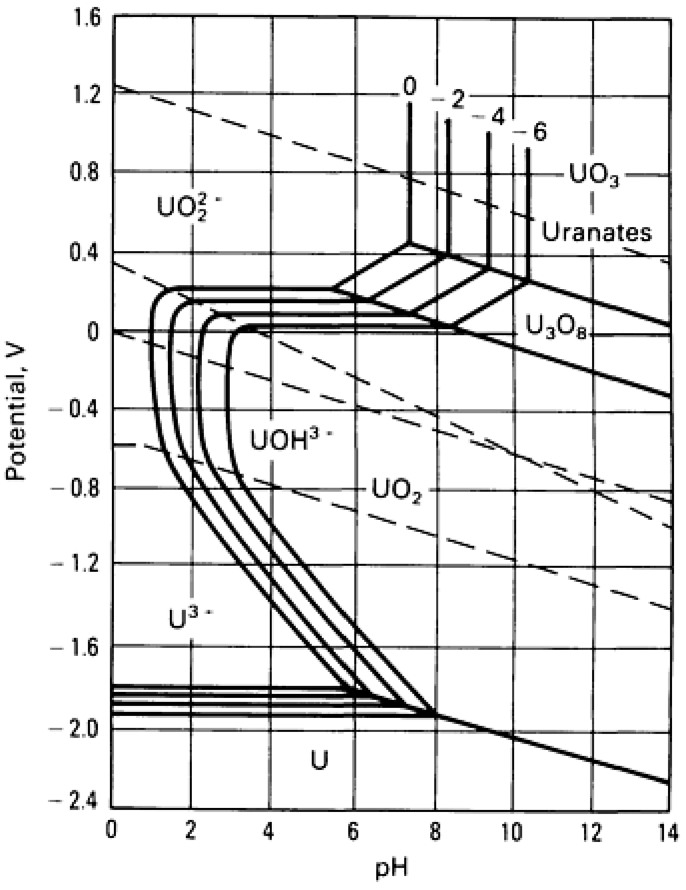

Fig. 9 Pourbaix diagram for uranium

Anodic polarization techniques have been used to study the effects of alloying constituent, temperature, solution chemistry, solution concentration, pH, and presence of chloride on the corrosion response of uranium alloys (Ref 24). An example of the effect of alloying on anodic polarization is shown in Fig. 10; the passive current densities vary inversely with alloy content. Figure 11 shows an example of the effect of solution chemistry , particularly the addition of chloride, on the anodic polarization behavior. The uranium-molybdenum alloy passivates more easily in sodium sulfate (Na_2SO_4) than sulfuric acid (H_2SO_4), and the addition of chloride prevents passivation entirely.

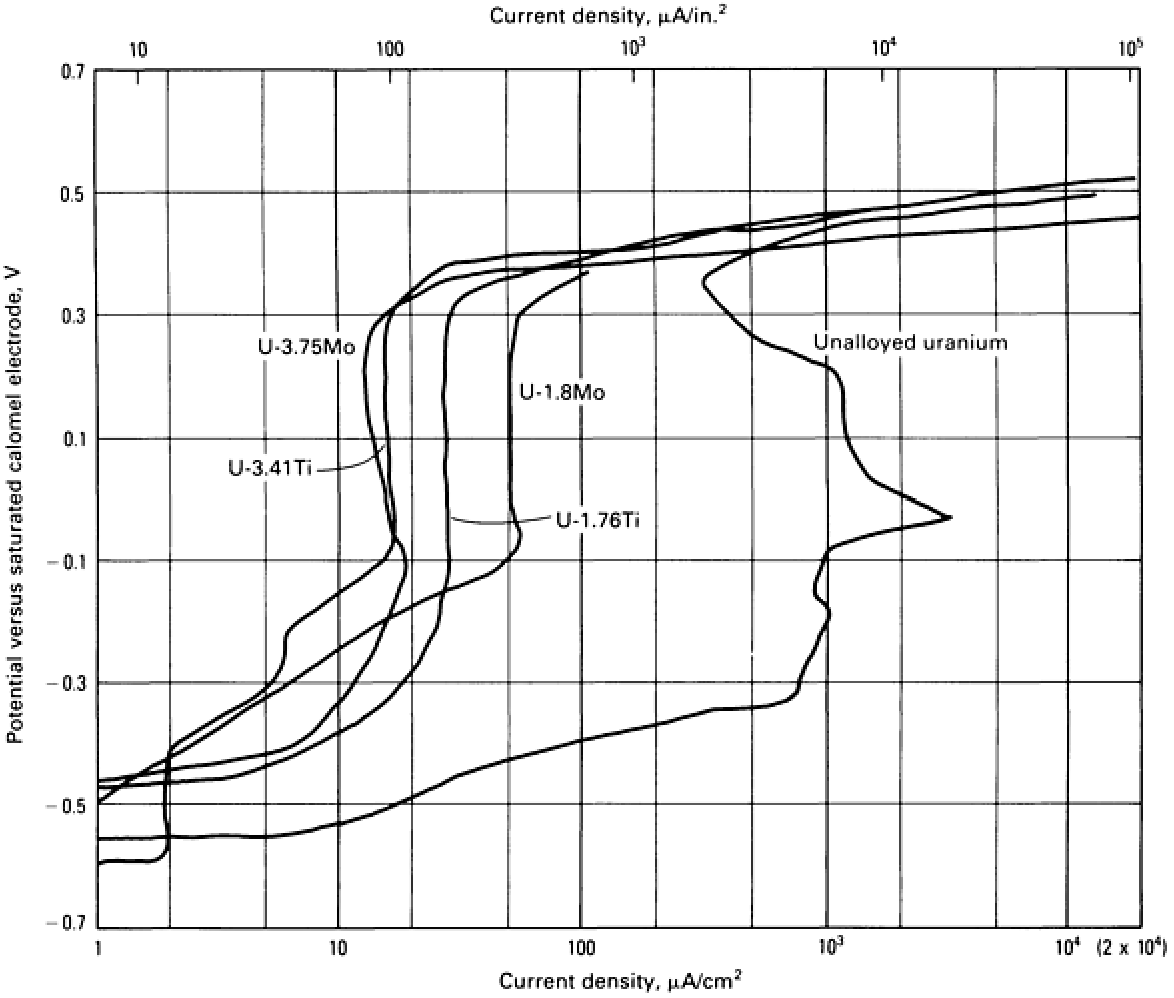

Fig. 10 Effect of alloying on the anodic polarization of uranium in H_2SO_4 at 25 °C (75 °F)

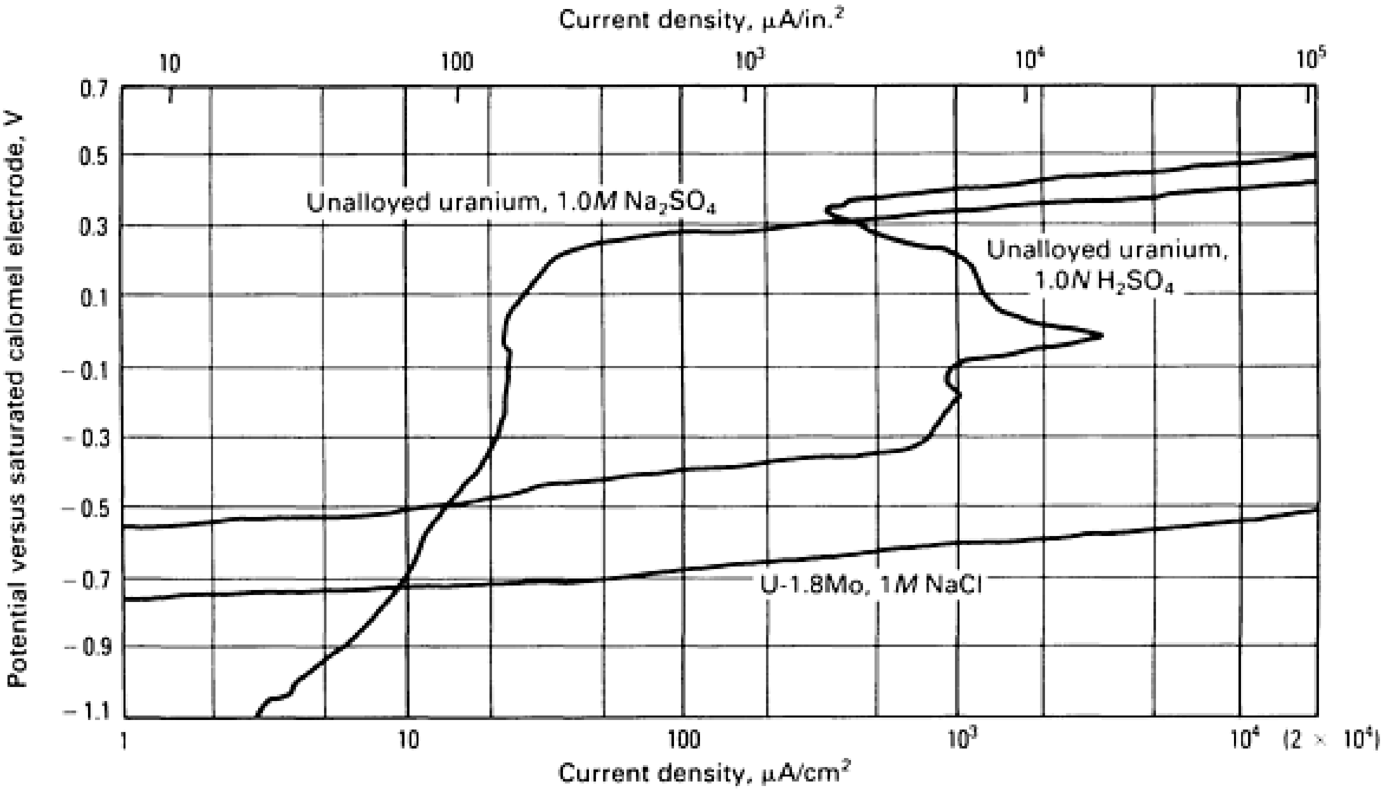

Fig. 11 Anodic polarization curves for uranium in differing aqueous solutions at 25 °C (75 °F)

Additional conclusions have been reached based on this work, as follows. Uranium binary alloys exhibit active-passive behavior in sodium hydroxide (NaOH), ammonium hydroxide (NH_4OH), sodium nitrate ($NaNO_3$), sodium chromate (Na_2CrO_4), and ammonium chromate ($[NH_4]_2CrO_4$). The critical current densities for passivity were inversely proportional to the H_2SO_4 concentration. Unlike those of most metals, the dissolution rates of uranium alloys decrease with increasing acid concentration. Chloride additions as small as 0.005 *M* affect the anodic polarization curve, but chromates, sulfates, and nitrates inhibit pitting at this low concentration of chloride. The uranium-titanium alloys were found to be more resistant to basic solutions than the uranium-molybdenum alloys.

Effect of Microstructure on Corrosion Properties

The influence of microstructure on the corrosion properties of uranium alloys is very much dependent on the particular uranium alloy. For example, the corrosion response of the U-0.75Ti alloy changes very little with process variables, but the U-6Nb alloy changes significantly.

U-0.75Ti. Research conducted for the United States Air Force measured the corrosion response of U-0.75Ti penetrators manufactured by various processes. The processing parameters included those in extrusion (temperature and rate), solutionizing (temperature, time, and media), aging (temperature, time, and atmosphere), and quenching (rate and media). In addition, U-0.75Ti penetrators made by such forming techniques as casting, swaging, forging, or grinding were tested. In all, more than 50 different combinations of processing techniques were investigated. The test environments chosen were a salt fog (to satisfy a military specification) and hot, moist nitrogen. The results showed that the largest difference in corrosion response to the salt fog environment between any two lots of material was a factor of two (Ref 25, 26). For hot, moist nitrogen testing, the difference in final weight loss between the most and least corroded material was a factor of ten. In that the weight loss in moist nitrogen for even the most susceptible material was very small, these differences were indeed small. Thus, the metal processing of the U-0.75Ti alloy did not significantly change the corrosion response.

U-6Nb. An investigation of the effect of cooling rate on the microstructure, mechanical behavior, corrosion resistance, and subsequent age hardenability of U-6Nb revealed that cooling rates exceeding 20 °C/s (36 °F/s) cause the parent γ phase to transform martensitically to a niobium-supersaturated variant of the α phase (Ref 27). This martensitic phase

exhibits low hardness and strength, high ductility, good corrosion resistance, and substantial age hardenability. As cooling rates decrease from 10 °C/s (18 °F/s) to 0.2 °C/s (0.4 °F/s), fine-scale microstructural changes (consistent with spinodal decomposition) occur to an increasing extent. These changes were found to produce large increases in hardness and strength as well as large decreases in ductility, slight decreases in corrosion resistance, and slight changes in age hardenability. At cooling rates less than 0.2 °C/s (0.4 °F/s), the parent phase undergoes cellular decomposition to a course two-phase lamellar microstructure. This lamellar microstructure was seen to exhibit intermediate strength and ductility, substantially reduced corrosion resistance, and no age hardenability.

Figure 12 shows the corrosion behavior of U-6Nb as influenced by cooling rate. Very rapid cooling results in a low rest potential, as would be expected for a corrosion-resistant material. At low cooling rates, the rest potential is substantially higher than that for any of the intermediate or high cooling rates, which suggests that a substantial decrease in corrosion resistance occurs at low cooling rates. Corrosion tests done at 75 °C (165 °F) in 95% relative humidity air or nitrogen confirmed the interferences drawn from the rest potential measurements. Samples cooled at intermediate and high rates exhibited no measurable weight change or visual tarnishing, but the samples cooled at low rates formed a black surface film and had an average weight gain of 0.01 mg/cm^2/d (equivalent to a penetration rate for UO_2 of 17 μm/yr, or (0.67 mils/yr). More information on the microstructures and metallography or uranium and uranium alloys is available in the article "Uranium and Uranium Alloys" in *Metallography and Microstructures,* Volume 9 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Galvanic Behavior

Some uses of uranium-base alloys require that they be in contact with other metals. When two dissimilar metals are electrically connected and immersed in a suitable electrolyte, a galvanic current flows between them. The driving force for the current flow is the potential difference between the two dissimilar metals. An electromotive force (emf) series is a list of metals and alloys arranged in order of the potentials generated when electrodes of each material are compared with one another in a specific environment. An emf series of a chloride-containing aqueous solution is often used for purposes of comparison for many applications.

Uranium-Niobium Alloys. The galvanic-corrosion behavior of uranium and uranium alloys, particularly uranium-niobium alloys, was investigated in ocean water and hydrochloric acid (HCl), and the emf series of selected materials generated in ocean water and in 0.1 *N* HCl are given in Tables 1 and 2. In addition, galvanic couples were immersed in 0.1 *N* HCl for 4 to 96 h, and the corrosion rates were determined for each couple. The emf series, based on electrode potentials in 0.1 *N* HCl at 25 and 70 °C (75 and 160 °F) and in oxygen-saturated ocean water, was found to be essentially the same as the series based on the gravimetric galvanic-corrosion tests. Therefore, the emf series based only on electrode potentials is useful for indicating potential galvanic-corrosion effects.

Polynary Uranium Alloys. The galvanic-corrosion behavior of polynary uranium alloys, particularly quaternary alloys, was studied in humid air and 4% salt spray; the results are summarized in Table 3. Galvanic corrosion became significant in water-saturated and condensing conditions, the different quad alloys behaved similarly, and aluminum alloy 6061-T6 and AISI type 304 stainless steel showed the best compatibility with the uranium alloys in resistance to humid atmospheres.

Table 3 Galvanic corrosion of uranium alloy couples

Galvanic Behavior

Some uses of uranium-base alloys require that they be in contact with other metals. When two dissimilar metals are electrically connected and immersed in a suitable electrolyte, a galvanic current flows between them. The driving force for the current flow is the potential difference between the two dissimilar metals. An electromotive force (emf) series is a list of metals and alloys arranged in order of the potentials generated when electrodes of each material are compared with one another in a specific environment. An emf series of a chloride-containing aqueous solution is often used for purposes of comparison for many applications.

Uranium-Niobium Alloys. The galvanic-corrosion behavior of uranium and uranium alloys, particularly uranium-niobium alloys, was investigated in ocean water and hydrochloric acid (HCl), and the emf series of selected materials generated in ocean water and in 0.1 *N* HCl are given in Tables 1 and 2. In addition, galvanic couples were immersed in 0.1 *N* HCl for 4 to 96 h, and the corrosion rates were determined for each couple. The emf series, based on electrode potentials in 0.1 *N* HCl at 25 and 70 °C (75 and 160 °F) and in oxygen-saturated ocean water, was found to be essentially

the same as the series based on the gravimetric galvanic-corrosion tests. Therefore, the emf series based only on electrode potentials is useful for indicating potential galvanic-corrosion effects.

Polynary Uranium Alloys. The galvanic-corrosion behavior of polynary uranium alloys, particularly quaternary alloys, was studied in humid air and 4% salt spray; the results are summarized in Table 3. Galvanic corrosion became significant in water-saturated and condensing conditions, the different quad alloys behaved similarly, and aluminum alloy 6061-T6 and AISI type 304 stainless steel showed the best compatibility with the uranium alloys in resistance to humid atmospheres.

Table 3 Galvanic corrosion of uranium alloy couples

Couple	Test duration, days	Environment	Surface observation	Appearance of interface at 100 ×

Stress-Corrosion Cracking of Uranium Alloys

One of the problems that has been encountered in the use of uranium alloys is SCC. Stress-corrosion cracking is defined as a cracking process that requires the simultaneous action of a corrosive environment and a sustained stress. In general, as the corrosion resistance and strength of an alloy increase, its susceptibility to SCC also increases. The conventional test methods use time to failure measurements on smooth specimens, incorporating both initiation and propagation processes, or precracked specimens in a fracture mechanics test, which tends to eliminate the initiation stages.

Uranium-Titanium Alloys. The U-0.75Ti alloy has been the only composition in the U-Ti system that has received a significant amount of stress-corrosion testing. Crack propagation tests using precracked specimens conducted in oxygen, hydrogen, water vapor, water, dry air, wet air, and chloride solutions have shown that water is the species responsible for cracking (Table 4). Oxygen apparently inhibits crack propagation in this alloy. The effect of the strength level on the susceptibility of U-0.75Ti to SCC has also been investigated (Ref 30). Figure 13 shows the relationship between ultimate tensile strength and K_{Iscc}, the threshold stress intensity for SCC. The data show that K_{Iscc} decreased linearly by a factor of two in the strength range investigated. All of the tests conducted in this alloy system found that transgranular cracking was the SCC mode, and there was no evidence of cracking along prior γ-phase grain boundaries.

Table 4 SCC thresholds for U-0.75Ti in air and in aqueous environments

Heat treatment	Yield strength		Environment	K_{Iscc}	
	MPa	**ksi**		**MPa$\sqrt{m}$**	**ksi$\sqrt{in.}$**

Uranium-Molybdenum Alloys. Uranium alloys with molybdenum concentrations from 0.6 to 12% have been found to be susceptible to SCC (Ref 29). Below 5% Mo, a series of metastable α-phase alloys is formed that has been found to be susceptible to cracking. Tests done in both wet and dry conditions on γ-phase alloys containing more than 5% Mo have shown that, contrary to the behavior observed with uranium-titanium alloys, oxygen is the species primarily responsible for SCC. Carbon content is important to the cracking behavior, alloys with higher carbon contents being more susceptible. The heat treating of quenched alloys can lead to significant improvements in SCC resistance in that alloys with equilibrium microstructures are much more resistant to cracking than metastable alloys. The predominant fracture mode observed in uranium-molybdenum alloys has been transgranular, particularly in nonaqueous environments. An intergranular mode has been observed in precracked tests conducted in aqueous environments (Ref 31).

Uranium-Niobium Alloys. The principal interest in the U-Nb system has centered on alloys with 2.3, 4.5, 6, and 8% Nb by weight, respectively. The SCC response is very much dependent on the particular alloy. The 2.3 and 4.5% Nb alloys are subject to SCC in water vapor, but the 6% Nb alloy is not. However, 6 and 8% Nb alloys will crack in environments containing oxygen, and water vapor will accelerate the SCC in these environments (Ref 32).

The U-4.5Nb alloy was shown to crack in either water vapor or oxygen and was more susceptible when both were present (Ref 32). Figure 14 shows that for the U-4.5Nb alloy the crack velocity decreases and K_{Iscc} increases as the oxygen pressure is decreased (Ref 32). The chloride ion (Cl^-) was also found to be very deleterious to the U-4.5Nb alloy in aqueous solutions (Ref 33). Specimens loaded at 33MPa$\sqrt{m}$ (30 ksi$\sqrt{in.}$) failed in 270 min in distilled water and in as little as 1 min in chloride solutions. However, another study revealed that the U-6Nb alloy was not susceptible to SCC initiation in chloride solutions when aged at temperatures below 200 °C (390 °F), but material aged between 250 and 400 °C (480 and 750 °F) was susceptible (Ref 34). When overaged (aged at temperatures above 600 °C, or 1110 °F), the alloy exhibited an increased resistance to cracking. In general, the data have shown for all of the uranium-niobium alloys that overaged specimens are more resistant to SCC than underaged specimens.

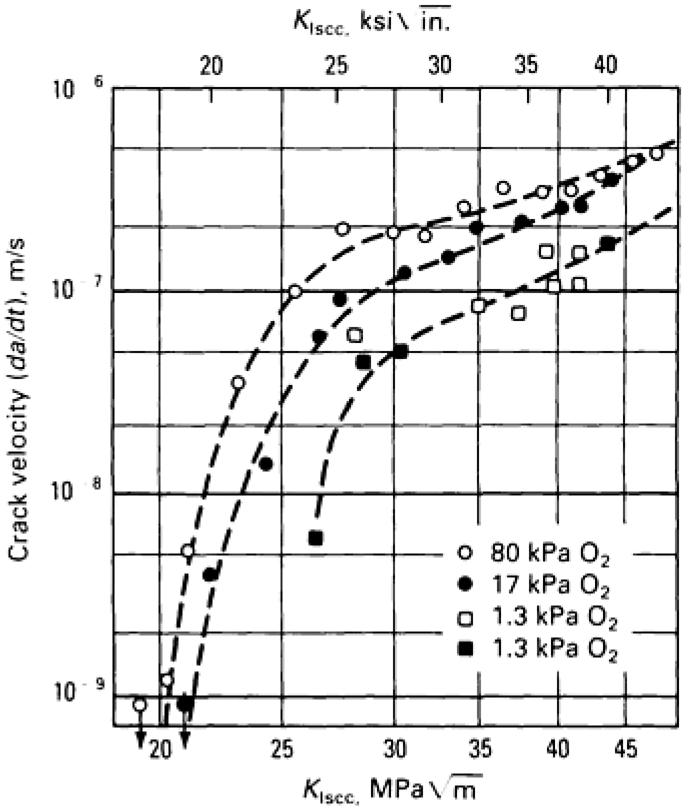

Fig. 14 Crack velocity versus SCC threshold as a function of oxygen pressure for U-4.5Nb. Source: Ref 32

Both transgranular and intergranular cracking was observed in the U-Nb system, with the mode observed being dependent on the alloy composition, the environment, and the type of specimen. In chloride solutions, smooth-specimen tests showed that the U-2.3Nb alloys cracked transgranularly and that the U-6Nb and U-8Nb alloys cracked intergranularly. The U-4.5Nb alloy exhibited intergranular cracking in smooth specimens and transgranular cracking in precracked specimens.

Uranium-Niobium-Zirconium Alloys. The only uranium-niobium-zirconium alloy that has been studied to any significant extent is mulberry. The SCC behavior of mulberry is similar to that of U-6Nb. The SCC behavior of this alloy was extensively studied in the 1970s and was later reviewed in Ref 29 and 32. Two types of SCC are observed in the alloy, each with its own fracture mode. The intergranular cracking initiates easily, but requires oxygen, water, and chloride to do so. The transgranular SCC does not initiate easily, but can propagate in pure oxygen or in solutions containing strong oxidizers.

An investigation of the effect of heat treatment on the SCC susceptibility of mulberry showed that the higher the aging temperature the greater the resistance to SCC initiation (Table 5). It was also found that crack propagation was fastest for material aged at intermediate temperature (350 to 450 °C, or 660 to 840 °F) and was slowest in the material aged at 150 °C (300 °F), the standard aging temperature for this alloy.

Table 5 Threshold stress for SCC initiation of mulberry in dilute chloride solutions as a function of heat treatment

Heat treatment	K_{Iscc}	
	MPa $\sqrt{m}$	**ksi** $\sqrt{in.}$
150 °C (300 °F), 1 h	<9	<8
350 °C (660 °F), 25 h	<13	<12
450 °C (840 °F), 5 h	~16.5	~15
550 °C (1020 °F), 9 h	>33	>30
600 °C (1110 °F), 8 h	>71	>65

Source: Ref 35

Polynary Uranium Alloys. The SCC behavior of a series of polynary uranium alloys containing small quantities of all the potent γ stabilizers (titanium, niobium, molybdenum, and zirconium) has been investigated, primarily by AMMRC (Ref 36). All of the SCC studies have been conducted on as-extruded material that has a partial microstructure of equilibrium phases in addition to the α phase from quenching. Precracked specimen tests have yielded K_{Iscc} values for polynary alloys tested in distilled water and in chloride solutions (Table 6). The data show that chloride increases the susceptibility to SCC. Tests done on smooth specimens have shown that these alloys are very resistant to crack initiation in humid air, but water promotes crack propagation in precracked specimens. All of the SCC failures have resulted in a transgranular stress-corrosion fracture.

Table 6 SCC thresholds for polynary uranium alloys in aqueous solutions

Alloy	Yield strength		Environment	K_{Iscc}	
	MPa	**ksi**		**MPa** $\sqrt{m}$	**ksi** $\sqrt{in.}$
U-0.75Nb-0.75Mo-0.75Zr-0.5Ti	772	112	Water	44	40
			3.5% NaCl	13	12

			50 ppm Cl^-	5.5	5
			3.5% NaCl	5.5	5

Stress-Corrosion Cracking of Uranium Alloys

One of the problems that has been encountered in the use of uranium alloys is SCC. Stress-corrosion cracking is defined as a cracking process that requires the simultaneous action of a corrosive environment and a sustained stress. In general, as the corrosion resistance and strength of an alloy increase, its susceptibility to SCC also increases. The conventional test methods use time to failure measurements on smooth specimens, incorporating both initiation and propagation processes, or precracked specimens in a fracture mechanics test, which tends to eliminate the initiation stages.

Uranium-Titanium Alloys. The U-0.75Ti alloy has been the only composition in the U-Ti system that has received a significant amount of stress-corrosion testing. Crack propagation tests using precracked specimens conducted in oxygen, hydrogen, water vapor, water, dry air, wet air, and chloride solutions have shown that water is the species responsible for cracking (Table 4). Oxygen apparently inhibits crack propagation in this alloy. The effect of the strength level on the susceptibility of U-0.75Ti to SCC has also been investigated (Ref 30). Figure 13 shows the relationship between ultimate tensile strength and K_{Iscc}, the threshold stress intensity for SCC. The data show that K_{Iscc} decreased linearly by a factor of two in the strength range investigated. All of the tests conducted in this alloy system found that transgranular cracking was the SCC mode, and there was no evidence of cracking along prior γ-phase grain boundaries.

Table 4 SCC thresholds for U-0.75Ti in air and in aqueous environments

Heat treatment	Yield strength		Environment	K_{Iscc}	
	MPa	**ksi**		**MPa** $\sqrt{m}$	**ksi** $\sqrt{in.}$

Uranium-Molybdenum Alloys. Uranium alloys with molybdenum concentrations from 0.6 to 12% have been found to be susceptible to SCC (Ref 29). Below 5% Mo, a series of metastable α-phase alloys is formed that has been found to be susceptible to cracking. Tests done in both wet and dry conditions on γ-phase alloys containing more than 5% Mo have shown that, contrary to the behavior observed with uranium-titanium alloys, oxygen is the species primarily responsible for SCC. Carbon content is important to the cracking behavior, alloys with higher carbon contents being more susceptible. The heat treating of quenched alloys can lead to significant improvements in SCC resistance in that alloys with equilibrium microstructures are much more resistant to cracking than metastable alloys. The predominant fracture mode observed in uranium-molybdenum alloys has been transgranular, particularly in nonaqueous environments. An intergranular mode has been observed in precracked tests conducted in aqueous environments (Ref 31).

Uranium-Niobium Alloys. The principal interest in the U-Nb system has centered on alloys with 2.3, 4.5, 6, and 8% Nb by weight, respectively. The SCC response is very much dependent on the particular alloy. The 2.3 and 4.5% Nb alloys are subject to SCC in water vapor, but the 6% Nb alloy is not. However, 6 and 8% Nb alloys will crack in environments containing oxygen, and water vapor will accelerate the SCC in these environments (Ref 32).

The U-4.5Nb alloy was shown to crack in either water vapor or oxygen and was more susceptible when both were present (Ref 32). Figure 14 shows that for the U-4.5Nb alloy the crack velocity decreases and K_{Iscc} increases as the oxygen pressure is decreased (Ref 32). The chloride ion (Cl^-) was also found to be very deleterious to the U-4.5Nb alloy in aqueous solutions (Ref 33). Specimens loaded at 33MPa$\sqrt{m}$ (30 ksi$\sqrt{in.}$) failed in 270 min in distilled water and in as little as 1 min in chloride solutions. However, another study revealed that the U-6Nb alloy was not susceptible to SCC initiation in chloride solutions when aged at temperatures below 200 °C (390 °F), but material aged between 250 and 400 °C (480 and 750 °F) was susceptible (Ref 34). When overaged (aged at temperatures above 600 °C, or 1110 °F), the alloy exhibited an increased resistance to cracking. In general, the data have shown for all of the uranium-niobium alloys that overaged specimens are more resistant to SCC than underaged specimens.

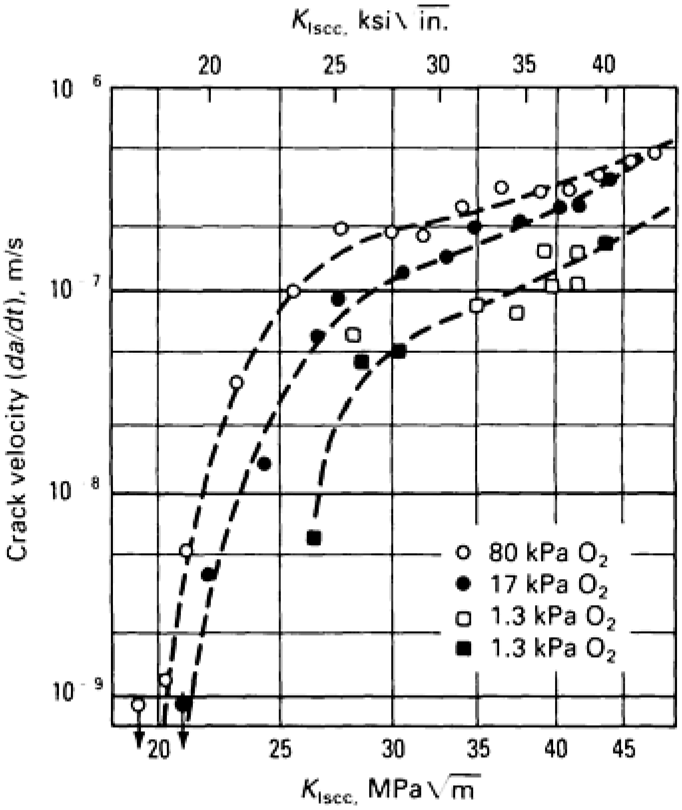

Fig. 14 Crack velocity versus SCC threshold as a function of oxygen pressure for U-4.5Nb. Source: Ref 32

Both transgranular and intergranular cracking was observed in the U-Nb system, with the mode observed being dependent on the alloy composition, the environment, and the type of specimen. In chloride solutions, smooth-specimen tests showed that the U-2.3Nb alloys cracked transgranularly and that the U-6Nb and U-8Nb alloys cracked intergranularly. The U-4.5Nb alloy exhibited intergranular cracking in smooth specimens and transgranular cracking in precracked specimens.

Uranium-Niobium-Zirconium Alloys. The only uranium-niobium-zirconium alloy that has been studied to any significant extent is mulberry. The SCC behavior of mulberry is similar to that of U-6Nb. The SCC behavior of this alloy was extensively studied in the 1970s and was later reviewed in Ref 29 and 32. Two types of SCC are observed in the alloy, each with its own fracture mode. The intergranular cracking initiates easily, but requires oxygen, water, and chloride to do so. The transgranular SCC does not initiate easily, but can propagate in pure oxygen or in solutions containing strong oxidizers.

An investigation of the effect of heat treatment on the SCC susceptibility of mulberry showed that the higher the aging temperature the greater the resistance to SCC initiation (Table 5). It was also found that crack propagation was fastest for material aged at intermediate temperature (350 to 450 °C, or 660 to 840 °F) and was slowest in the material aged at 150 °C (300 °F), the standard aging temperature for this alloy.

Corrosion of Powder Metallurgy Materials

Erhard Klar, SCM Metal Products

Introduction

POWDER METALLURGY (P/M) is a branch of metallurgy that may be defined as the technology and art of producing metal powders and using them to construct massive materials and shaped objects. Although the commercial use of P/M dates back to the beginning of the 20th century, the major classes of P/M materials developed during the first four decades (cemented carbides, composite electrical contacts, self-lubricating bronze bearings, and composite friction materials) did not pose any major problems with regard to corrosion resistance in that the service lives of these materials were normally not limited by their corrosion properties. With the appearance of iron-base sintered structural parts in the 1940s, the P/M method began to compete with other metal-forming techniques, such as casting, machining, and forging. The rapid increase in the utilization of iron and copper powders from 1940 to 1970 is linked to the advent of mass production in the automotive industry, and the successful use of P/M technology was based mainly on labor and material savings. With the growth of the industry and the development of stronger sintered parts came the demand for improved corrosion resistance, which led to the development of several surface treatments for sintered iron and steel parts (steam treatment; impregnation with oils, plastics, and waxes; metallization; tumbling with fillers; and electroplating) and to the development of sintered stainless steels in the 1950s.

With the development of fully dense P/M materials in the 1950s and 1960s, and particularly with the appearance of rapid solidification technology in recent years, it became increasingly clear that P/M processing was capable not only of cost savings from reduced labor and reduced material usage (net shape and near net shape processing) but also of producing superior materials. The superior microstructures possible with P/M technology were responsible for significant improvements in mechanical and magnetic properties, workability, and corrosion resistance. Two classes of materials in which such improved properties are of utmost importance are fully dense P/M superalloys and P/M aluminum alloys. Powder metallurgy superalloys are currently used in advanced turbine engines. Although wrought P/M aluminum alloys are still in the evaluation stage, they have been used in aerospace structures on a limited trial basis in non-critical applications.

The corrosion properties of the above-mentioned major classes of P/M materials will be described in the following sections. Corrosion resistance will be compared with that of similar conventional alloys where possible. Brief accounts will be given for the manufacture and use of these materials. More detailed descriptions of all aspects of the P/M process, such as powder production, compaction, sintering, and other state-of-the art consolidation methods, are available in *Powder Metal Technologies and Applications,* Volume 7 of the *ASM Handbook.* In addition to these major classes of P/M materials, there are many P/M specialty materials in which corrosion resistance may also play an important role (see, for example, the article "Corrosion of Cemented Carbides," in this Volume). Information on such materials is also provided in *Powder Metal Technologies and Applications,* Volume 7 of the *ASM Handbook.*

Sintered Iron Base P/M Parts

Powder metallurgy iron and carbon steel parts exhibit little resistance to corrosion. Therefore, steam treatment and/or impregnation with oils is widely used to prevent or minimize rusting in mild environments. Steam treatment will be described in this section.

Oxidation of small sintered iron and steel parts (Fig. 1) with superheated steam has been in use for over 40 years as an economical process to improve their hardness, compressive strength, wear, and corrosion resistance. This treatment can be combined with tempering and is then referred to as steam tempering. It leaves a tightly adhering bluish to black oxide that is usually acceptable as a final finish. The pores become coated or filled with the oxide as a result of the lower density of the oxide. This provides a certain pressure tightness and minimizes the entry of contaminants.

Fig. 1 P/M parts steam treated using the cycle shown in Fig. 2

The Process. A typical procedure for the steam treatment (Fig. 2) of clean (degreased) parts involves heating to a temperature above 100 °C (212 °F) but below the critical point of air oxidation and discoloration (425 °C, or 800 °F). A temperature of 315 °C (600 °F) is typically used for the first stage. Parts are soaked for 15 min or until the center of the load is above 100 °C (212 °F). Steam is then introduced into the chamber at a high flow rate (4.5 to 165 kg/h, or 10 to 360 lbs/h, depending on furnace size) to purge air from the furnace through the relief valve.

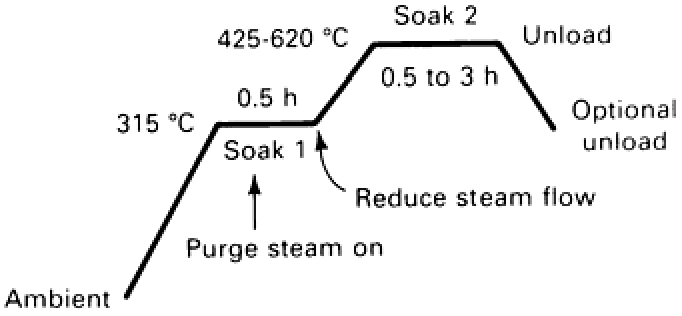

Fig. 2 Typical steam-treating cycle for iron P/M parts

Once the purge has been completed, steam flow is halved and temperature is increased to between 425 and 620 °C (800 and 1150 °F). The load is then soaked for 30 min to 3 h, depending on the amount of oxide required. When the soak has been completed and the load removed, the furnace is cooled to below 425 °C (800 °F) for the next load (Ref 1).

With correct processing, only two types of iron oxide form: FeO and Fe_3O_4. The furnace is purged of air before admitting the steam in order to avoid the formation of ferric oxide (Fe_2O_3) (red rust). Furthermore, the coldest part of the furnace charge must be above 100 °C (212 °F) before admission of steam to prevent the formation of iron hydroxide ($Fe(OH)_3$) and Fe_2O_3. Dark blue or light gray oxides form, depending on the temperature of the second soak.

The disadvantages of the treatment include some losses in tensile strength, impact resistance, and ductility (Ref 2). Details on the kinetics of oxidation, thermochemical equilibria, permeability and dimensional changes, oxide adherence, and hardness increases can be found in Ref 3, 4, 5, 6.

Corrosion Resistance. Phase composition and other structural characteristics of oxidation products depend on the oxidation technique and the cooling conditions (Ref 4). For example, the corrosion resistance of a low alloy sintered steel [0.12% C, 0.01% Si (max), 0.24% Mn, 0.010% P, 0.025% S, 0.02% Cr, 0.01% Ni (max), 0.019% Al, 1.86% Cu, 0.01% Ti (max)] with a density of 6.4 g/cm^3 in 3% aqueous sodium chloride (NaCl) (by immersion) was inferior at low (580 °C, or 1075 °F) and high (630 °C, or 1165 °F) oxidation temperatures. The latter was attributed to the lower adherence of the oxides to the metallic phase.

In one study, potentiostatic anodic polarization measurements of steam-treated carbon steel in dilute (0.5%) sulfuric acid (H_2SO_4) and aqueous NaCl solutions (400 ppm chloride ion Cl^-), revealed significant reduction of corrosion rates for the Cl^- environment, while H_2SO_4 testing showed an increase in corrosion rate (Ref 7). The latter was attributed to the solubility of the oxides in dilute H_2SO_4 and their increased attack compared to the unoxidized steel.

Sintered (Porous) P/M Stainless Steels

In its first decade of rapid commercialization, sintered stainless steel use increased at a compound annual rate of nearly 20% to reach a consumption of 2000 tons per year in 1973 for the North American market. During this period, the major developmental efforts were aimed at improving the compacting properties of water-atomized stainless steel powder. Interest in corrosion resistance increased after the market had peaked at a consumption of about 3000 tons per year.

Although powder and processing requirements for improving corrosion resistance were better defined and improved stainless steel powders became available, the basic understanding of corrosion as well as corrosion data development for sintered stainless steels are both still in their infancy. There are many factors that distinguish sintered stainless steel from cast and wrought stainless steel. Complicating the issue is the fact that the corrosion resistance of sintered stainless steels depends as much on the sintering process as it does on the properties of the powder. Neither guidelines nor standards relating to corrosion behavior exist for most of the critical composition and process parameters. Furthermore, much of the published literature on specific corrosion data of sintered stainless steels is nearly obsolete because of the lack of information on process conditions.

Application and Selection of Sintered P/M Stainless Steels

In the absence of detailed and reliable corrosion data, tentative selection of a P/M stainless steel for a specific application is made by following the same principles developed for cast and wrought stainless steels. Thus, for better corrosion resistance, the austenitic grades are preferred. However, type 410L stainless steel is often used for its good abrasion resistance. Because the corrosion resistance of sintered stainless steels depends so much on powder quality and parts-processing details, appropriate field testing is advisable to ensure compliance with specifications.

Table 1 provides on overview of market segments and applications for sintered stainless steels. The 300-series austenitic grades account for about two-thirds of total usage, and among the austenitic grades, type 316L is the most important. In terms of market distribution, automotive applications constitute the largest volume, followed by hardware and tools, filters, appliances, office machines, and a large segment of miscellaneous uses.

Properties of Sintered Parts

Sintered properties depend not only on powder characteristics but also on processing and sintering conditions. The effects of the most important processing parameters are shown in Fig. 3, 4, and 5. Sintering in a nitrogen-containing atmosphere results in the absorption of considerable amounts of nitrogen, along with an increase in strength and a decrease in ductility. Additional mechanical properties are summarized in Table 3.

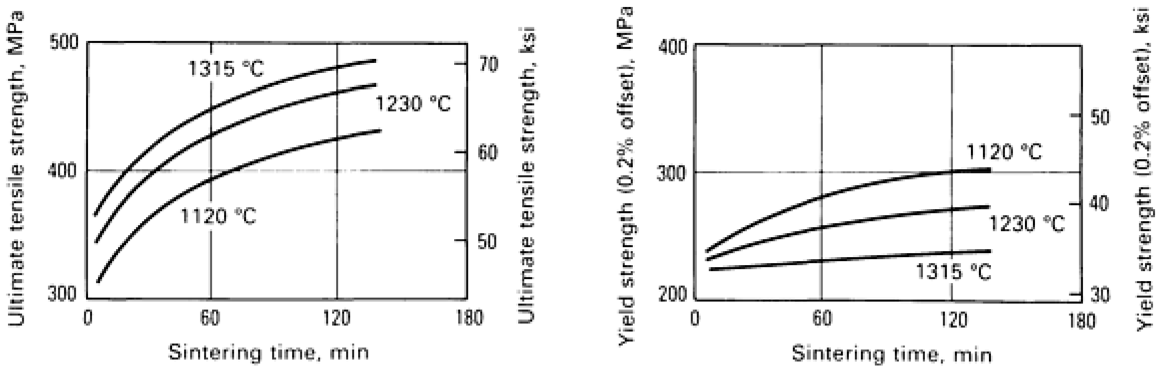

Fig. 5 Effect of sintering time on tensile and yield strengths of type 316L stainless steel. Parts were pressed to 6.85 g/cm^3 and sintered at various temperatures in dissociated NH_3.

Corrosion Resistance of Sintered Stainless Steels

As noted above, reliable information on the corrosion behavior of sintered stainless steels remains scarce. Therefore, emphasis in the following discussion will be placed on summarizing recent basic and practical information on powder selection and on sintering process control for maximizing corrosion resistance.

Table 4 compares the corrosion resistance of sintered type 316L stainless steel of 85% of theoretical density with that of wrought stainless steel of similar composition in a 5% aqueous solution of NaCl after a 100-h 5% aqueous NaCl salt spray test in 10% ferric chloride ($FeCl_3$) and in 10% nitric acid (HNO_3) solutions (Ref 9). For both dilute $FeCl_3$ and HNO_3, sintered type 316L performed similarly to wrought type 316L. For chloride environments, however, the P/M product is inferior. Because NaCl is probably the single most important corrodent for sintered stainless steels, a summary of recent investigations is presented below. Most of the data are for type 316L, but the general conclusions should also be valid for other stainless steel grades of the 300 and 400 series.

Table 4 Corrosion resistance of wrought and sintered type 316L stainless steel

Corrodent	Wrought type 316L	P/M type 316L[(a)]
5% aqueous NaCl salt spray, 100 h[(b)]	Clean	Profuse, voluminous corrosion product and pitting
5% aqueous NaCl immersion[(c)]	>1000 h[(d)]	5 to 500 h[(d)]
10% aqueous $FeCl_3$, 25 °C (75 °F)[(e)]	70 $g/m^2/h$	70 $g/m^2/h$
10% aqueous HNO_3, 20 °C (70 °F)	<0.1 $g/m^2/h$	0.001 to 0.4 $g/m^2/h$

(a) 85% of theoretical density.

(b) Per ASTM B 117.

(c) Per ASTM G 31.

(d) Time in hours at which 90% of specimens had 1% of surface covered by stain.

(e) Per ASTM G 48.

The limited corrosion resistance of sintered stainless steels, particularly in a chloride environment, is commonly though to derive from the presence of residual pores that give rise to crevice corrosion as a result of oxygen depletion within the pores. There is evidence, however, that factors other than porosity often determine corrosion life. For example, despite similar pore volumes, pore sizes, and pore shapes, type 316L parts prepared from various powder lots and sintered under varying conditions had corrosion resistances in 5% aqueous NaCl that varied between 5 and 500 h for a specified degree of corrosion (Table 4) (Ref 9, 10). Furthermore, a comparison of wrought and sintered (85% of theoretical density) type 316L for susceptibility to crevice corrosion in 10% $FeCl_3$ showed that the wrought part was even more severely attacked than the porous P/M part (Fig. 6). Lastly, surface analyses of water-atomized stainless steel powders showed the presence of large amounts of oxidized silicon concurrent with a severe depletion of chromium (Ref 10). The surface composition of a sintered part depended on its sintering conditions.

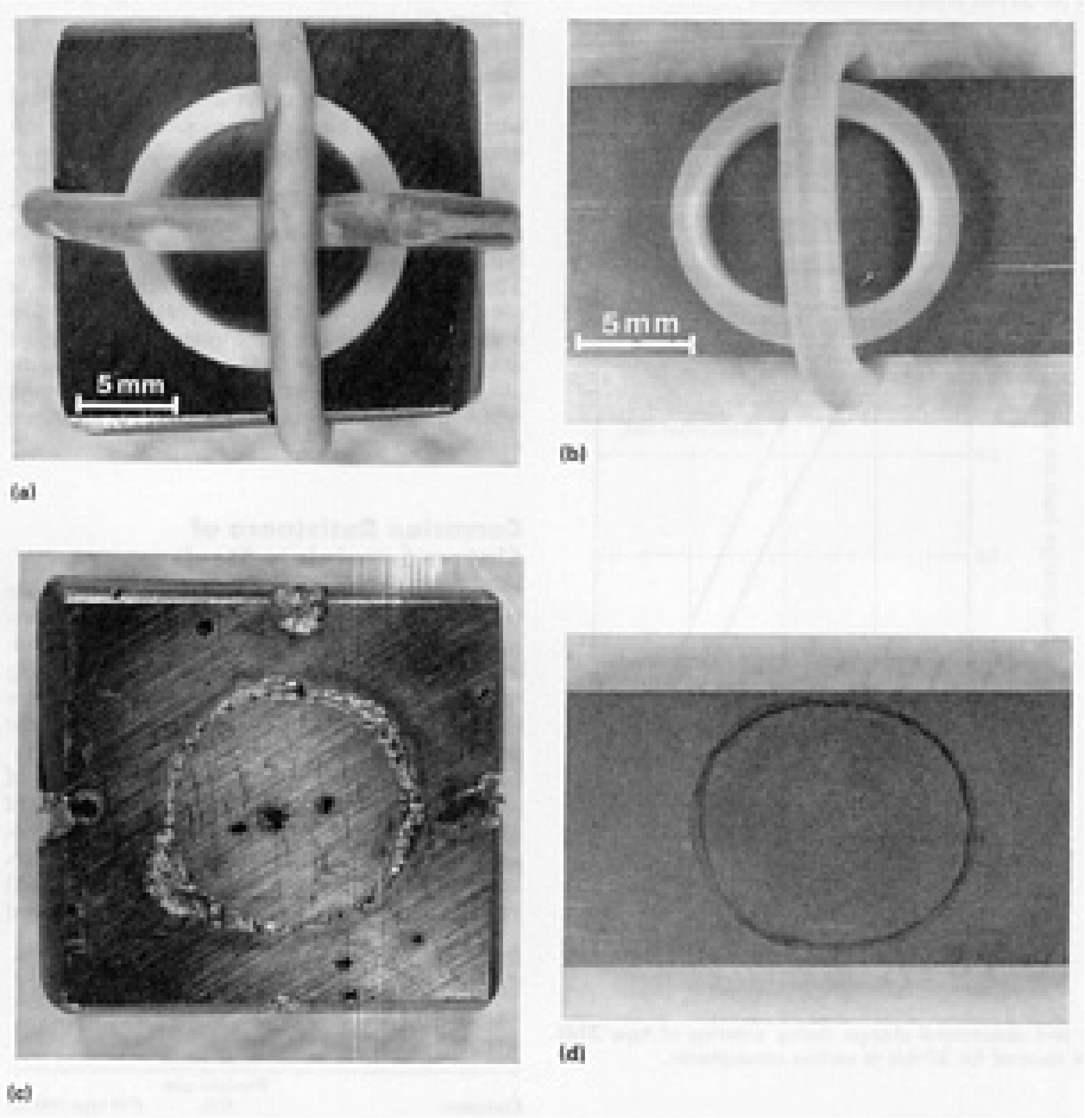

Fig. 6 Comparison of wrought and sintered type 316L stainless steels before and after testing in 10% aqueous $FeCl_3$ (a) Assembled crevice corrosion test specimen of wrought type 316L (100% dense). (b) Assembled crevice corrosion test specimen of sintered type 316L (85% dense). (c) Wrought specimen after test showing severe attack at four crevices under rubber bands and under teflon ring. (d) Sintered specimen after test showing slight attack under teflon ring. Source: Ref 10

It is clear that the factors of critical importance for the corrosion resistance of sintered stainless steels include control of iron contaminants, carbon, nitrogen, oxygen, and sintered part density (Ref 9, 10, 11, 12, 13). The effects of these variables are discussed in the following sections and are summarized in Table 5. In addition, the precautions necessary for maximizing corrosion resistance differ with the sintering atmosphere.

Table 5 Effect of iron, carbon, nitrogen, and oxygen on corrosion resistance of sintered austenitic stainless steels in NaCl

Variable	Origin of problem	Effect on corrosion resistance	Suggested solutions	Ref
Iron	Contamination of prealloyed powder with iron or iron-base powder at powder or parts producer's facility	Lowering of corrosion resistance by more than 99% due to galvanic corrosion	Utmost cleanliness at both powder and parts producer's manufacturing facilities, preferably separate and dedicated equipment and facilities	9
Carbon	Inadequate lubricant removal; carburizing sintering atmosphere; soot in sintering furnace; high carbon powder	Inferior resistance to intergranular corrosion	Use L-grade designation of stainless steel powder.	9, 10
			Ensure adequate lubricant removal (before sintering)	
			Use clean soot-free sintering furnace and carbon-free sintering atmospheres; carbon content of sintered part should be $\leq$0.03%.	
Nitrogen	Sintering in dissociated NH_3 or other nitrogen-containing atmosphere combined with slow cooling	Inferior resistance to intergranular corrosion	Reduce percentage of nitrogen in sintering atmosphere.	9, 11, 12, 13, 14
			Use fast cooling of parts preferably >150 to 200 °C/min (270 to 360 °F) through critical temperature range (700 to 1000 °C, or 1290 to 1830 °F).	
			Use higher sintering temperature.	
			Use intermediate dew points (-37 to -45 °C, or -35 to -50 °F) in cooling zone of furnace.	
			Use tin-modified stainless steel powders.	
Oxygen	Excessive oxygen in powder; excessive dew point of sintering atmosphere; slow cooling after sintering	Inferior resistance to general corrosion	Use low oxygen content powder, preferably <2000 ppm.	9, 11, 14
			Control dew point within sintering furnace to ensure reducing conditions.	
			Fast cooling, preferably >200 °C/min (360 °F/min)	
			For nitrogen-containing atmospheres, used dew point of -37 to -45 °C (-35 to -50 °F) in cooling zone.	
			For sintering in H_2, ensure that water vapor	

			content of atmosphere is below 50 ppm.	
Density of sintered part	High sintered density	Inferior resistance to crevice corrosion	Use lower density to increase pore size and circulation of corrodent. In acidic environments, corrosion resistance improves with increasing density due to a decrease of specific surface area.	9, 11, 15, 16, 17

Effect of Iron Contamination. Contamination of stainless steel powder with iron or iron-base powder may originate at the powder producer or the part manufacturer. Even extremely small amounts of iron contamination have a disastrous effect on the corrosion resistance of sintered parts in a saline environment. Utmost cleanliness, for example, through the use of separate production facilities and dedicated equipment, is mandatory. In saline solutions, active iron or iron-base particles form galvanic couples with the passive stainless steel and corrode anodically in preference to the stainless steel. Figure 7 shows this type of corrosion for iron particles embedded in the surface of a pressed and sintered type 316L part. Rusting occurs within minutes after exposure. The buildup of the initial corrosion product forms a crevice in which oxygen depletion causes acidification of the solution inside the part and further corrosion.

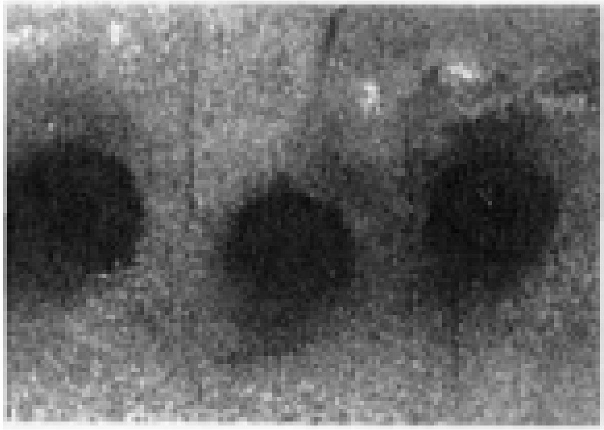

Fig. 7 Small circles of rust around iron particles embedded in the surface of sintered type 316L stainless steel after testing in 5% aqueous NaCl. 35× Source: Ref 9

Because of its severity, iron contamination overshadows the other factors that affect corrosion resistance (Fig. 8). Active iron or iron alloy particles present in stainless steel powder or on the surface of a sintered stainless steel part will be revealed by placing the powder or part in a concentrated aqueous solution of copper sulfate ($CuSO_4$). The dissolved copper plates out on the iron particles within minutes, making them easy to identify with a low-magnification microscope. The powder must be tested in the unlubricated condition because lubricant will prevent the solution from wetting the powder. Experiments with very fine iron powder particles combined with high-temperature (>1260 °C, or 2300 °F), sintering have shown that this type of corrosion can be avoided if the sintering conditions result in complete alloying of the iron particles with the stainless steel matrix (Ref 9).

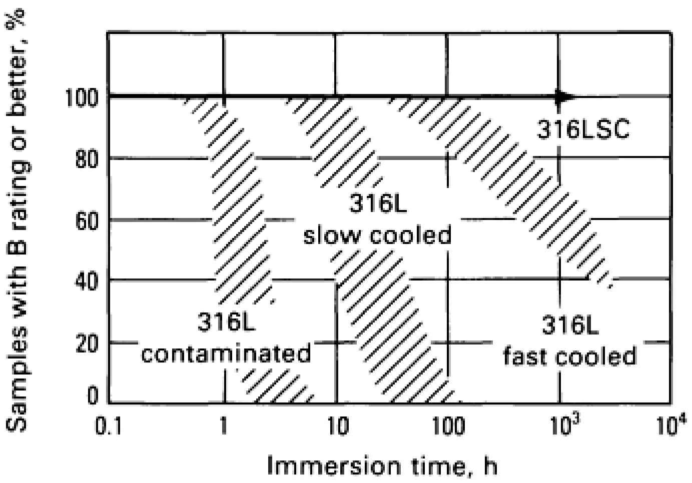

Fig. 8 Typical corrosion behavior of regular and copper-tin modified (type 316LSC) sintered type 316L stainless steel sintered in dissociated NH_3 under various conditions of cooling and contamination. B rating indicates that <1% of the specimen surface is covered by stain. Testing of the modified stainless steel was terminated after 1500 h. Source: Ref 9

Effect of Carbon. Water-atomized austenitic and ferritic grades of stainless steel powders have low (<0.03%) carbon contents (Table 2) in order to resist intergranular corrosion from sensitization during cooling of the sintered part. However, in P/M sintering, there are additional sources of potential carbon contamination, and because stabilization with titanium, niobium, and tantalum is not practiced due to the excessive oxidation of these elements during water atomization, the phenomenon of sensitization will be discussed as it applies to sintered stainless steels.

Because of the decreasing carbon solubility with decreasing temperature (Fig. 9), grain-boundary precipitation of carbon as chromium-rich carbide ($M_{23}C_6$) with attendant chromium depletion occurs during cooling in the sintering furnace for materials with carbon contents exceeding 0.03%. The chromium-depleted regions will exhibit inferior corrosion resistance.

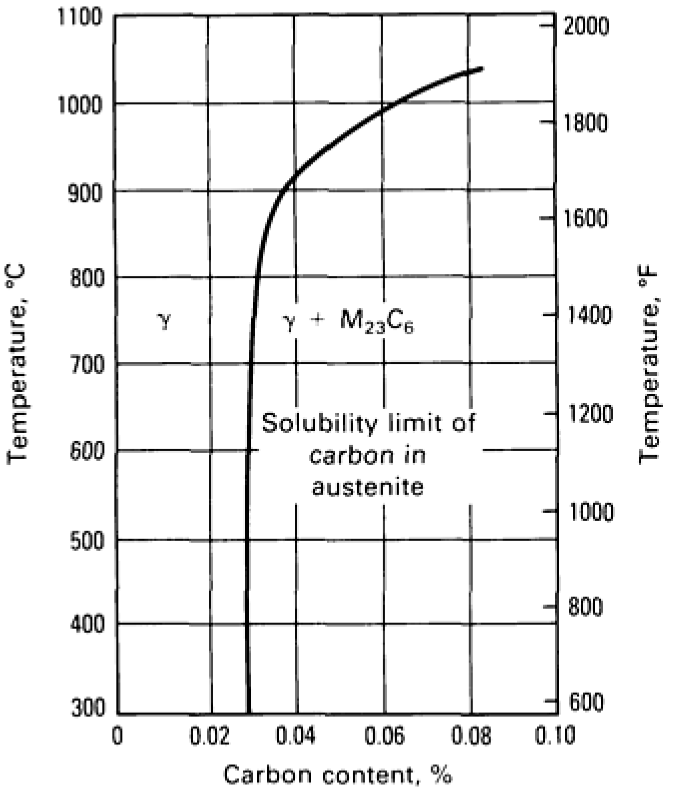

Fig. 9 Solid solubility of carbon in an austenitic stainless steel. Source: Ref 18

Figure 10 shows the microstructure of two sintered type 316L parts with carbon contents below and above the critical concentration of 0.03%. The low-carbon material has clean, thin grain boundaries, but the high-carbon material has grain boundaries with heavy precipitates of chromium-rich carbides.

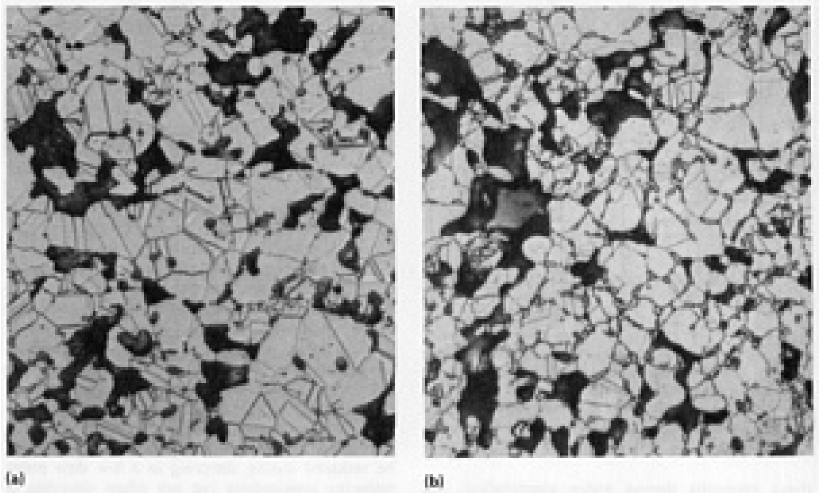

Fig. 10 Microstructures of type 316L stainless steel sintered in hydrogen at 1150 °C (2100 °F). (a) Low carbon content. (b) Excessive carbon content. Both 400×

The two main sources of carbon contamination of sintered stainless steels are (1) the organic lubricant present in prelubricated powder or added by the part manufacturer (typically 0.5 to 1%) to minimize die water during powder compaction and (2) carbon (soot) contaminated sintering furnaces. Adequate lubricant removal is accomplished by a so-

called dewaxing, or lubricant burnoff, process (Ref 15), which consists of heating the green parts in air or nitrogen to 425 to 540 °C (800 to 1000 °F). Length of heating should take into consideration the size (mass) of the parts. The oxygen absorbed during dewaxing in air will be reduced during sintering in a low dew point reducing atmosphere but not when sintering is done in a vacuum furnace.

Soot-containing sintering furnaces, that is, when a furnace was used with a low dew point endothermic atmosphere, can carburize stainless steel parts when soot that adheres loosely to furnace walls falls onto the stainless steel parts. Moisture that is from the sintering atmosphere or is formed by reduction of oxides can react with soot to form carbon monoxides (CO) and carburize the stainless steel.

For vacuum sintering of stainless steels, it may actually be beneficial to use powders with carbon contents exceeding 0.03%. With correct processing, the excessive carbon will be used up for the reduction of some of the oxides of the water-atomized stainless steel powders (typically 0.2 to 0.3% O) and thus improve the mechanical strength, ductility, and corrosion resistance of the sintered part. The phenomenon is illustrated in Fig. 11 for a vacuum-sintered ferritic stainless steel. Both parts were processed identically except for an addition of 0.2% graphite to one of the powders for the purpose of reducing its oxygen content. As expected, the graphite-containing material (Fig. 11a) produced clean grain boundaries, indicating the absence of both carbides and oxides, but the graphite-free powder (Fig. 11b) showed a heavy decoration of the grain boundaries with oxides, with an accompanying deterioration of corrosion resistance. Grain-boundary corrosion due to carbide sensitization, although somewhat less severe than the type of corrosion discussed above, still severely limits the attainment of adequate corrosion resistance of sintered P/M stainless steels.

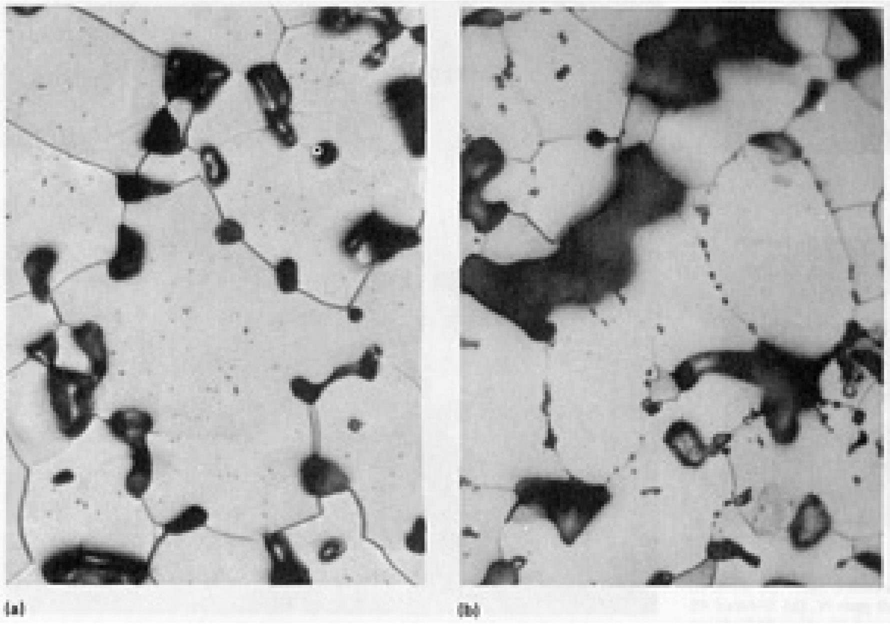

Fig. 11 Cross sections of vacuum-sintered (30 min at 1330 °C, or 2430 °F) type 430L stainless steel. (a) No oxides are present in grain boundaries after addition of 0.2% C. (b) Small, gray, rounded oxide particles in grain boundaries

Remedies such as heat treatment to rediffuse chromium back into the chromium-depleted austenite and the use of carbide stabilizers (titanium, vanadium, and niobium) are not practiced in the P/M industry. Such remedies are unnecessary if carbon pickup during sintering is avoided, because the various powders are available as low-carbon (L) grades.

Effect of Nitrogen. As with carbon, the key to understanding the effect of nitrogen on the corrosion resistance of sintered stainless steels is the solubility of nitrogen in the stainless steel matrix. Under certain conditions, dissolved nitrogen will precipitate as chromium nitride (Cr_2N), with accompanying chromium depletion and deterioration of corrosion resistance. Under industrial conditions of sintering in dissociated ammonia (NH_3), synthetic nitrogen-base atmospheres (typically 5 to 10% H_2, rem N_2) or in a vacuum with a partial pressure of nitrogen, the stainless steel part absorbs nitrogen in accordance with known phase equilibria (Fig. 12). The amount of nitrogen absorbed during sintering decreases with increasing sintering temperature and with decreasing chromium concentration of the stainless steel. Also,

absorption follows Sievert's law; that is, absorption is proportional to the square root of the partial pressure of nitrogen in the sintering atmosphere. This nitrogen absorption provides significant strengthening (Fig. 3). Upon completion of sintering, when the part enters the cooling zone of the furnace, the solubility of nitrogen decreases sharply with temperature (Fig. 12). As a result, Cr_2N begins to precipitate at the temperature at which the nitrogen content crosses the solubility limits. More important, below about 1150 °C (2100 °F), additional nitrogen is absorbed from the sintering atmosphere, leading to more Cr_2N precipitation and chromium depletion along the grain boundaries. The net result is inferior corrosion resistance due to grain-boundary corrosion.

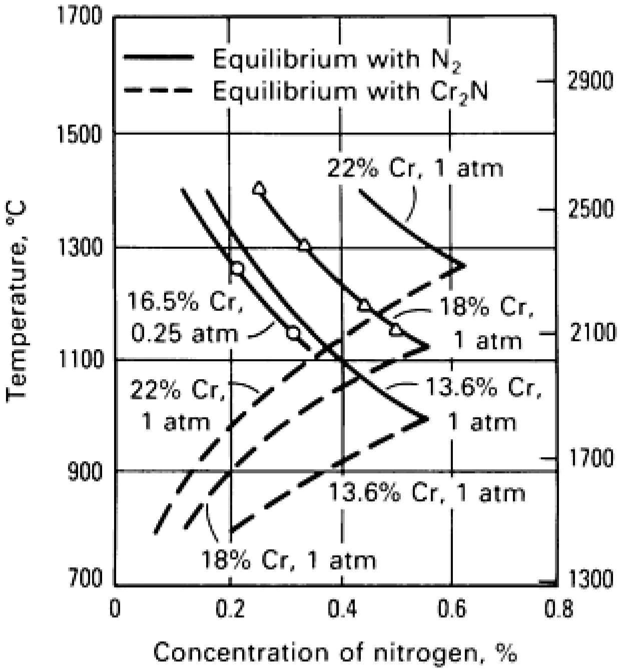

Fig. 12 Solubility of nitrogen in austenitic stainless steel in equilibrium with gaseous nitrogen or Cr_2N. Source: Ref 9

The rate of this detrimental nitrogen absorption increases with decreasing part density and with decreasing dew point. A high dew point, however, leads to the problem of excessive oxidation. The basic relationship of this phenomenon is shown in Fig. 13. The data in Fig. 13, which were developed for the bright annealing of stainless steel in dissociated NH_3 atmospheres, show the extent of nitrogen and oxygen absorption as a function of dew point. At high dew points (higher than about -37 °C, or -35 °F, depending on part size), the rate of oxidation is severe enough to produce a dull surface. At dew points of about -45 °C (-50 °F) or lower, nitrogen absorption increases so much that the corrosion resistance deteriorates because of excessive Cr_2N formation. Thus, optimum bright annealing of austenitic stainless steels must be done within a narrow dew-point range. Although the authors (Ref 14) caution against applying these findings to sintered stainless steels based on the unexplained higher nitrogen contents found for their parts sintered in dissociated NH_3, it should be noted that such higher nitrogen contents are expected on the basis of known solubility data for nitrogen in type 316L (Fig. 12) considering the differing methods of nitrogen analysis used.

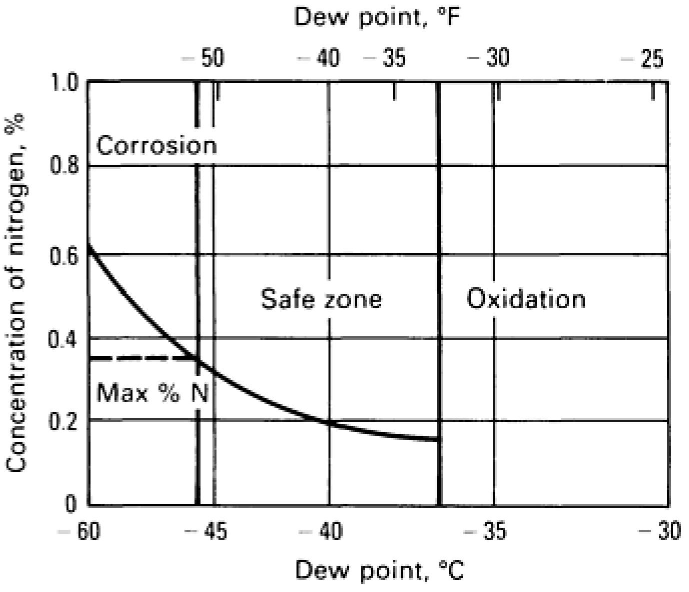

Fig. 13 Safe operating parameters with respect to dew point can be developed for a specific set of operating conditions and quality requirements. The safe zone here is for sintering in an atmosphere of 30% H_2-70% N_2 at 1035 °C (1900 °F). Source: Ref 14

Chromium nitride sensitization may in some cases be limited to a very shallow surface depth of the part. With very slow cooling, however, absorption and precipitation proceed toward the interior of the porous part. Figure 14 shows Cr_2N precipitates in the grain boundaries of parts that were sintered under conditions that produced nitrogen contents from 55 to 6650 ppm. Increasing nitrogen content correlates with increasing amounts of precipitation and increasing localized corrosion (Fig. 14). Figure 15 shows the microstructure of a type 316L part that was sintered in dissociated NH_3 and cooled very slowly. Slow cooling produced a lamellar structure of Cr_2N and low-chromium austenite of very poor corrosion resistance.

Corrosion resistance data for sintered types 304L and 316L in NaCl solutions and in 10% HNO_3, reflecting the effect of Cr_2N precipitation, are shown in Fig. 8, 16, and 17. Figures 8 and 16 show that a higher sintering temperature, fast cooling rates (75 °C/min, or 135 °F/min, versus 8 °C/min, or 14 °F/min), and the use of type 316L rather than type 304L provide better corrosion resistance. That these measures are beneficial follows directly from the austenite-nitrogen phase diagram (Fig. 12).

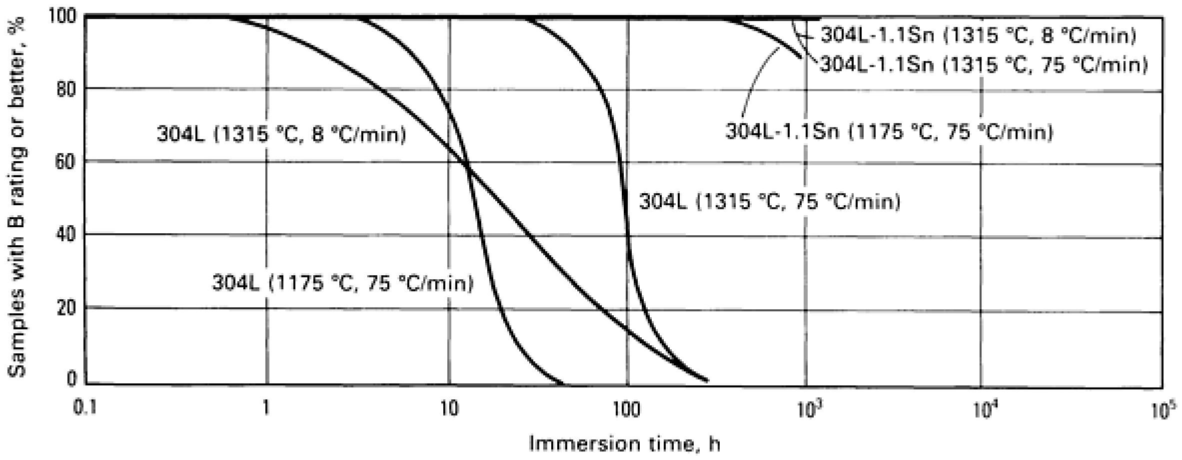

Fig. 16 Effect of composition, cooling rate, and sintering temperature on corrosion resistance of type 304L and tin-modified type 304L P/M stainless steels (sintered density: 6.5 g/cm^3; sintering atmosphere: dissociated NH_3) in 5% aqueous NaCl. B rating indicates <1% of specimen surface stained. Parenthetical values designate sintering temperature and cooling rate. Source: Ref 19

Figure 18 shows potentiodynamic corrosion curves for sintered type 316L in 10% HNO_3. The corrosion current density in the passive range increases and the corrosion potential decreases under conditions that promote Cr_2N precipitation, that is, lower sintering temperature, slower cooling rate, and high nitrogen concentration of the sintering atmosphere. Figure 19 is similar to Fig. 18 except that internal rather than external cross sections were used. The significantly lower corrosion currents of the internal surface confirm that Cr_2N precipitation is most severe on the surface of a sintered part.

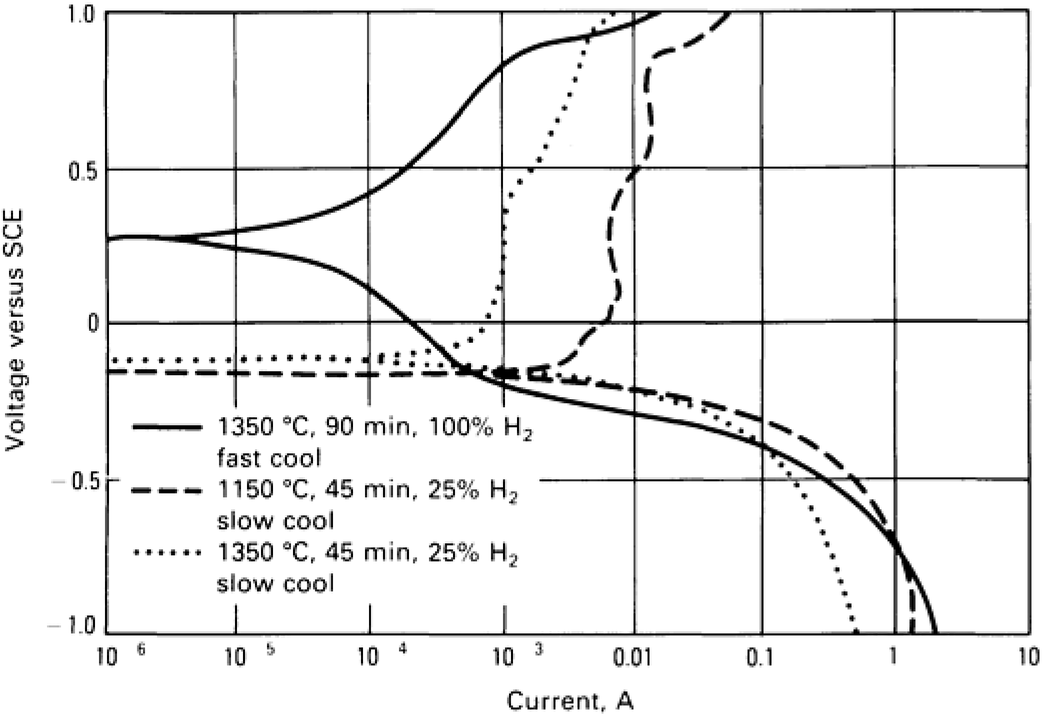

Fig. 18 Forward scan potentiodynamic corrosion curves for external surfaces of three sintered type 316L stainless steel samples in 10% HNO_3 at 25 °C (75 °F). Note the increasing corrosion currents in the 0- to 1-V range and the decreasing corrosion potential with nitrogen additions to the atmosphere, slow cooling, and lower sintering temperatures. Corrosion susceptibility in 10% HNO_3 at 25 °C (75 °F) increases with a lower sintering temperature and slow cooling. Cr_2N precipitation is most severe on the surface of a sintered part. See also Fig. 18. Source: Ref 20

Recently developed tin-containing grades of type 304L (Table 2) and 316L stainless steels have shown less sensitivity to nitride precipitation and correspondingly improved corrosion resistance (Fig. 8 and 16). The beneficial effect of tin has been confirmed in several studies (Ref 9, 10, 16, 19, 20, 21, 22) and has been attributed to an enrichment of the surfaces of both the water-atomized powder and the sintered part with tin, presumably as a result of the low solubility of tin in solid stainless steel (Ref 10). Tin may also form stable acid-resistant passive films in a crevice and may cause cathodic surface poisoning, but its major beneficial effect is believed to lie in its formation of an effective barrier to nitrogen (and possibly also to oxygen) diffusion. This reduces the rate at which nitrogen is absorbed on the surface of the sintered part as it enters the cooling zone of the furnace. Auger composition depth profiles of regular and (1.5%) tin-containing type 316L parts sintered in dissociated NH_3 (Fig. 20) show that the presence of tin on the surface effectively suppresses nitrogen absorption. In addition, on the basis of potentiodynamic polarization tests in 10% HNO_3 and 5 *N* H_2SO_4, improvement in corrosion resistance has also been reported due to the presence of tin (Ref 20, 22).

The effect of oxygen on the corrosion resistance of sintered stainless steels is probably the most complex and least understood variable for several reasons. First, commercial water-atomized compactible stainless steel powders have typical oxygen contents of about 2000 ppm or more. Although much of this oxygen resides on the surfaces of individual powder particles as oxidized silicon (Fig. 21a), the exact nature and distribution of the oxides depends on atomizing conditions. Second, with typical industrial sintering practice, the reduction of these oxides remains incomplete and depends on many process parameters. Lastly, as a sintered part enters the cooling zone of the furnace, certain elements will oxidize upon reaching the temperature for the oxide-metal equilibrium of the high oxygen affinity elements (Fig. 22). Thus, a sintered part still reflects the history of its powder-making process, compaction, and sintering. Figure 21(b) shows the Auger composition depth profile of a type 316L part after sintering in hydrogen at 1260 °C (2300 °F). It is apparent that much of the oxidized silicon present in the green part has become reduced and that severely depleted chromium has been replenished.

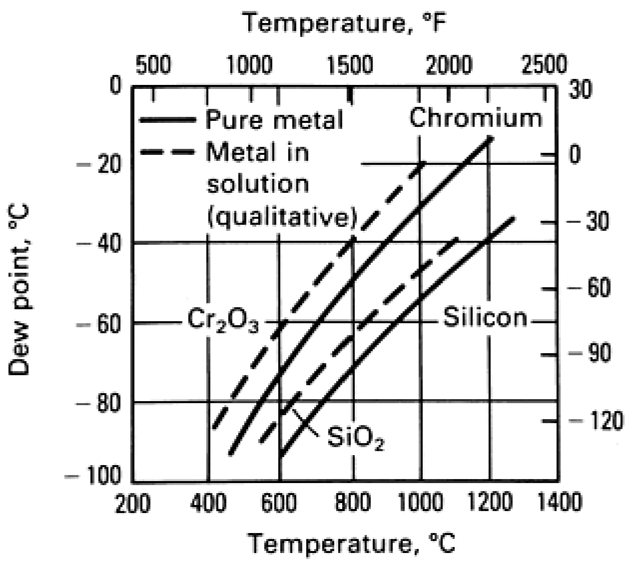

Fig. 22 Redox curves for chromium and silicon alone and in solution. Source: Ref 9

An empirical correlation between the saltwater corrosion resistance of sintered type 316L and the oxygen content of the sintered parts suggests that sintering conditions resulting in lower oxygen contents provide better corrosion resistance (Fig. 23). With excessive dew points (>-34 °C, or -30 °F), the oxygen content of a sintered part may increase considerably. The microstructure (Fig. 24) of such a part shows a lack of particle bonding (compare with Fig. 10a for low oxygen content), and its mechanical strength and corrosion resistance are both inferior.

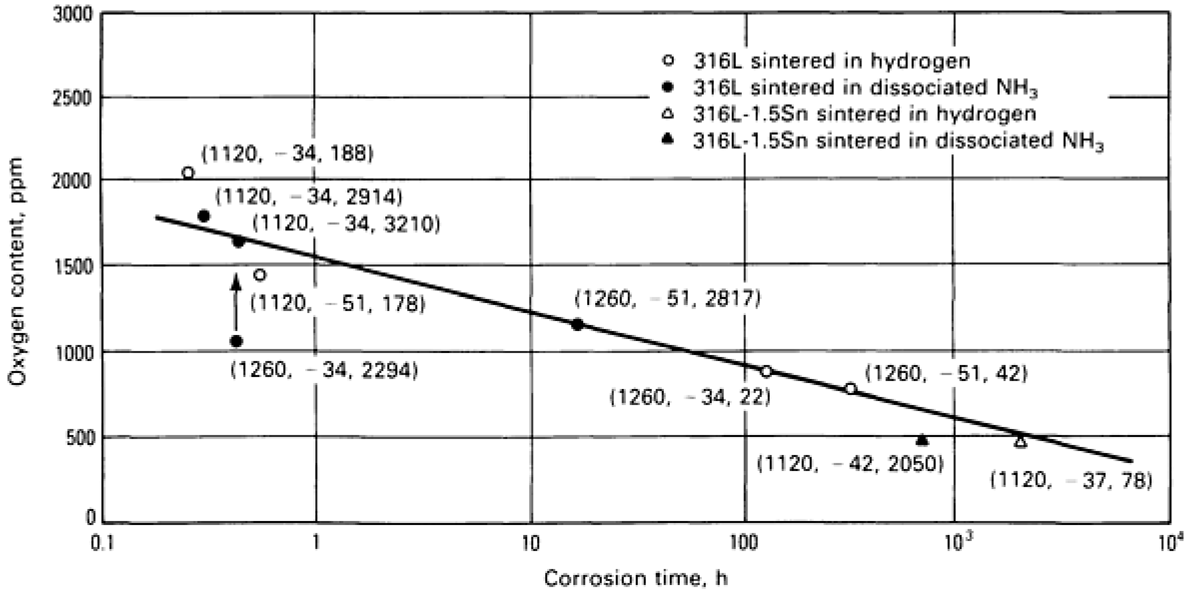

Fig. 23 Effect of oxygen content on corrosion resistance of sintered type 316L and tin-modified type 316L (sintered density: 6.65 g/cm^3; cooling rate: 75 °C/min, or 135 °F/min). Parenthetical values are sintering temperature (°C), dewpoint (°C), and nitrogen content (ppm), respectively. Time indicates when 50% of specimens showed first sign of corrosion in 5% aqueous NaCl. Source: Ref 10

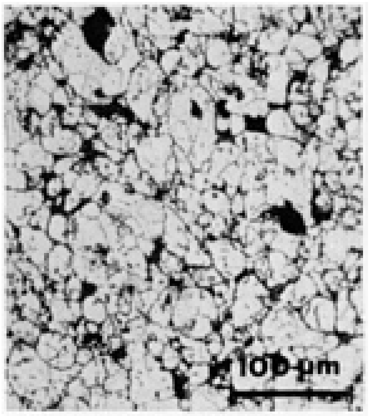

Fig. 24 Microstructure of type 316L stainless steel sintered in a high dew point atmosphere. Oxygen content: 5100 ppm; sintered density: 7.5 g/cm^3. Etched with Marble's reagent. 200×. Source: Ref 9

For optimum corrosion resistance, it appears that the following precautions are beneficial:

- Use of a powder with low oxygen content
- Sintering conditions that ensure a high degree of oxide removal
- Fast cooling through the high-temperature range after sintering

Cooling in a hydrogen atmosphere should be done with a water vapor content of less than 50 ppm (Ref 12). Cooling in a nitrogen-containing atmosphere should be done with a dew point between about -37 and -45 °C (-35 and -50 °F) (Ref 14).

Effect of Sintered Density. Applications of sintered stainless steels cover a wide density spectrum. Low densities of about 5 g/cm^3 may be typical of filters, but densities of 6.5 g/cm^3 or greater are typical of structural parts. It is therefore of interest to know the effect of density on corrosion resistance. Corrosion studies of sintered austenitic stainless steels have shown that the corrosion resistance improves significantly with increasing density in acidic environments, such as dilute H_2SO_4, HCl, and HNO_3. Figure 25 illustrates this behavior for three austenitic stainless steels (18Cr-11Ni to 18Cr-14Ni) that were vacuum sintered 1 h at 1150 and 1250 °C (2100 and 2280 °F) and tested in boiling 40% HNO_3.

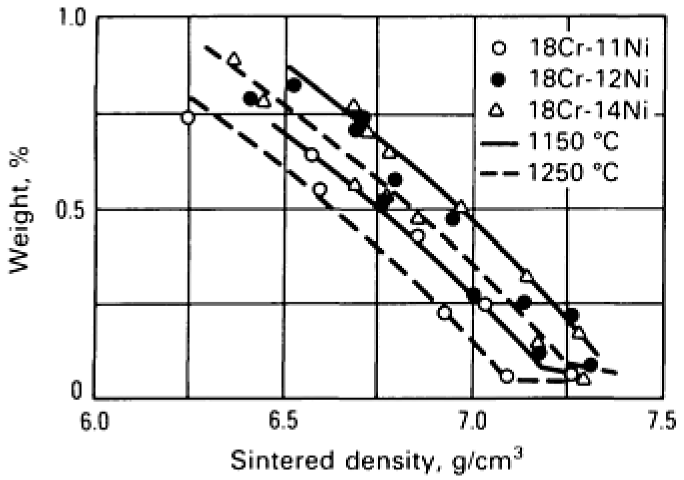

Fig. 25 Relationship between sintered density and weight decrease of three austenitic stainless steels in 40% HNO_3 solution. Source: Ref 23

For saline solutions, some investigations have found the effect of increasing density to be beneficial (Ref 20) while others have found it to be detrimental (Ref 10, 16, 23). This lack of agreement is perhaps not surprising considering that concentration changes in several of the critical variables, such as oxygen, carbon, and nitrogen, also depend on the density of a part. It should be noted, however, that the positive relationship between density and corrosion resistance was derived from short-term potentiodynamic polarization measurements (Ref 20), whereas the negative relationships were all derived from longer-term salt immersion tests.

Table 6 summarizes recent results on the effect of density on the salt corrosion resistance immersion in 5% aqueous NaCl) of vacuum-sintered type 316L parts. Unlike sintering in a reducing atmosphere, vacuum sintering does not lower the oxygen content with decreasing density. Thus, an improvement in corrosion resistance with decreasing density, as shown in Table 6, should not be attributed to a lower oxygen content, but is perhaps better explained in terms of reduced crevice corrosion as a result of the improved circulation of the corrodent through large pores (Ref 9). The average pore diameters of the parts pressed at the lower compacting pressures (Table 6), as measured by mercury porosimetry, were 60 to 80% larger than the size of pores of the high-density parts. The standard deviations of the pore size distributions were similar and were around 2. Therefore, sintered stainless steel parts with densities from about 60 to 90% of theoretical have average pore sizes from about 10 to 2 or 3 μm that are likely to affect the circulation of the corrodent and thus its resistance to crevice corrosion.

Table 6 Effect of density on corrosion performance of vacuum-sintered type 316L stainless steel

Effect of Copper Additions to Type 304L. One study found that the corrosion resistance of copper-containing type 304L vacuum-sintered parts (1 h at 1200 °C, or 2190 °F; 88% dense) improved with increasing copper content (Ref 17). Figure 26 shows the weight loss of the parts kept for 6 h in boiling 5% H_2SO_4. Higher nickel content is also beneficial. Salt spray testing for 24 h with 5% NaCl solution resulted in almost no pitting. The effect of copper in P/M stainless steels is said to be identical to that observed in cast stainless steels.

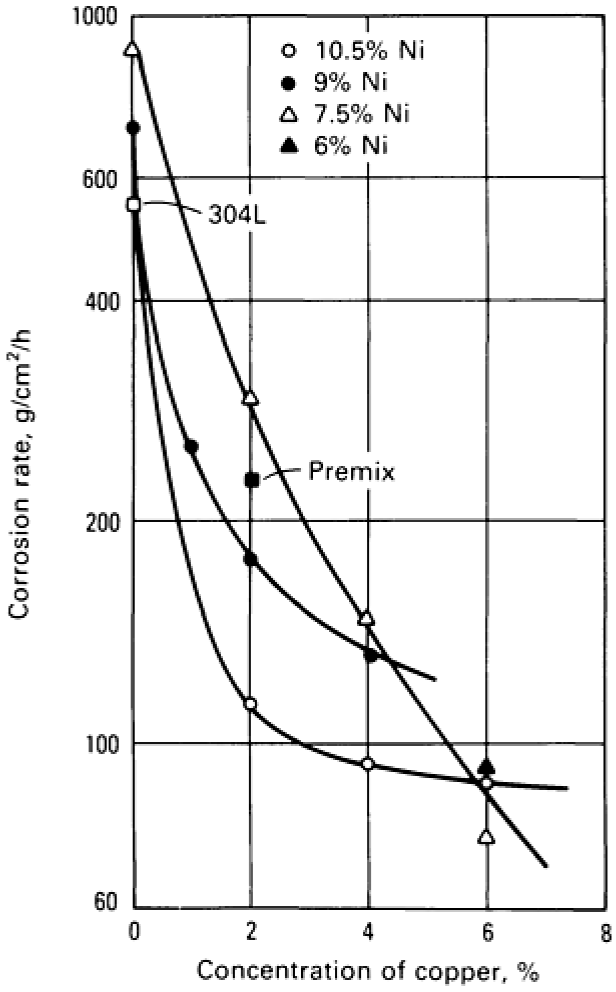

Fig. 26 Effect of nickel and copper additions on the corrosion rate of sintered austenitic stainless steel compacts exposed to boiling H_2SO_4 for 6 h. Relative sintered density is 88%. Source: Ref 17

Oxidation Resistance. Sintered stainless steels are not widely used for elevated-temperature service. Thus, information on elevated-temperature oxidation resistance is scarce.

Figure 27 shows the weight gain in air at 700 °C (1290 °F) for type 310L stainless steel parts that were vacuum sintered 1 h at 1250 °C (2280 °F) as a function of sintered density (circular plates), mesh size of powder used, and sintering temperature. This initial weight gain did not always show a parabolic course of oxidation. Within the density range studied, oxidation increased almost exponentially with decreasing density. Silicon-modified (4.06% Si) type 310L stainless steel showed weight gains that were less than 50% of those of regular type 310L. The increased oxidation of the parts made from the finer powder fraction is due to their large internal surface area. Higher sintering temperature and higher compacting pressure (higher densities) reduce surface porosity and specific pore surface area, thus lessening

internal oxidation through early pore closure. The maximum recommended operating temperature for sintered austenitic stainless steels is 700 °C (1290 °F).

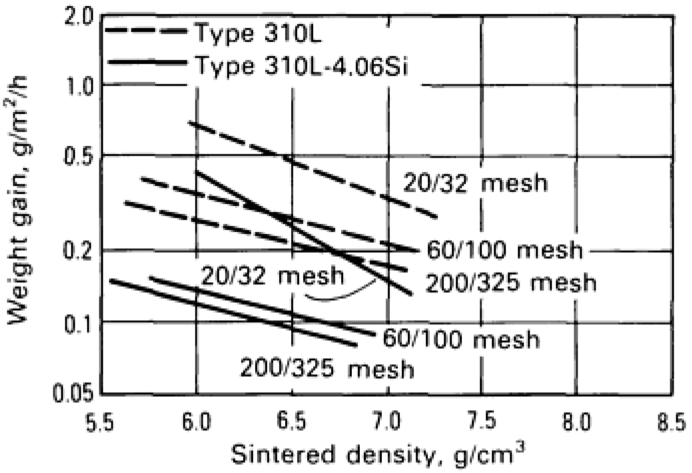

Fig. 27 Weight gain versus sintered density curves for materials prepared from powders of various particle sizes. Parts were sintered 1 h at 1250 °C (2280 °F). Source: Ref 24

Higher-Alloyed Stainless Steels. Although the common stainless steel grades used in industry have maximum chromium and nickel contents of 20 and 14%, respectively (Table 2), higher-alloyed stainless steels have been used in the past to obtain improved corrosion resistance. Such steels are available from powder procedures. In one investigation, a high-nickel/chromium/molybdenum austenitic stainless steel P/M material (SS-100) performed comparably to wrought type 216, 316, or 317 in 16-h salt solution immersion tests (Ref 25).

Other Approaches to Improving the Corrosion Resistance of Sintered Stainless Steels. If the corrosion resistance of sintered stainless steel parts remains inadequate after composition and process optimization, passivation and coating treatments are sometimes used. Chemical and thermal passivation treatments for sintered type 316L, effective in dilute H_2SO_4, are described in Ref 26. Chemical passivation with HNO_3 solutions similar to those applied to wrought stainless steels is not suitable for every material. On the basis of rest potential measurements of sintered type 316L, thermal passivation by heating the sintered parts for 20 to 30 min in air at temperatures of 400 to 500 °C (750 to 930 °F) is recommended.

In another study, the corrosion resistance of vacuum-sintered type 304L (6.9 g/cm^3) in 5% H_2SO_4 was improved by activating the parts in a mixture of 13 to 15% HNO_3, 2% hydrofluoric acid (HF), and 0.3% hydrochloric acid (HCl), followed by passivation for 30 min in 30% HNO_3 at 70 °C (160 °F) (Ref 27). After testing for 2 h in 5% H_2SO_4 (Fig. 28), the passivated specimens showed no weight loss, whereas the as-sintered specimens rapidly lost weight and turned the solution green. In addition, Ref 28 describes a phosphate-base passivating treatment for sintered stainless steels that is effective in acetic acid.

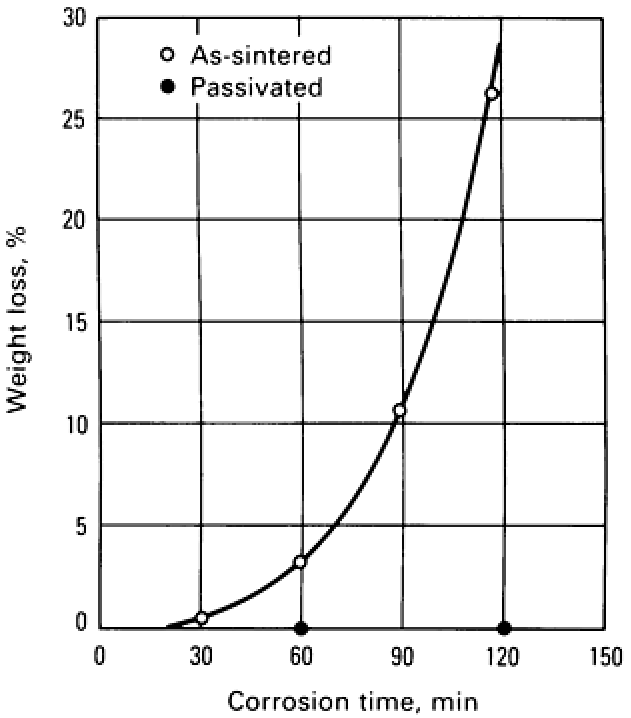

Fig. 28 Relationship between weight loss and corrosion time of vacuum-sintered type 304L stainless steel in 5% H_2SO_4

Improvement of the corrosion resistance of sintered stainless steel through the chemical vapor deposition (CVD) or chromium is discussed in Ref 29. The chemical vapor deposition of chromium onto sintered stainless steel parts was applied by pack cementation. Considerable infilling of the pores with chromium takes place; 50-μm thick pores with diameters of up to 50 μm may become sealed. Immersion of coated and uncoated specimens in 5 and 10% H_2SO_4 solutions for 168 h at room temperature showed significant attack of the uncoated specimens and no noticeable attack of the coated specimens. Electrochemical testing in 5% H_2SO_4 gave similar results, and a 3% salt spray test at room temperature showed many local sites of corrosion for the uncoated specimen and no corrosion after 250 h for the coated specimen. Sealing or coating of the pores of a sintered stainless steel part with an organic resin (Ref 25) or with water glass is sometimes recommended, but performance data proving the effectiveness of this treatment are lacking.

Fully Dense P/M Stainless Steels

In the fully dense category of P/M stainless steels, parts made from water-atomized powders must be distinguished from those made from inert gas atomized powders.

Water-atomized powders, because of their irregular particle shape, are cold compactible and permit the pressing of complex parts, which, at temperatures approaching the melting point of the material, can be sintered to nearly full density. However, water-atomized stainless steel powders typically have oxygen contents of 2000 ppm or more, and sintering to full density usually does not reduce the oxygen content to the low level of the corresponding ingot material. The commercial production of such parts is still in its infancy, and corrosion data are not yet available.

Inert gas or centrifugally atomized powders are spherical and noncompactible. They have low oxygen contents (about 50 to 200 ppm) and are consolidated to full density by such process as hot isostatic pressing (HIP), hot forging, and extrusion.

One company has manufactured seamless stainless steel tubes from gas-atomized powder since 1980. The P/M method is said to offer a competitive alternative to conventional production methods due to:

- Efficient use of raw materials

- Low energy consumption
- Short total production time
- High flexibility (less material in process; short delivery times)
- The ability to make difficult compositions (Ref 30)

The process consist of cold isostatic compaction of the encapsulated nitrogen-atomized powder, followed by heating to the extrusion temperature and hot extrusion. The capsule material is removed by decladding. Standard grades include most of the common austenitic stainless steels as well as some special austenitic, ferritic-austenitic, and ferritic stainless steels, together with nickel-base alloys.

In comparison to conventional material, the extruded P/M products possess a more homogeneous structure with reduced microsegregation due to the rapid cooling of the powder particles. Also, the grain size is somewhat finer, slag inclusions (particularly sulfides) are smaller, and the nitrogen content is somewhat higher (900 versus 500 ppm for wrought type 316).

Mechanical Properties and Corrosion Resistance. Attributed to the above differences are slightly higher yield and tensile strength (Table 7) without a loss in elongation. Mechanical properties at elevated temperatures are practically identical to conventionally produced materials. The impact toughness of the P/M material, although good, is lower than that of conventional material when tested in the longitudinal direction. Creep strength is similar to that of conventional material.

Table 7 Typical mechanical properties of cold-worked and annealed stainless steel tubes extruded from powders

(a) C, conventional production; P/M, powder metallurgy.

No difference between P/M and conventional material has been found regarding the resistance to intergranular corrosion according to practice C and practice E of ASTM A 262 (Ref 31). As shown in Fig. 29, the resistance to pitting attack, as measured by the pitting corrosion breakthrough potential, is superior for several P/M grades compared to the corresponding conventional grades. Table 8 gives the general and selective corrosion information from tests according to ASTM A 262, practice C (Ref 31) for two austenitic P/M grades. The improved corrosion resistance of the P/M grades is attributed to their lower segregation rate, their finer and more uniform distribution of inclusions, and their finer grain size.

Fig. 29 Comparison of pitting resistance of P/M and conventional stainless steels. Source: Ref 30

The enhancement of the corrosion resistance of stainless steel parts made from rapidly solidified powders has been confirmed by several investigators. For example, the significantly superior oxidation resistance of type 303 stainless steel, made by extrusion of rapidly solidified powder, was attributed to the elevated-temperature grain growth inhibiting effect of uniformly dispersed manganese sulfide (MnS) particles (Ref 32). Figure 30 shows that this material maintains its good corrosion performance in aqueous environments, and potentiodynamic polarization curves in 1 *M* H_2SO_4 indicate that the P/M material exhibits the lowest corrosion rate at the corrosion potential. Finally, although wrought type 303 was highly susceptible to pitting, the P/M alloy showed no obvious pits on the surface and only a low pit density within the material. The pits were related to the presence of sulfide stringers in the wrought material, from which it was concluded that P/M steels with lower sulfur contents and with spherical sulfide morphology, such as type 304 and 316, might exhibit improved pitting resistance.

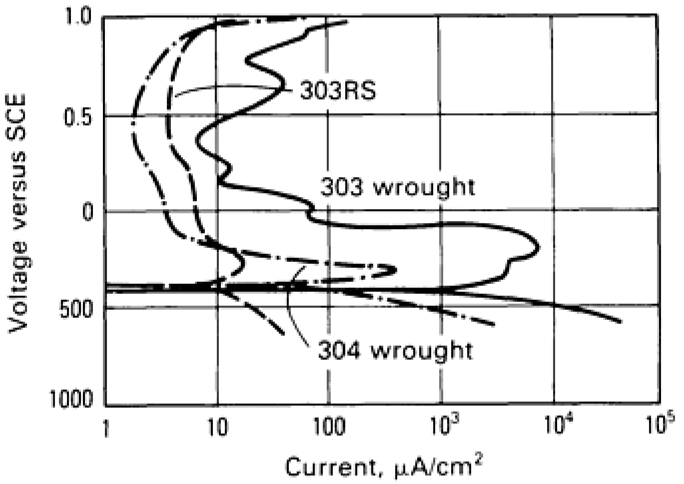

Fig. 30 Potentiodynamic polarization curves for conventional type 303 and 304 stainless steels and for rapidly solidified type 303 in deaerated 1 *M* H_2SO_4 at 30 °C (85 °F). Source: Ref 33

Injection molding technology (see the article "Powder Injection Molding" in *Powder Metal Technologies and Applications,* Volume 7 of the *ASM Handbook*) is currently used to manufacture small and nearly fully dense stainless steel parts from the powders. However, information on the corrosion performance of such parts is unavailable.

P/M Superalloys

Development of P/M superalloys began in the 1960s with the search by the aerospace industry (and later the electric power industry) for stronger high-temperature alloys in order to operate engines at higher temperatures and thus improve fuel efficiency. Figure 31 illustrates the great advances achieved since the 1940s by the introduction of new processes and alloys, such as vacuum melting, directional solidification of eutectics, development of alloys with high volume fractions of γ' phase, and P/M processing with and without oxide dispersions.

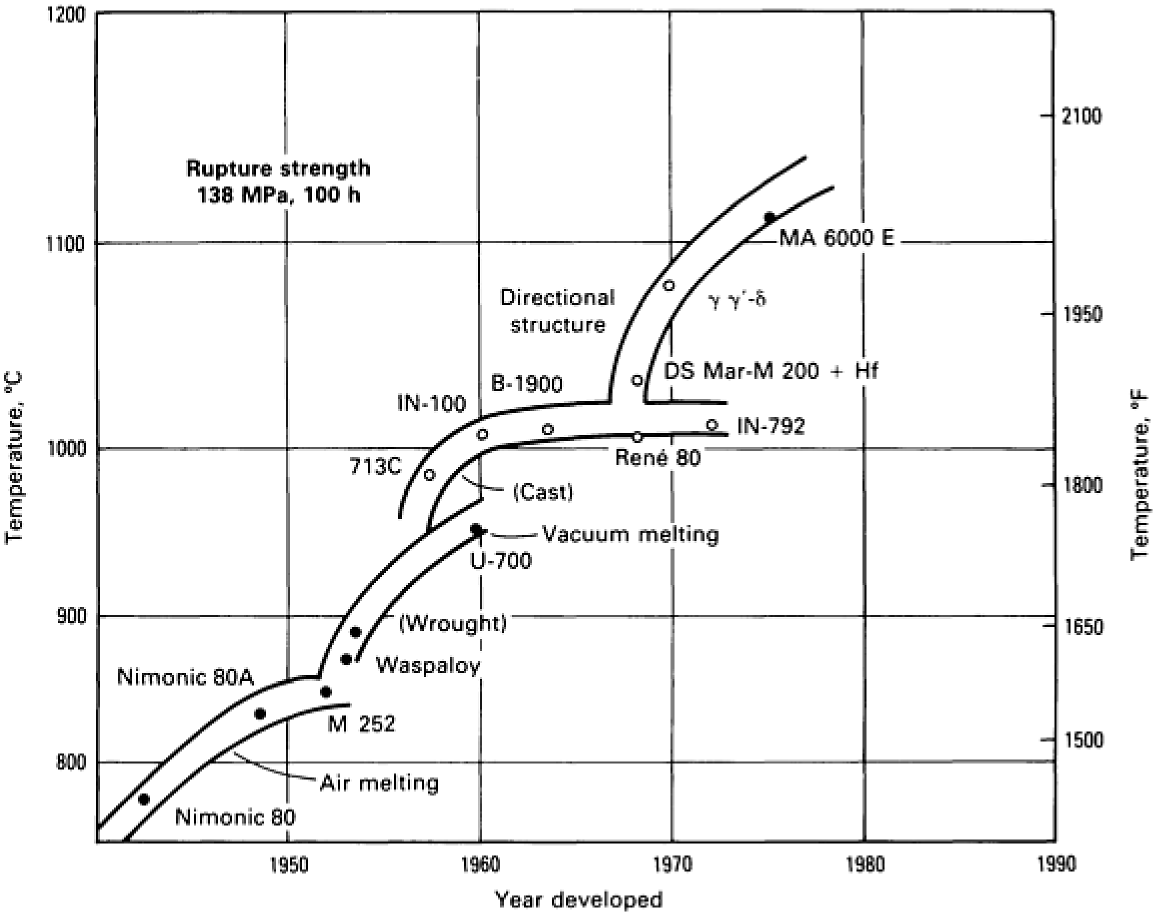

Fig. 31 Trends in alloy processing and development. Source: Ref 34

Initially, lower production costs were a major objective in exploring the P/M approach. Figure 32 illustrates the material savings possible with two different P/M methods due to their near net shape capabilities. Later, specific advantages linked on the P/M approach, such as the use of more complex and greater volume fractions of dispersoids, reduced segregation, and improved workability, led to the development of stronger alloys and to the use of these alloys not only in turbine disks but also in the higher-temperature turbine blades.

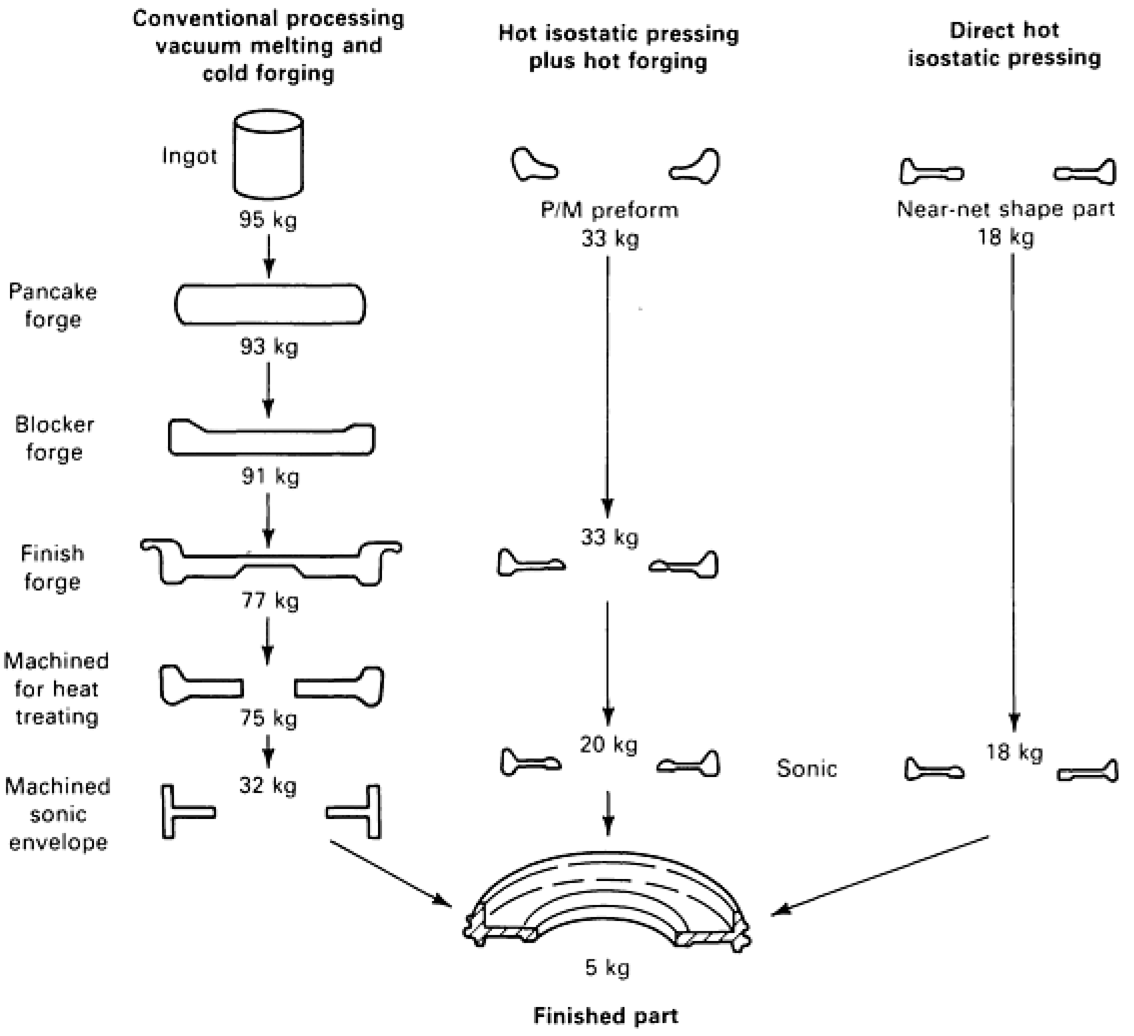

Fig. 32 Processing sequence in the production of jet engine compressor disks

Much effort is currently being directed toward reducing the cost of consolidating superalloy powders, particularly of oxide dispersion strengthened (ODS) superalloys, through the development of suitable forging techniques (Ref 34). Efforts are also underway to exploit the advantage of microcrystallinity and extended solid solutions of rapid solidification technology.

Uses and State of Commercialization. P/M superalloys were first used in military engines in the mid-1970s. Table 9 summarizes the uses of P/M superalloys in terms of components, engine use, and reasons for using P/M technology. Other uses of superalloys include nuclear reactors, heat exchangers, furnaces, sour gas well equipment, and other high-temperature applications.

Manufacturing of P/M Superalloys. An important prerequisite for making P/M superalloys that possess reliable dynamic properties is the use of clean powders. Years of intensive work were spent in identifying and controlling the problems related to unclean powders. Today, argon and vacuum (also known as soluble gas process) atomization, as well as atomization by the rotating electrode process, are known to be suitable for producing powders with the required low oxygen content and low degree of contamination (details on these processes are available in the article "Atomization" in *Powder Metal Technologies and Applications,* Volume 7 of the *ASM Handbook*). The so-called prior particle boundary (PPB) problem, that is, the presence of carbides segregated at PPBs, was solved through the development of low-carbon alloys. Special equipment is used for removing ceramic particles and particles containing entrapped argon. Some of these problems are minimized or avoided in ODS alloys made by mechanical alloying. In mechanical alloying, elemental and master alloy powders as well as refractory compounds are mechanically alloyed by high-energy milling (Ref 36, 37).

Two established powder consolidation techniques for P/M superalloys are hot isostatic pressing (HIP) and isothermal forging. Figure 33 illustrates schematically the steps of the P/M processes in comparison to conventional processing. Both P/M methods permit the manufacture of so-called near net shape parts with attendant improved material use and reduced machining costs. Powder metallurgy forging exploits the improved forgeability deriving from the higher incipient melting temperature and reduced grain size of P/M material. Hot compaction by extrusion leads to very fine grain size, improved hot ductility, and superplasticity.

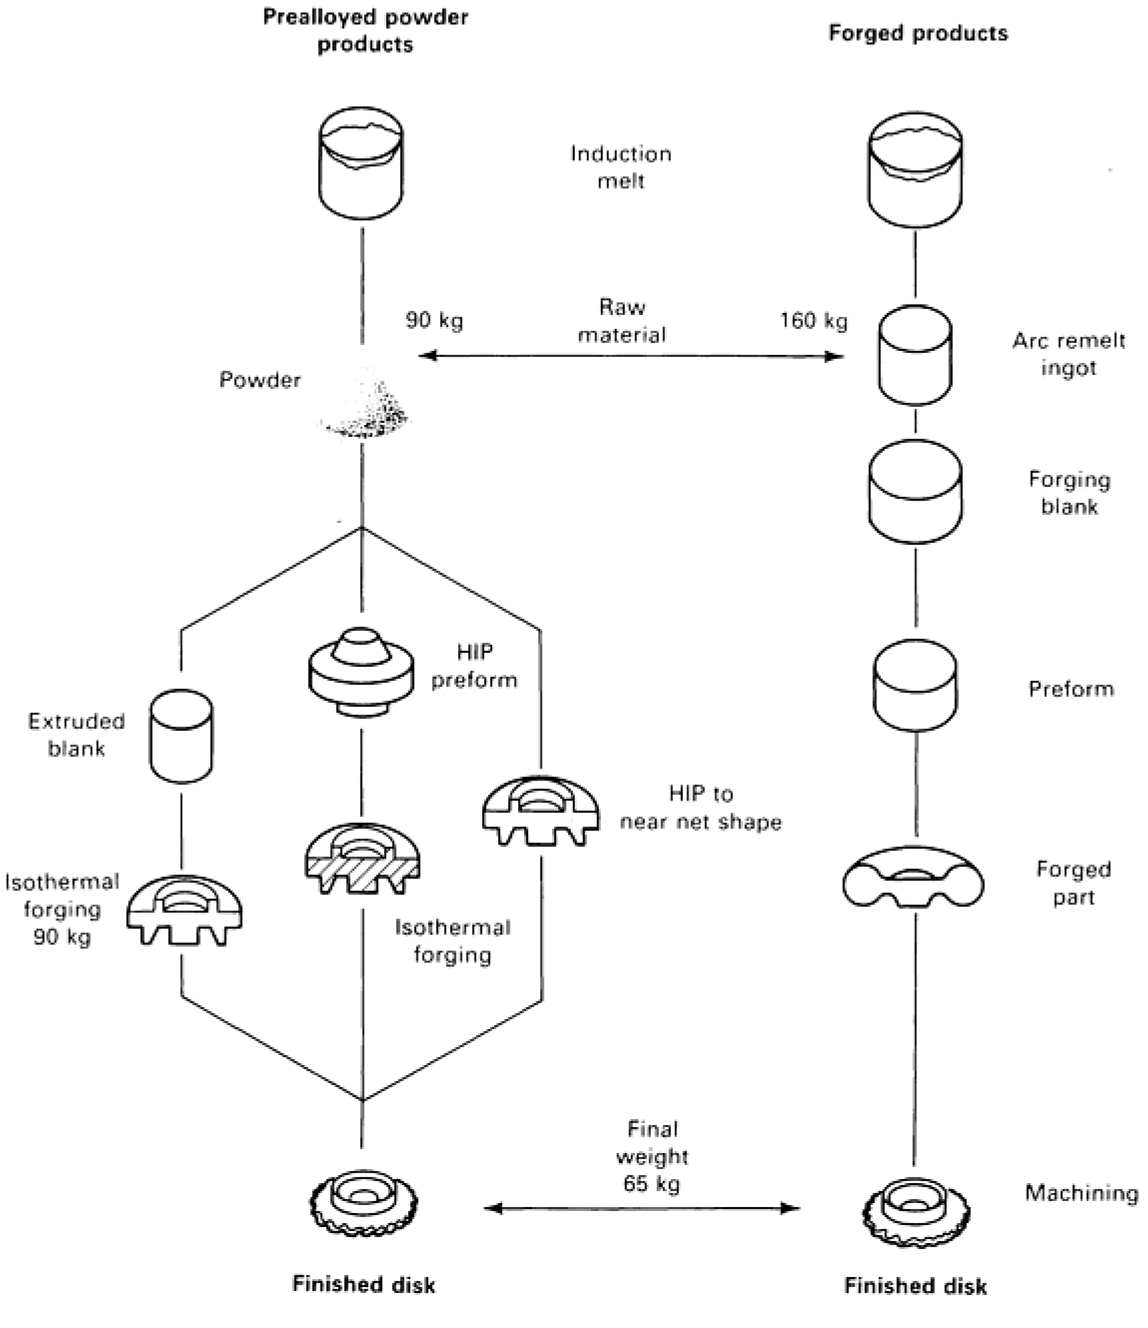

Fig. 33 Comparison of conventional processing and P/M processing for the fabrication of superalloy disks. Source: Ref 35

Depending on the application of a superalloy part, the powder consolidation process can be controlled in order to yield either a fine or a coarse grain size. Fine grain size is preferred for intermediate temperatures (up to about 700 °C, or 1290 °F) because of its higher strength and ductility at these temperatures. For high-temperature blade and vane applications, however, a large grain size (ASTM 1 to 2) provides superior creep strength due to reduced grain-boundary sliding. Grain coarsening of ODS alloys is achieved through special heat treatments after consolidation (Ref 34).

Compositions and Properties. Table 10 shows the compositions of the best known P/M superalloys. Many have the same compositions as cast alloys but are manufactured similarly to wrought alloys. The important P/M superalloys--IN-100, René 95, and Astroloy--were adapted to the P/M process by reducing their carbon content and by adding stable carbide formers to eliminate the problem of PPB carbides. To facilitate HIP, alloy compositions were modified to increase the temperature gap between the γ' solvus (above which HIP has to be carried out for increasing grain size) and the solidus temperature.

Oxidation. Nickel-, cobalt-, and iron-base superalloys use the selective oxidation of aluminum or chromium to develop oxidation resistance (Ref 38). These alloys are therefore often referred to as aluminum oxide (Al_2O_3) or chromium oxide (Cr_2O_3) formers, depending on the composition of the oxide scale that provides protection. Alloy composition, surface conditions, gas environment, and cracking of the oxide scale affect the selective-oxidation process (Ref 38). Figure 34 shows the development of superalloys in terms of the progress achieved against high-temperature oxidation.

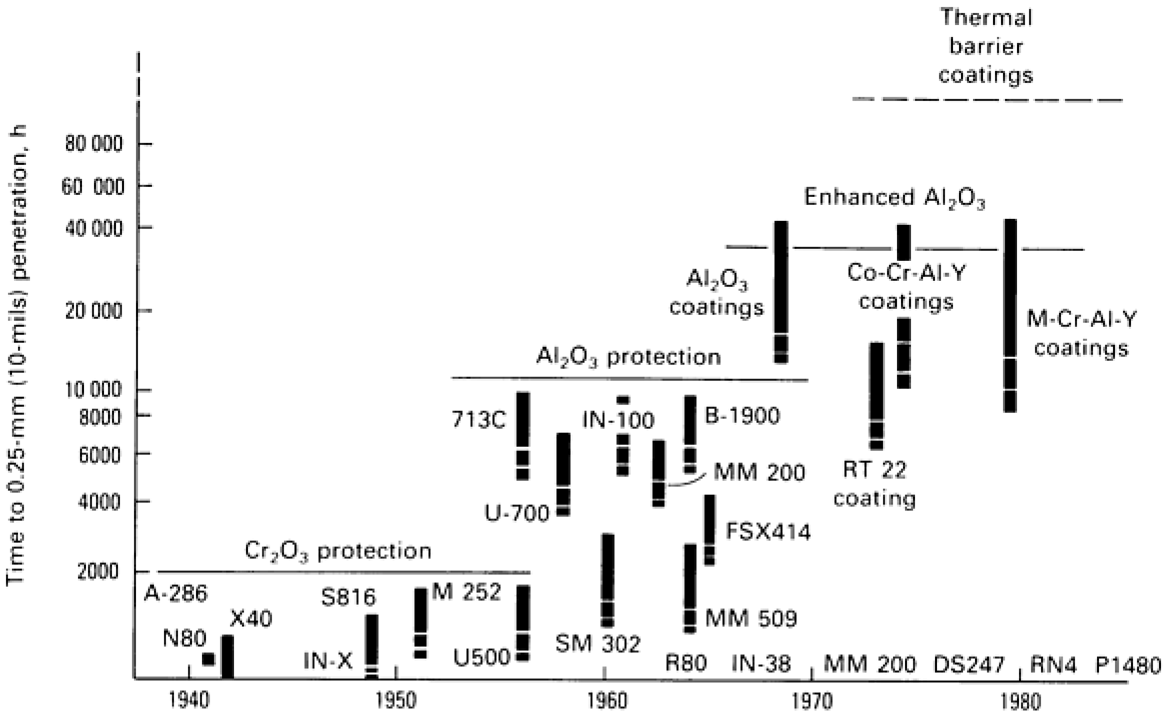

Fig. 34 Advancing steps is the protection of superalloys against oxidation at high temperatures showing life (in hours) to 0.25-mm (10-mils) penetration at 980 °C (1800 °F) Source: Ref 39

Cyclic oxidation causes protective scales of Al_2O_3 and Cr_2O_3 to crack and spall. Regeneration of the scales will eventually result in the complete depletion of chromium and aluminum. The length of time for which superalloys are Al_2O_3 or Cr_2O_3 formers under given conditions is very important because of the subsequent appearance of less protective oxides. The importance of chromium for imparting oxidation resistance is demonstrated in Table 11, which lists fatigue crack growth rates for different alloys.

Table 11 Relative increase in fatigue crack growth rates after 15 min at 650 °C (1200 °F)

ΔK = 30 MPa $\sqrt{\text{m}}$ (27 ksi $\sqrt{\text{in.}}$)

Figures 35 and 36 show comparisons of the oxidation resistances of superalloys with and without oxide dispersions. May studies have confirmed the beneficial effect of dispersed oxides on oxidation resistance. The lower oxidation rates of ODS alloys have been attributed to the reduced time required to form a continuous Cr_2O_3 scale due to the presence of dispersed oxides, which act as nuclei for oxidation (Ref 41). Based on marker studies with platinum, one investigation attributed the beneficial effect of oxide dispersions to the predominant, inward diffusion of oxygen ion (O^{2-}) and slowdown of the chromic ion (Cr^{3+}), diffusion (Ref 42). The latter may be caused by the blocking of the dispersions in the Cr_2O_3 scale. With the dispersed oxides becoming dissolved in the scale, it also appears possible that trivalent ions, such as yttrium (Y^{3+}) and lanthanum (La^{3+}), will reduce the number of vacant cation sites, thus lowering the diffusivity of Cr^{3+}.

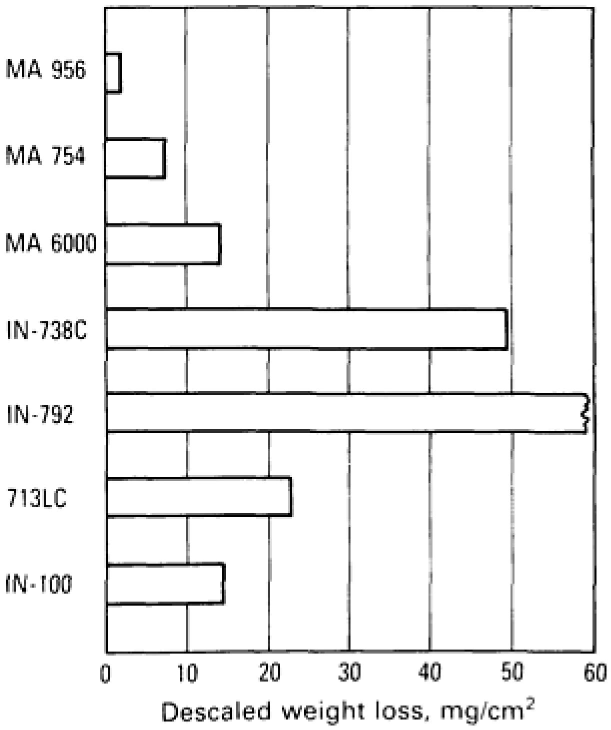

Fig. 35 Comparison of the oxidation resistance of ODS alloys MA 956, MA 754, and MA 6000 with that of other superalloys. Testing conditions: 504 h at 1100 °C (2010 °F) in air containing 5% H_2O. Temperature was cycled between test temperature and room temperature every 24 h. Source: Ref 40

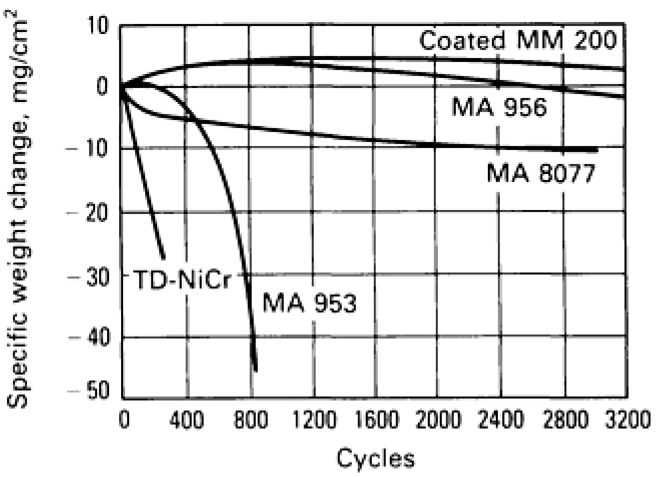

Fig. 36 Cyclic oxidation of ODS alloys MA 956, MA 8077, MA 953, and TD-NiCr compared to that of coated alloy MM 200. Testing conditions: held at 1100 °C (2010 °F) for 1 h and cooled by a 3-min air blast. Source: Ref 40

Dispersed oxides may also improve scale adhesion because of the thinner scale or because of increased porosity or smaller grain size in the oxide scale (Ref 40). It was reported that at 1300 °C (2370 °F) the outer regions of the Al_2O_3 film of MA 956 (Fe-20Cr-4.5Al-0.5Ti-0.5Y_2O_3) became enriched with titanium, giving rise to a continuous layer of titanium-rich oxide (Ref 43). Pegging of the oxide titanium carbide particles and the irregular metal/oxide interface is said to contribute to the good spalling resistance of the alloy.

In oxidation tests in air and in an inert atmosphere at 1260 °C (2300 °F) for MA 754 (Ni-20Cr-05Ti-0.5Y_2O_3-0.3Al-0.05C), Ni-20Cr (cast/wrought), and an ODS nickel-chromium alloy, subsurface porosity was attributed to the oxidation of chromium and aluminum (Kirkendall porosity), and thermally induced porosity was excluded as a cause (Ref 44). This type of porosity decreases with improving oxidation resistance of the alloy.

Results of cyclic oxidation tests at 1100 °C (2010 °F) for MA 956, TD-NiCr, and Hastelloy X are given in Table 12. The superior resistance of MA 956 attributed to a very stable Al_2O_3 film and parabolic oxidation for over 500 h. Tables 13 and 14 list sulfidation and carburization resistance data for MA 956. As in the case of oxidation, the alloy shows marked superiority to the other alloys tested. Tables 15 and 16 provide similar data for alloy MA 6000E (Ni-15Cr-4.5Al-4W-2Mo-2Ta-2.5Ti-1.1Y_2O_3) (Ref 45). The functions of the various alloying elements are as follows:

- Aluminum, titanium, and tantalum for γ' hardening
- Y_2O_3 for high-temperature strength and stability
- Aluminum and chromium for oxidation resistance
- Titanium, tantalum, chromium, and tungsten for sulfidation resistance
- Tungsten and molybdenum for solid-solution strengthening

Hot Corrosion. The requirement of hot corrosion resistance of superalloys derives from the use of sodium-and sulfur-containing fuels and the presence of salt in the air necessary for combustion. Under such conditions, combustion gases often leave deposits of sulfates or chlorides with metallic constituents of sodium, calcium, magnesium, or potassium on the surfaces of superalloys. The resulting corrosion problems are particularly severe if these condensed phases are liquid. Hot corrosion may occur in gas turbines, boiler tubes, and incinerators. Typically (and similar to what happens in pure oxidation), hot corrosion of superalloys occurs in two stages: a slow rate initiation stage, followed by a propagation stage of rapid degradation. The difference, compared to oxidation, is that the conditions causing hot corrosion simply shorten the time in which superalloys form protective Al_2O_3 or Cr_2O_3 scales by selective oxidation (Ref 38). Factors affecting the length of the initiation stage (at the end of the initiation stage, the superalloy must be removed from service because of the start of excessive corrosion) include alloy composition, alloy fabrication conditions, gas composition and velocity, deposit composition and its physical state, amount of deposit, temperature, temperature cycles, erosion, and specimen geometry.

When a protective scale dissolves into a liquid deposit, so-called fluxing reactions can occur with the appearance of other basic or acidic nonprotective reaction products. Propagation may also be caused by components from the deposit that can accumulate in the deposit or the alloy and thus cause a nonprotective scale to form. Chlorine and sulfur produce such effects, and hot corrosion caused by the latter is known as sulfidation (see the section "High-Temperature

Oxidation/Sulfidation" in the article "General Corrosion" in this Volume). Figure 37 shows the temperature ranges over which the various hot corrosion propagation modes are important. Additional information on the effects of individual elements on corrosion resistance is available in Ref 38 and in the articles "Corrosion of Nickel-Base Alloys" and "Corrosion of Cobalt-Base Alloys" in this Volume.

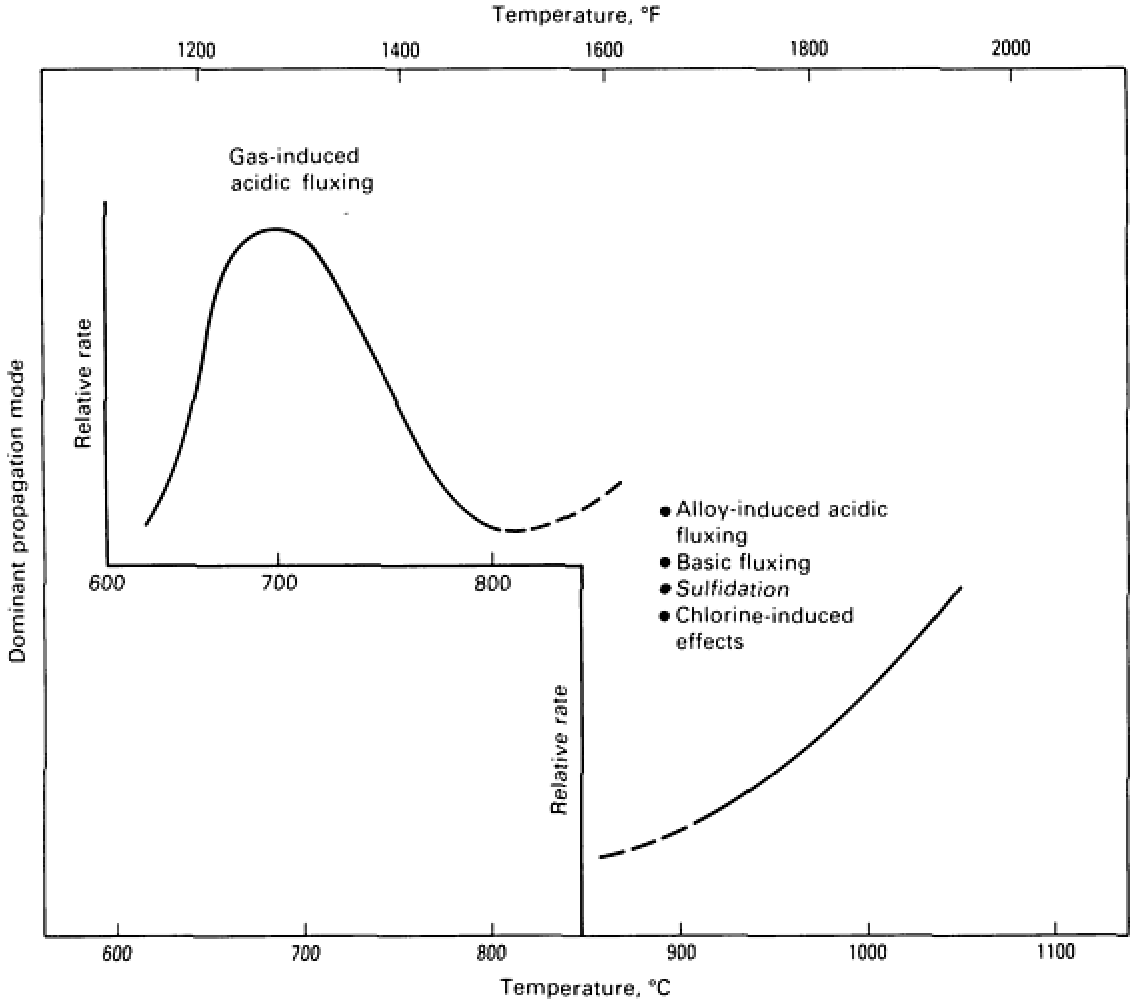

Fig. 37 Schematic showing the temperature regimes over which different propagation modes are most prevalent

Some superalloys corrode in several modes. For example, hot corrosion of IN-738 proceeds by alloy-induced acidic fluxing, but is preceded by other propagation modes, including a basic fluxing mode. The higher chromium content alloys IN-738 and IN-939 were developed to improve the hot corrosion resistance of land-based gas turbines. Carbide stabilization through tungsten and tantalum and delay of $M_{23}C_6$ formation in service were expected to allow the large chromium content to impart improved hot corrosion resistance. Increasing the chromium and decreasing the Al_2O_3, however, lowered γ' solution temperatures and strength, which necessitated the use of coatings. The use of coatings led to the current use of enhanced aluminum, that is, carefully balanced coating alloys (based on nickel), iron, or cobalt with chromium, aluminum, and other active elements). Generally, all superalloy load-bearing parts used at very high temperatures under dynamic conditions are coated (Ref 39). Nevertheless, coatings generally last longer on more corrosion-resistant base materials.

In a model study, IN-738 was used to demonstrate the effect of grain size and Y_2O_3 dispersions on hot corrosion behavior (Ref 46). Under gas turbine simulated hot gas corrosion test conditions at 850 and 950 °C (1560 and 1740 °F) (Fig. 38), the presence of a Y_2O_3 dispersion lowered the corrosion rate. At 950 °C (1740 °F) a finer grain size further reduced the corrosion rate, which was thought to be mainly due to a higher diffusion rate of chromium and aluminum. The effect of

the dispersion was predominant at 850 °C (1560 °F). Reduced sulfate formation at 850 °C (1560 °F) was attributed to the likely formation of yttrium oxysulfide.

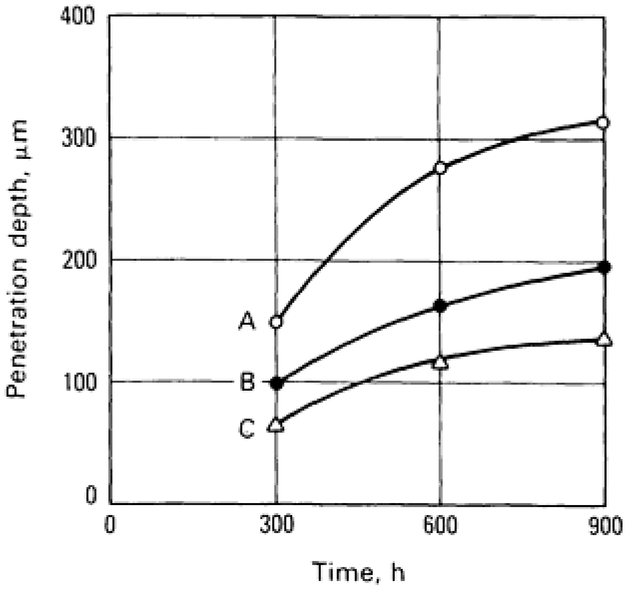

Fig. 38 Corrosion resistance of alloy IN-738LC in hot (850 °C, or 1560 °F) gases. A, IN-738LC; B, IN-738LC with Y_2O_3 dispersion, annealed at 1270 °C (2320 °F); C, IN-738LC with Y_2O_3 dispersion, annealed at 1100 °C (2010 °F). Source: Ref 34

In a study of the oxidation and hot corrosion resistance of P/M LC Astroloy and IN-100, isostatically pressed samples were found to be moderately attacked in a sulfate-chloride environment and heavily corroded by pure sodium sulfate (Na_2SO_4) (Ref 47). Heat treatment and the use of coarse powder (62 to 150 μm for Astroloy and 88 to 200 μm for IN-100) lowered the susceptibility to catastrophic corrosion. Additions of yttrium to IN-100 improved the corrosion resistance in pure sulfate, but were detrimental when NaCl was present. Therefore, yttrium additions to IN-100 cannot be recommended for marine turbines. It was concluded that in many cases impregnation coatings must be considered for components made of IN-100 alloys.

As a part of an evaluation of improved alloys for use in oil and gas drilling a depths of 6100 m (20,000 ft). HIP nickel-base alloy Inconel 625 was studied in a simulated deep, hot, sour cell environment (Ref 48). The alloy demonstrated resistance to pitting and crevice corrosion, sulfide stress cracking, chloride stress-corrosion cracking (SCC), and elevated-temperature anodic stress cracking. Hot isostatic pressed Inconel 625 exhibit essentially the same corrosion resistance as wrought Inconel 625.

Fatigue and Creep Crack Growth. Fatigue crack growth rates of nickel-base superalloys measured at frequencies above 0.1 Hz, at intermediate temperatures, and at an intermediate stress intensity range, ΔK, were found to be several times higher than those measured in inert atmospheres (Ref 49). The buildup of corrosion products with decreasing ΔK, however, was thought to enhance crack closure, thus reducing the effective stress intensity range and leading to fatigue thresholds higher than those in inert environments.

Table 17 shows creep crack growth rates of IN-750 with various grain-boundary carbide microstructures (Ref 40, 49). Aggressive environments (helium + 3% sulfur dioxide, SO_2, and air) produce order of magnitude increases over the rates in inert gas. In general, the reaction of both oxide dispersoid-free P/M superalloys and cast and wrought superalloys to aggressive environments is similar. This suggests that crack growth is governed mainly by microstructure and alloy chemistry.

Table 17 Dependence on carbide microstructure of creep crack growth rates of alloy IN-750 in four environments

Grain-boundary carbide microstructure	Crack growth rate (*da*/*dt*), mm/min[a]			
	Helium	**Air**	**Helium + 4% methane**	**Helium + 3% SO_2**

ODS Alloys. Mechanical alloying has removed many constraints on the development of new superalloys. Many new ODS alloys were designed specifically for corrosion resistance because alloying requirements for precipitation strengthening can be greatly reduced. Superior creep, corrosion, and erosion resistance at high temperatures have been claimed to enable the use of lower-grade fuels (Ref 50). Figures 39, 40, 41, and 42 show the corrosion resistances of ODS alloys MA 956, MA 6000, and MA 754 compared to several conventional superalloys.

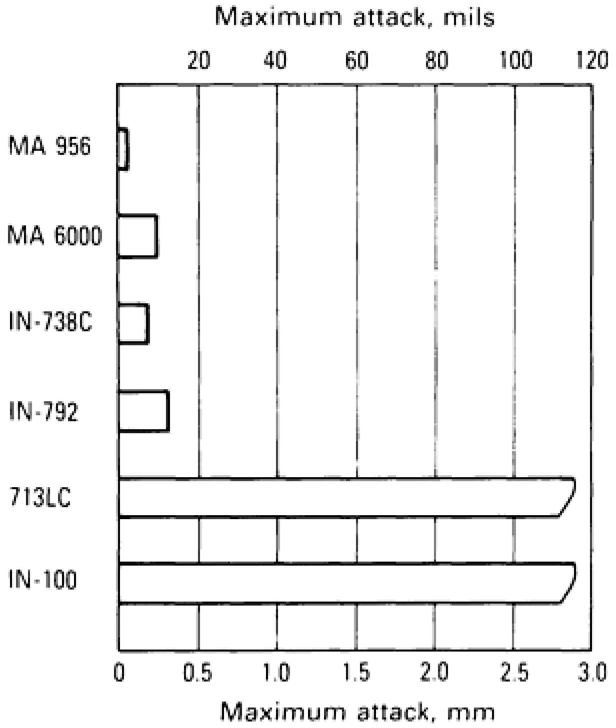

Fig. 39 Comparison of the corrosion resistance of MA 6000 and MA 956 with that of other superalloys. Tested in a burner rig for 312 h using a 30:1 air to fuel ratio. Fuel contained 0.3% S and 5 ppm seawater, and specimens were held at temperature for 58 min of each hour, then cooled 2 min with an air blast. Source: Ref

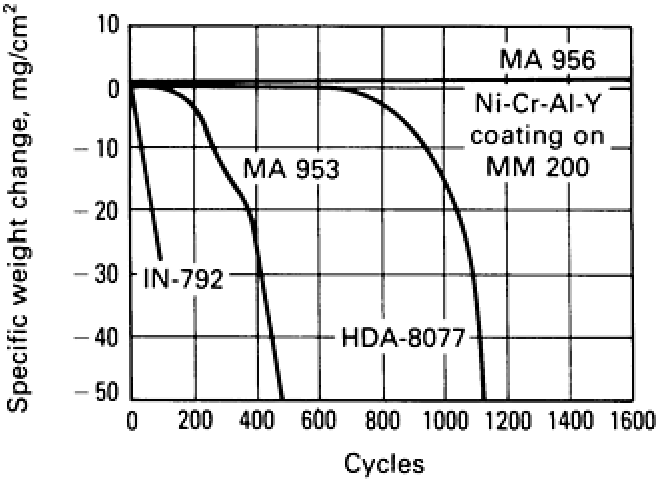

Fig. 42 Hot corrosion of alloys MA 953, HDA 8077, and MA 956 compared to that of some non-ODS alloys. Test conditions: 900 °C (1650 °F), 1 h, followed by a 3-min air blast, 5 ppm sea salt. Source: Ref 40

Coatings for ODS alloys. As mentioned above, for extended high-temperature service, superalloys require additional protection through coatings. The use of aluminide coatings appears to be unsatisfactory due to the development of subsurface Kirkendall porosity and early spalling of the protective scale. Kirkendall porosity decreases with increasing aluminum content of the substrate alloy as well as with decreasing grain size (Ref 50). Only limited information exists on the properties of chromium-aluminum-yttrium coatings (Ref 40) and on diffusion barrier coatings (Ref 51, 52, 53, 54).

P/M Aluminum Alloys

Although low- to medium-strength sintered (porous) P/M aluminum alloy parts were reported over 40 years ago and then commercialized in recent years, interest in the corrosion properties of P/M aluminum alloys paralleled the development of fully dense P/M aluminum products, which dates back some 25 years. Early work showed that heat-treated extrusions of alloy powders higher in zinc, magnesium, and copper than the conventional, 7000-series ingot metallurgy (I/M) wrought alloys provided higher tensile strength (Ref 55). In addition, it was found that high strength and resistance to SCC superior to that of I/M alloys could be obtained (Ref 56). Subsequently, rapid solidification processing and mechanical alloying were further exploited with additions of iron, nickel, cobalt, and oxides for grain refinement and stabilization of the structure without the deleterious segregation effects that occur when I/M alloys are overalloyed (Ref 57).

The large, active constituents often found in conventional alloys are absent in these P/M alloys. Also absent are impurities and grain-boundary depletion of alloying elements, both of which can cause localized attack. Elements that are insoluble in the solid state are often soluble in the liquid state and may be uniformly dispersed in the powder particles by rapid quenching; metastable phases may also be formed (Ref 58). Figure 43 illustrates the differences in appearance between P/M and I/M microstructures. Additional information on the development of high-strength aluminum P/M alloys is available in Ref 59, 60, 61, 62, 63, 64.

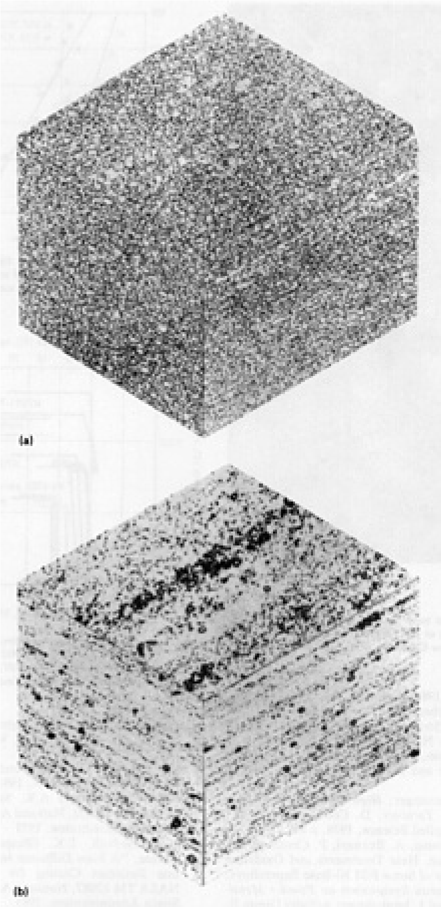

Fig. 43 Comparison of grain structure in P/M and I/M aluminum alloys. (a) P/M alloy X7090. (b) I/M alloy 7178. Both 500×

Because of higher solute contents, the P/M aluminum alloys can be aged to considerably higher yield strength than conventional alloys, with accompanying improvements in fatigue and toughness and without loss in SCC resistance. Rapid soldification processing and mechanical alloying also permit increased alloying contents. For example, increased amounts of lithium are possible (supersaturation), which results in lower density (7 to 20% weight savings) and higher specific elastic modulus.

Uses, Market, and State of Commercialization

Depending on alloy type, the attractiveness of these alloys in comparison to conventional alloys lies in their superior room-temperature strength combined with excellent corrosion and stress-corrosion resistance, their improved elevated-temperature properties, and their lower density and higher elastic modulus. High-performance P/M aluminum alloys are expected to find increasing use in aerospace, military, and marine applications and to replace heavier and more costly titanium alloys--for example, in major airframe primary load-carrying structural members, such as upper wing skins and landing gear components; helicopter rotors; low-temperature fan and compressor cases, vanes, and blades for gas-turbine engines; and fins, winglets, and rocket motor cases in missiles.

The addition of silicon carbide (SiC) to various aluminum alloy matrices by P/M or I/M processing results in lightweight, high-modulus composites. Potential uses include antennae yolks, torpedo hulls, mobile bridges, gyroscope supports, tractor tread shoes, and helicopter landing skids (Ref 60). The limited ductility and high price of these composite alloys, however, are impeding commercialization for use in sports equipment.

According to a recent market assessment, the targets of the high-performance P/M aluminum alloys are the high-strength 2*xxx* and 7*xxx* alloys (Ref 65). About 50,000 short tons (45,000 Mg), out of a total of 100,000 to 200,000 short tons (90,000 to 180,000 Mg) per year, are used by the United States aerospace industry. If the functional price can be made comparable to that of conventional alloys, a large potential also exists in the automotive market.

Of the many P/M alloys under development, only the aluminum-zinc-magnesium-cobalt alloys X7090 and X7091, which were introduced in 1981, are being produced commercially. Alloy X7090 is expected to be used for the landing gear support beam and the landing gear door actuator for the Boeing 757 aircraft. According to Ref 65, the following barriers must be overcome to achieve market introduction:

- Lack of exposure and experience
- Inadequate industry standards and the lack of reliable, repeatable, nondestructive tests for P/M parts
- The rate of technology change, which can inhibit major capital investment

The manufacture of high-performance fully dense P/M aluminum alloys is based on the use of either rapidly solidified materials, powders and particulates or mechanically attrited powders. Detailed. descriptions of how these powders are produced are available in Ref 66 and the articles "Atomization" and "Milling of Brittle and Ductile Materials" in *Powder Metal Technologies and Applications,* Volume 7 of the *ASM Handbook.* Both methods can be used to produce compositions that are not practical with I/M and that have very fine and uniform dispersions of intermetallic particles.

The powders are usually degassed and then consolidated through the application of heat and pressure, that is, by forging, extrusion, hot pressing, or hot rolling, into a billet or near net shape part. Additional information on the critical steps of degassing and consolidation of these alloys is available in Ref 59.

Classes of High-Performance Aluminum P/M Alloys

As noted above, from an applications point of view, it is convenient to distinguish among three classes of high-performance P/M aluminum alloys (Ref 59, 60, 62, 63): high room-temperature strength, SCC/corrosion-resistant alloys; low-density high-stiffness alloys; and elevated-temperature alloys.

High Room-Temperature Strength SCC/Corrosion-Resistant Alloys. Table 18 shows the composition of six P/M aluminum alloys characterized by high room-temperature strength and high SCC resistance. Their room-temperature properties are given in Tables 19 and 20. Alloy CW67 (Table 20), a recent second-generation P/M product in the 7*xxx* series, is a zirconium- and nickel-containing aluminum-zinc-magnesium-copper alloy. It is still in the laboratory evaluation stage. Strength increases of 20 to 30% over wrought aluminum alloy 7075 translate into weight savings of 10% or more in aerospace structures. In the damage-tolerant T7 temper, CW67 demonstrates superior combinations of strength, fracture toughness, and resistance to fatigue and SCC compared to other I/M and P/M alloys (Ref 67, 68). Of the alloys shown in Table 18, alloys X7090 and X7091 are farthest along in the development of P/M high-strength aluminum alloys. In these alloys, cobalt is present as an intermetallic dispersoid of the composition Co_2Al_9 (in iron- and nickel-containing alloys, the analogous dispersoid is $(Fe,Ni)_2Al_9$) and is beneficial to both strength and SCC resistance. Figure 44 shows a transmission electron micrograph of a P/M MA 67 (the experimental precursor of alloy X7090) heat-treated die forging showing the uniformly distributed and small (0.05-μm) Co_2Al_9 particles as dark spheroids present on grain boundaries and within grains. In the T7*x* tempers, there were generally no precipitate-free zones surrounding the Co_2Al_9 particles. The magnesium- and aluminum-base oxide particles, another distinctive P/M feature, appear as clusters of dark particles, lighter and much finer than Co_2Al_9 (0.02 to 0.004 μm) and predominantly at grain boundaries.

In 1975, it was proposed that the superior SCC resistance of P/M aluminum-zinc-magnesium-copper alloys containing iron and nickel or cobalt may be related to the following factors: grain morphology (SCC fracture is intergranular and the crack path is tortuous because of the presence of fine dispersoids); grain-boundary movement restriction from the dispersoids (including oxides); hydrogen recombination at the cathodic Co_2Al_9 dispersoids; blunting of the leading edge of cracks by dispersoid particles; and shifting of the chemistry within cracks to more alkaline conditions at grain boundaries containing corroding oxide particles (Ref 58). The effect of different cobalt concentrations on the SCC behavior of several aluminum powder alloys was recently investigated in more detail (Ref 69, 70, 71). It was concluded that the increased SCC resistance was not due to the smaller grain size but to a direct effect of cobalt attributable to the cathodic behavior of the Co_2Al_9 particles that serve as sites for hydrogen recombination, thus reducing both the absorption of atomic hydrogen into the grain boundaries and hydrogen embrittlement.

Based on precracked double-cantilever beams in chromate inhibited brine, alloys X7090 and X7091 exhibited the greatest susceptibility to SCC in their undertempers (Ref 72). Susceptibility decreased in the peak-aged tempers and was absent in the overaged tempers after 500 h of immersion. In comparison, conventional alloy 7075, which uses chromium and manganese as dispersoid-forming elements, has a lower strength in its peak-aged temper and exhibits similar SCC propagation behavior to X7091 under the same test conditions.

Figure 45 shows time to failure curves for unnotched (reflecting both initiation and propagation behavior) specimens of alloys 7075 and X7091 in acetic acid brine. For a given strength, the P/M alloys exhibit superior SCC resistance. An investigation of the effect of varying amounts of dispersoid contents of Co_2Al_9 and $(Fe,Ni)_2Al_9$ found that the SCC resistances of Co_2Al_9 and $(Fe,Ni)_2Al_9$ dispersoid-containing alloys are similar in their T7 tempers (Ref 73). The influence of dispersoids on SCC was evident in the T6 but not the T7 tempers. Electrochemical tests showed a tendency for high

cathodic reaction rates in the dispersoid-containing alloys. Anodic polarization tests revealed several distinct breakdown potentials.

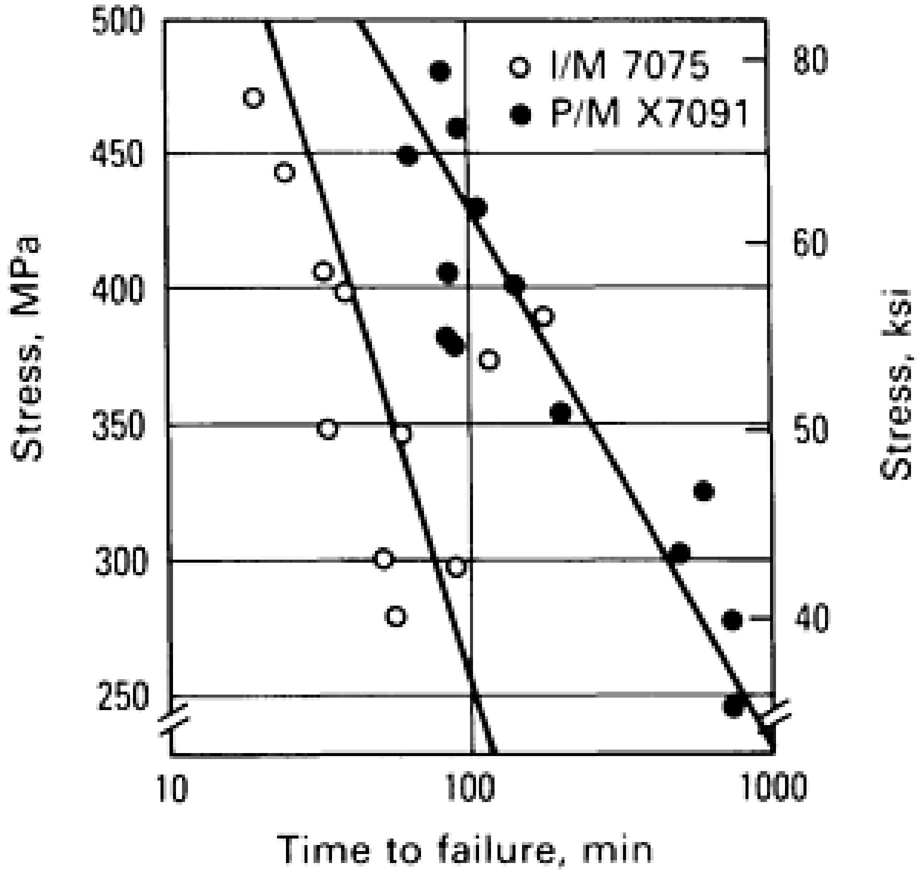

Fig. 45 Stress versus time to failure curves for unnotched specimens of conventional alloy 7075 and powder alloy X7091 at the same level in acetic acid brine. Source: Ref 33

Based on constant-amplitude (R = 0.5) fatigue crack growth rates measured in an inert and an aggressive environment, it was found that the corrosion fatigue crack growth rates for I/M 7075-T651 alloy are ten times faster than those for P/M X7091-T7470 (Ref 74). The results were explained in terms of crack closure of the P/M alloy with an effective load reduction of up to 40% of the applied load amplitude. Exfoliation tests of P/M X7091 (T7E73 temper) using EXCO (Ref 75), salt spray, and marine exposure tests showed that this alloy resisted exfoliation because of its fine equiaxed grain structure (Ref 76). The dispersoid is beneficial to the stabilization of this structure.

The aluminum-magnesium alloys IN-9052 and IN-9021 are made by mechanical alloying. Uniform dispersions of MgO, Al_2O_3, and Al_4C_3 effectively pin the boundaries of the very fine grains (0.3 to 2 μm). In general corrosion tests in accordance with ASTM G 44 (Ref 77) (alternate immersion in NaCl solution), IN-9052 had a corrosion rate over two orders of magnitude lower than that of conventional 7075-T73 (Ref 78, 79). Figure 46 shows a comparison of crack velocity versus stress intensity factor of IN-9052 with alloys 7090, 7091, and conventional alloy 7075 in their highest-strength conditions for double-cantilever beam specimens in a chromate-inhibited brine solution.

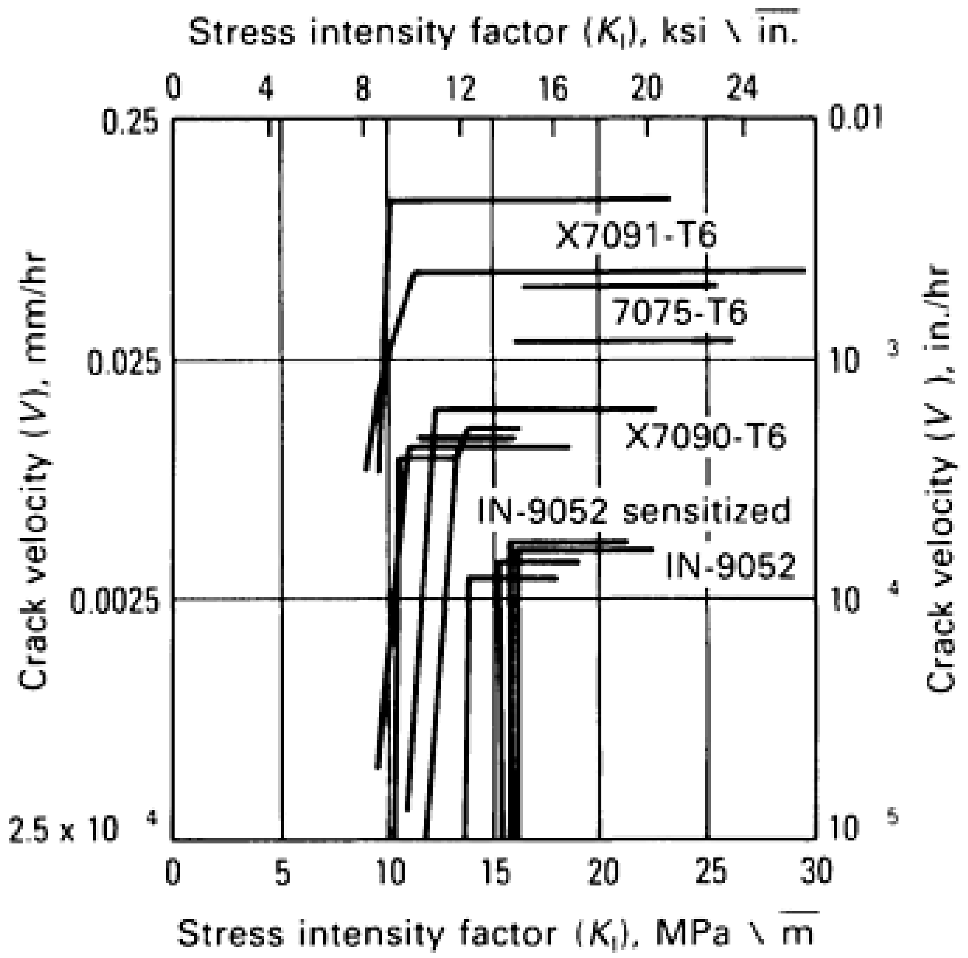

Fig. 46 Crack velocity versus stress intensity factor for P/M alloys IN-9052, X7090, and X7091 as well as conventional alloy 7075. All alloys were in their highest-strength conditions. Source: Ref 71, 72

Table 21 compares the mechanical and SCC properties of P/M alloy IN-9052 with those of I/M alloy 5083, which is of similar composition. The high increase in strength of IN-9052 is obtained without sacrificing the excellent corrosion resistance and at a marked improvement of SCC resistance after sensitization. Alloy IN-9052 is also superior in exfoliation resistance when tested in accordance with EXCO and Asset (Ref 80) and did not exhibit pitting. The factors responsible for the good SCC resistance of IN-9052 compared to conventional alloy 5083 are believed to be its fine grain size, the absence of Mg_2Al_3 grain boundary precipitates, and the small degree of segregation of magnesium to grain boundaries (Ref 71, 72). In another study using short-term exposure in a 3.5% NaCl solution, IN-9021 was found to be very susceptible to pitting and to exhibit a high general corrosion rate (three times the corrosion rates of conventional alloys 7075 and 2024) (Ref 81).

Source: Ref 72

(a) 90-day alternate immersion in 3.5% NaCl; sensitized at 95 °C (200 °F) for 7 days and tested in the short-transverse direction.

The low-density high-stiffness P/M aluminum alloys contain lithium, which decreases the density and increases the elastic modulus. Binary aluminum-lithium alloys, however, contain the ordered metastable δ' precipitate (Al_3Li), which causes strain localization and accompanying low ductility and toughness. Alloy development work concentrates on the addition of dispersoids to overcome this problem.

With I/M, the maximum lithium content is about 2.5% due to difficulties in direct-chill casting at higher concentrations. With rapid solidification technology and mechanical alloying, lithium concentrations in ternary alloys can be as high as 4%. Alloys with ultimate tensile and yield strengths exceeding 600 MPa (87 ksi) and an elongation of 5% have been made and are under evaluation. A recent patent (Ref 82) claimed a UTS of >758 MPa (110 ksi) for an experimental mechanically alloyed aluminum-lithium binary alloy. Preliminary baseline corrosion studies on binary aluminum-lithium alloys have indicated that susceptibility to SCC is possible when the lithium concentration exceeds the room-temperature solid solubility limit (Ref 83). Overaged tempers have been found to be nonsusceptible, but peak-aged tempers have given the highest susceptibility.

In one investigation, the SCC behavior of two aluminum-lithium-copper P/M alloys (2.6% Li) was studied with and without magnesium additions by using three test methods: threshold stress test on tuning fork specimens, slow crack growth tests on fracture mechanics specimens, and slow strain rate tests on electrically isolated tensile coupons (Ref 84). Each of these test methods, together with other experimental parameters was found to yield important information on the SCC behavior of the alloys.

Another study compared the SCC susceptibility of the aluminum-lithium alloys (Ref 85). It was found that alloys exposed to aqueous 3.5% NaCl exhibited time-dependent fracture and that SCC susceptibility was composition dependent. Alloy X2020 and mechanically alloyed Al-3Li-2.1Mg appeared very resistant to SCC. The lower limit of threshold stress necessary to cause fracture in the most susceptible P/M alloy (Al-2.6Li-1.4Cu-1.6Mg) was about 355 MPa (51.5 ksi). The P/M aluminum-lithium-copper alloys were susceptible to intergranular crack initiation in aqueous NaCl, but were resistant to sustained subcritical crack growth for stress intensity factors up to 15 MPa$\sqrt{m}$ (13.7 ksi$\sqrt{in.}$). Intergranular corrosion began at active pitting sites correlated to oxide particles strung along the extrusion direction of the alloys.

Elevated-Temperature Alloys. Table 22 shows the compositions and Table 23 shows the elevated-temperature properties of P/M aluminum alloys exhibiting superior elevated-temperature strength. These alloys are currently under development, but preliminary results indicate that they have good corrosion and SCC resistance. In these ternary and

quaternary alloys, iron functions as the major dispersoid-forming element. The solute levels of iron and other intermetallic compound forming transition metals are considerably higher than is acceptable in conventional alloys (Ref 86).

Corrosion of Cemented Carbides

Herbert S. Kalish, Adamas Carbide Corporation

Introduction

CEMENTED CARBIDES consist of hard refractory metal compounds that have a lower-melting ductile metal binder or cement (internationally, the term hardmetal is used in preference to the term cemented carbides, which is used almost exclusively in the United States). Figure 1 shows microstructures of both the basic tungsten carbide-cobalt (WC-Co) materials and materials containing titanium carbide (TiC) and tantalum carbide (TaC). Table 1 shows the physical properties of the commonly available refractory metal or hard metal carbides used to make cemented carbides. Only two--WC and TiC--are used as true base compound materials that comprise over 50% of the composition. Tungsten carbide base materials are by far the most predominant and have been in widespread use for more than 50 years. They were originally used as early as 1916 (Ref 3, 4, 5). During this time, it was found that WC could be combined with cobalt to make a high-hardness, wear-resistant, strong material. This material was initially used for wire drawing dies instead of diamond dies.

Table 1 Physical properties of carbides used in the manufacture of cemented carbides

Carbide	Microhardness, kg/mm^2	Melting point		Density, g/cm^3
		°C	**°F**	
TiC	3200	3200	5790	4.94
VC	2950	2830	5125	5.71
HfC	2700	3890	7030	12.76
ZrC	2560	3530	6385	6.56
NbC	2400	3500	6330	7.80
Cr_2C_3	2280	1895	3440	6.66
WC	2080	2600	4710	15.67
Mo_2C	1950	2675	4850	9.18
TaC	1790	3780	6835	14.50

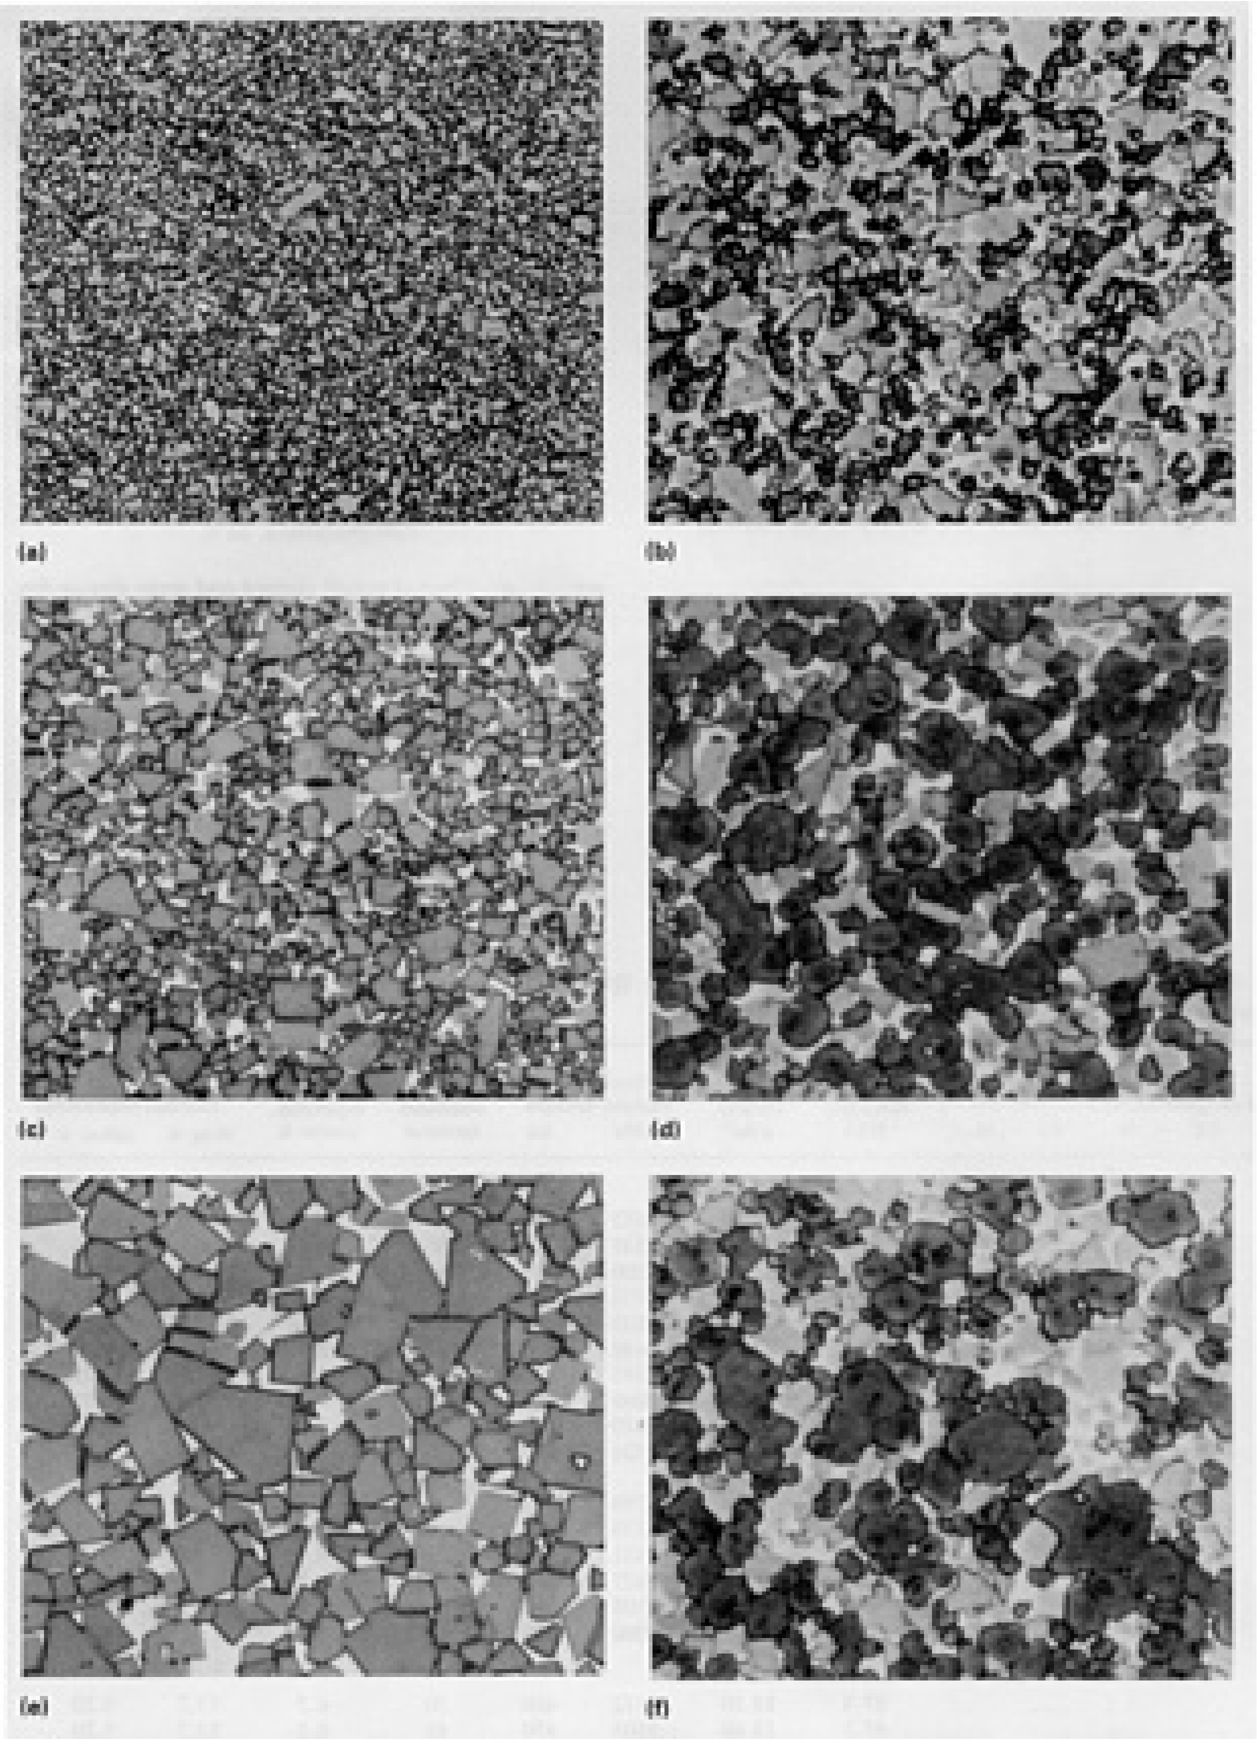

Fig. 1 Microstructures of WC-Co (a, c, and e) and WC-TaC-TiC-Co (b, d, and f) cemented carbides. In a, c, and e, the white areas are cobalt binder phase. In b, d, and f, the darker, more rounded grains are the $W_xTa_yTi_zC$ cubic solid-solution γ phase. (a) and (b) Fine grain structures. (c) and (d) Medium grain structures. (e) and (f) Coarse grain structures. All 1500×. Source: Ref 1 and 2

The first key to the successful development of cemented carbides was that these refractory metal compounds, particularly WC, are best produced as powders. In fact, the only logical way to produce tungsten is the hydrogen reduction of WO_3 or ammonium paratungstate powder into tungsten metal powder. The carburization of tungsten to WC also results in a fine powder. The second key was the discovery of the eutectic system WC-Co (Fig. 2). Liquid-phase sintering is possible well below the melting point of the WC and even below the melting point of cobalt.

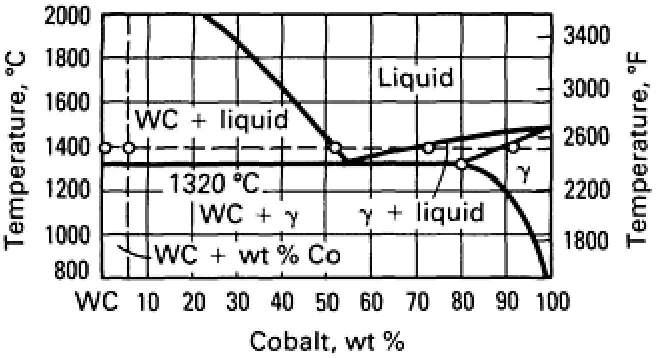

Fig. 2 Quasi-binary phase diagram for the WC-Co system

Cemented WC is produced by mixing from 3 wt% or less up to as much as 30 wt% of cobalt metal powder with a balance of WC powder. The mixed powders are ball milled, generally in volatile solvents, for times ranging from a few hours to as long as 7 days. Alternatively, the powders are milled in an attritor for 1 to 10 h.

A suitable transient binder is added to the powder, which is then pelletized and pressed to form the shape. Finally, the part is sintered at temperatures between 1300 and 1600 °C (2370 and 2910 °F), most often in vacuum. Because a liquid phase is formed during sintering, virtually 100% density is achieved. More information on the production of cemented carbides is available in the articles "Cermets and Cemented Carbides" and "Production Sintering Practices" in *Powder Metal Technologies and Applications,* Volume 7 of the *ASM Handbook.*

Effect of Composition on Properties

The two most common variables in cemented carbides are the cobalt or binder content and the grain size. As shown in Fig. 3, increased grain size decreases hardness, and increased cobalt content also decreases hardness (Ref 6). Increased contents of cobalt or other binders, however, are necessary to increase strength. As shown in Fig. 4, strength increases with increased cobalt content; although a maximum appears to occur at about 15 to 18% Co, this is true only for transverse rupture strength (Ref 6). Very high impact strength requires very high cobalt contents (up to 25 or 30 wt%) and coarse-grain carbide. In corrosion applications, however, the binder content ranges from virtually nil (there are some so-called "binderless" compositions that actually contain 1 to 2% binder) up to about 10%, with exceptions running up to 15% binder.

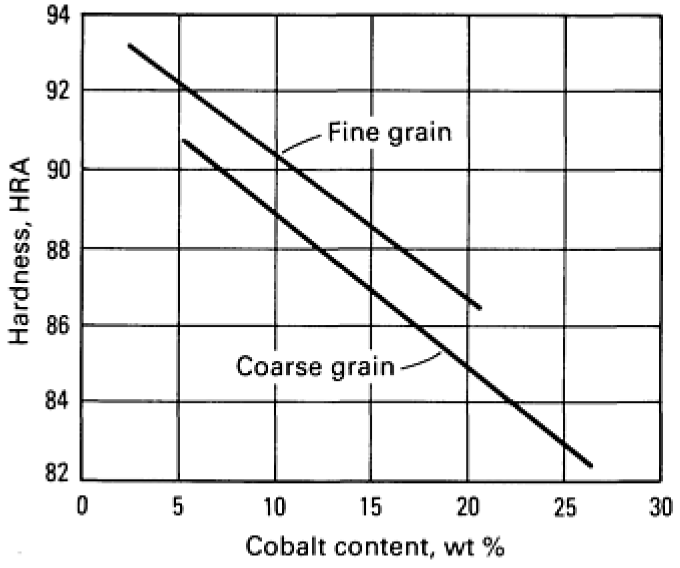

Fig. 3 Effect of cobalt content and grain size on the hardness of WC-Co cemented carbides

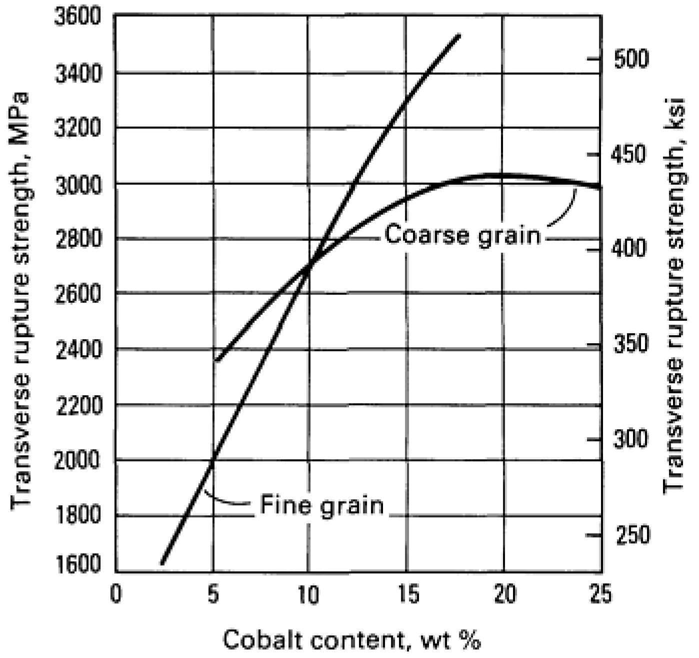

Fig. 4 Effect of cobalt content and grain size on the transverse rupture strength of WC-Co cemented carbides

Cemented carbides are not selected for corrosion applications *per se.* They are extremely important in corrosion conditions in which high hardness, wear resistance, or abrasion resistance is required. When this is the case and the selection of a cemented carbide is logical, the corrosion-resistant properties are examined. For ordinary corrosion resistance, many metals and ceramics are better choices, but when wear resistance is also a requirement, the cemented carbide is needed.

Binder Composition and Content. The corrosion resistance of cemented carbides is based on the two very different components. The cobalt binder has very poor corrosion and oxidation resistance, and the WC has excellent corrosion resistance and good oxidation resistance. Alternate binders, such as nickel, have better corrosion resistance than cobalt and are used in spite of their lower hardness and strength. Nickel is a superior binder for cemented TiC and therefore is

used in all cemented TiC materials regardless of the need for corrosion resistance. In some applications, cemented TiC shows repair corrosion resistance, and in other applications, cemented WC is better.

The addition of nickel to the usual cobalt binder used for WC, or the substitution of it entirely for cobalt, always improves corrosion resistance. There is, however, a sacrifice in strength, hardness, and wear resistance. A chromium addition also enhances corrosion resistance.

The most important variable in the corrosion of cemented carbides is the binder content. Because the binder corrodes more than the carbide, the smaller the amount of binder the better. On the other hand, decreasing the binder decreases the strength.

Carbides. Additions of TaC and TiC to the WC-Co materials are common for the compositions used for machining steel. These additives give the carbide crater resistance. Cratering on the top of a metal-cutting insert is the result of a physicochemical reaction. The addition of TaC and/or TiC will slow this reaction; indeed, it has been found that TaC also enhances the outright chemical corrosion resistance of these materials.

Other additives, such as chromium carbide (Cr_2C_3), molybdenum carbide (Mo_2C), niobium carbide (NbC), and vanadium carbide (VC), are often added in small quantities as grain growth inhibitors. Little has been published about their effect on corrosion, but chromium has been shown to be a beneficial binder additive to WC-Ni binder compositions (Ref 7). Vanadium carbide and Mo_2C will probably have a weakening effect on the strength of a WC-base hardmetal.

For TiC-base hardmetals, Mo_2C is invariably added to the composition, but there are no known studies of the effect of molybdenum on corrosion resistance. The molybdenum has always been added to enhance the liquid-phase sintering of the TiC-base compositions. In general, these compositions have been made for their hardness and strength characteristics, with corrosion resistance being a secondary consideration. Most rescent TiC-base compositions have titanium nitride (TiN) added, and this has been shown to improve the corrosion resistance (Ref 8).

Perhaps it is not surprising that compositions developed primarily for machining should show improved corrosion resistance. In machining, there is heat with resultant oxidation and often corrosionlike mechanisms. Thus, some of the improved machining compositions also show better corrosion behavior. On the other hand, optimum corrosion resistance is obtained by tailoring the composition and amount of the binder phase. This can result in lower-strength materials with limited usefulness in machining applications.

Because carbon is the basis of cemented carbides, its variation within a given composition is very important to properties and corrosion resistance. Figure 5 shows the range of carbon content allowable in the simple WC-Co compositions as cobalt content is varied (Ref 9, 10, 11). Corrosion-resistant compositions have three problems:

- The lower the cobalt or binder content, the better the resistance to corrosion, but this limits the safe zone, in which neither carbon porosity nor ηphase (hard, brittle M_6C or $M_{12}C$ intermetallics) exist
- The lower the carbon content, the better the corrosion resistance, but falling into the η-phase zone results in embrittlement of the material
- The addition of alternate binders, such as nickel, decreases the safe zone

In making corrosion-resistant cemented carbides, manufacturers must be aware of these problems and limitations. Information on the metallography and microstructures of these materials is available in the article "Cemented Carbides" in *Metallography and Microstructure,* Volume 9 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

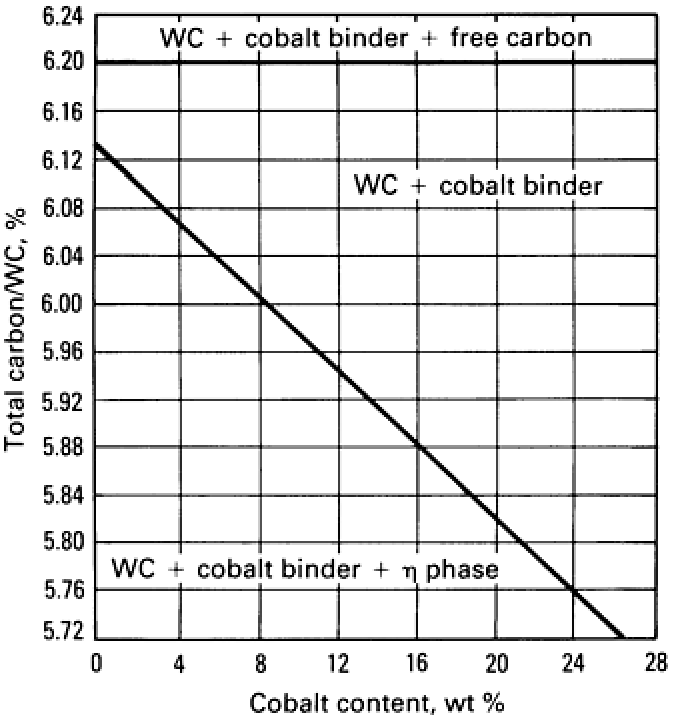

Fig. 5 Effect of cobalt content and carbon content on the phases present in WC-Co cemented carbides

Applications of Cemented Carbides

The major applications of cemented carbides actually involve environments that are inherently corrosive. For example, the major use of cemented carbides is for metal-cutting (machining) applications. In these applications, extreme heat is generated whether or not coolants are used, and in those cases in which coolants are used, the corrosive attack of the coolant is a factor in the performance of the cutting tool. In general, however, very little heed is paid to this factor; cemented carbides are more often chosen for their wear resistance in such applications as mining and oil well drilling. In actuality, there is a corrosive environment to be contended with in mining (Ref 12) and oil well drilling; the natural waters and other fluids involved are often very corrosive. Other well-known examples in which cemented carbide is performing in a corrosive environment include balls for ball point pens and dental drills. In both of these examples, the corrosion resistance of the most frequently used WC-6Co composition was serendipitous. The material was selected for its wear resistance. It just happens to have good corrosion resistance in the saline and ink solutions. The dulling of cemented carbide saw tips used for sawing green or unseasoned wood is a corrosive as well as a wear phenomenon (see the section "Saw Tips and Corrosion" in this article).

Examples of the use of cemented carbide in true corrosion applications include the following:

- Ball point pen balls
- Dental drills and burrs
- Surgical and orthodontic tweezers, pliers, and clamps
- Valve seats
- Valve balls and valve stems
- Valve and shaft seals (seal rings)
- Spray nozzles
- Pulverizing hammers
- Compressor plungers
- Bearings
- Cage mills

- Ball mill linings and balls
- Internal parts in industrial meters

The article "Cermets and Cemented Carbides" in *Powder Metal Technologies and Applications*, Volume 7 of the *ASM Handbook* contains more information on applications for cemented carbides.

Selection of Cemented Carbides for Corrosion Applications

The selection of cemented carbides is a very difficult problem for the user. There has been a lack of standardization on the part of the producers, and this lack has not been answered by any national or international standards organization. Some attempts have been made to standardize with regard to metal-cutting applications. There is International Organization for Standardization (ISO) standard 513 for metal-cutting applications for carbide (Ref 13). It is widely used in Europe and most other parts of the industrial world, but it is not recognized in the United States (Ref 11). In addition, there is no ISO standard for cemented carbides used for wear, mining, or corrosion applications, and if any exist in other industrialized countries, the producers choose to ignore them, or they may be so broad that a given producer can have three or more grades falling into one category (Ref 14, 15).

The producers also tend to disregard attempts at standardization in the hope of having a unique product. Even in the established WC-6Co grades, the producers offer several different varieties based on different grain size or different minor element additions. For example, the company that developed the WC-6Co composition about 70 years ago offers five different grades of this composition, and two of them have identical published properties. They are not alone. In some cases, three grades are shown with the same composition and properties. A good example is the nine differently designated 6% Co compositions of one company. Five of the nine are indeed different because of small TaC additions or grain size, but one of the compositions has three designations, and two of them have two designations. More often, the reason for the multiple designations of the same composition is that one designation is for cutting tools, another for wear parts or dies, and another for mining. Another problem area is the selection of composition by the manufacturer. For example, if one producer establishes a WC-25Co composition, another producer will make and market a grade with 24% Co, and another a product with 26% Co. Despite these problems, Table 2 lists the properties of various representative grades for corrosion applications; Table 3 lists approximate compositions and proprietary designations for a number of corrosion-resistant grades.

Table 2 Some physical properties of corrosion-resistant cemented carbide grades

Properties of a carbon steel, a tool steel, and a cast cobalt alloy are included for comparison.

Table 3 includes grades from 16 manufacturers worldwide. These are meant to be representative only in a general sense. There are well over 100 manufacturers throughout the world (over 25 in the United States alone); therefore, it is not feasible to include all. In addition, cross comparisons are not precisely possible. For example, a grade listed with an approximate composition of WC-25Co may be cross referenced with a comparable grade that contains only 24% Co. Reference 15 contains more complete data on any grade, and manufacturers can be consulted for more information.

In addition to small differences in cobalt content from one manufacturer to another, there are small differences in minor additives and in grain size. For example, with the 6% Co grades, there are two basic grain size classes--fine and coarse--but these two are not precisely the same from one manufacturer to another. Some have a slightly finer or coarser size within the defined category of fine and coarse. Again, precise standards are lacking. References 1, 2, and 18 are the attempts at standardization, but they are useful only in a general sense; moreover, no producer ever refers to the specifics of these standards in designating the cemented carbide it produces. Another factor is the intentional addition of minor elements such as tantalum, titanium, vanadium, chromium, and molybdenum as grain growth inhibitors or the inadvertent introduction of minor amounts of these and other elements in the raw materials or through recycling. These elements affect hardness and strength and cannot be discounted in the selection of a cemented carbide for corrosion applications.

Other processing variables also affect properties and performance. Among the important results of processing variables is the amount of porosity in the final cemented carbide product. In some cases, the porosity is negligible, and theoretical density is achieved. In other cases, porosity is present. This can be rated in accordance with ISO 4505 (Ref 19) or ASTM B 276 (Ref 20), both of which are based on the same standard photomicrographs. The ultimate in freedom from porosity is achieved by hot isostatic pressing. This operation, when carried out properly at about 138 MPa (20,000 psi) and at temperatures of 1200 to 1400 °C (2190 to 2550 °F), has no detrimental or beneficial effect on the cemented carbide except for the removal of the last vestiges of porosity. Table 4 shows some typical values of selected mechanical properties of cemented carbide grades that may also be helpful in selecting a proper composition for a particular application.

Corrosion in Aqueous Media

The corrosion of cemented carbides is based on the solubility of the key ingredients used in the various compositions. Although some alloying occurs, the solubility of the WC or TiC in cobalt or nickel is very limited. The main alloying in the WC-Co compositions is primarily based on the addition of TiC, TaC, and NbC, which form cubic-phase solid solutions with WC.

Table 5 shows the relative solubilities of the chief constituents of cemented carbides in various media. Tungsten carbide is insoluble in most acids as well as in basic and salt solutions. It is soluble only in very strong mixtures of nitric acid plus hydrochloric acid (HNO_3 + HCl) and HNO_3 plus hydrofluoric acid (HF). Cobalt and nickel show the same significant solubility in all acids. Even so, the nickel binder compositions show somewhat less attack in some acid solutions than the cobalt binder alloys. From this elementary information, it is obvious that the lower the binder content, the less the corrosion.

Table 5 Relative solubilities in acids and bases of the basic constituents of cemented carbides

Constituent	Medium and solubility[(a)]						
	Dilute HNO_3	**HCl**	**H_2SO_4**	**20HNO_3-60HCl-20H_2O**	**25HNO_3-25HF-50H_2O**	**Alkali solutions**	**Salt solutions**
Cobalt	V	SI	SI	V	V	I	I
Nickel	V	SI	SI	V	V	I	I
WC	I	I	I	S	S	I	I
TaC	I	I	Sl?[(b)]	S	S	I	I
TiC	S	I	I	S	S	I	I

Source: Ref 21, 22

(a) Solubility: V, very soluble; Sl, slightly soluble; I, insoluble; S, soluble.

(b) Data from Ref 21 and Ref 22 are contradictory.

Corrosion of cemented carbides, therefore, is generally based on the surface depletion of the binder phase such that at the surface region only a carbide skeleton remains; because the applications are invariably for wear or abrasion, this skeleton is rapidly worn away. At low binder phase contents, the rate of attack is diminished, and in conditions in which the corrosion is not too severe, the reduced binder content will be beneficial. In more severe corrosion, however, the use of a cobalt binder is prohibited, and the WC-Co grade is simply not resistant enough. In these cases, certain corrosion-resistant grades should be used.

The most common of these are WC with nickel alloy binders and TiC-Ni-Mo_2C-base cemented carbide. Figure 6 shows the corrosion rate as a function of pH for these different types of cemented carbides tested in buffered solutions. These tests included a final surface wear treatment by tumbling in order to obtain a true value of the depth of the corroded surface.

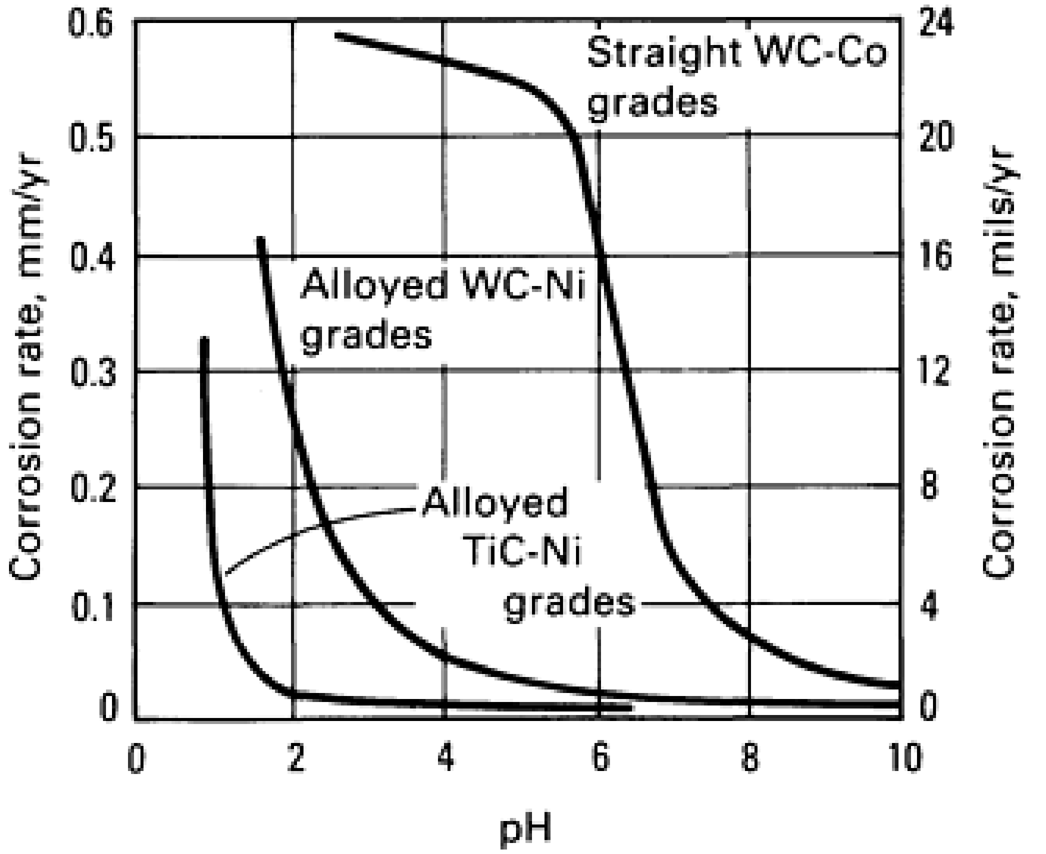

Fig. 6 Corrosion rate of various cemented carbide grades as a function of pH. Source: Ref 23

As can be seen in Fig. 6, straight WC-Co grades are resistant down to pH 7. This is also valid for WC-Co grades containing cubic carbides such as TiC, TaC, and NbC. The highest corrosion resistance is obtained for certain alloyed TiC-Ni grades, which are resistant down to about pH 1, but compared to the straight WC-Co grades, they are less tough and have lower thermal conductivity. They also have the disadvantages of being difficult to grind and braze; therefore, they are used only in specific applications.

In many corrosion-wear situations, the proper choice is specially alloyed WC-Ni grades, which are resistant down to pH 2 to 3. Even in certain solutions with pH values less than 2, they have proved to be resistant to corrosion. Because WC is the hard principal constituent and because nickel and cobalt are similar metals in many respects, their mechanical and thermal properties are comparable to those of the straight WC-Co grades.

The pH value is one of the most important parameters when determining the corrosivity of a medium, but other factors such as temperature and electrical conductivity also have a great influence. The latter is dependent on the ion concentration, that is, the amount of dissolved salts in the solution. Thus, one cannot define the corrosivity of a certain medium in a simple way, and accordingly, no general rules that are valid in all situations can be given. However, Table 6 gives general guidelines for the corrosion resistance of WC-Co and TiC-Ni cemented carbides in various room-temperature media. Table 7 gives compatibility data for several types of cemented carbides in aqueous media at various temperatures, and Table 8 lists weight loss as a function of cobalt content for cemented carbides in mineral acids.

(a) A, highly resistant, negligible attack; B, resistant, light attack; C, poor resistance, medium attack; D, not resistant, not suitable. This table should be used only as a guide. Many factors, such as temperature variations, changes in chemical environment, purity of solutions, and stress or loading conditions, may invalidate these recommendations. Tests under operating conditions should be made.

(b) Results were obtained under laboratory conditions in pure solutions and are classified with reference to corrosion resistance only.

(c) Coupled to brass.

Source: Ref 25

In general, it can be stated that the corrosion of cemented WC is fair to good in a limited way in all acids except HNO_3. The corrosion resistance of cemented TiC is excellent in phosphoric acid (H_3PO_4), boric acid, and picric acid and is somewhat better than cemented WC in HCl or sulfuric acid (H_2SO_4). Cemented TiC is poor in HNO_3. As expected, increasing the cobalt content to increase strength significantly decreases the corrosion resistance (Table 8). The same situation exists in virtually all corrosive environments, and because the same effect is seen for abrasion resistance, it is recommended that the minimum cobalt content be used for all wear and corrosion applications. This means that for a given application the hardest grade that will give adequate strength, impact resistance, and resistance to chipping should be chosen.

Special Corrosion-Resistant Grades. To obtain corrosion resistance above and beyond that available with the regular WC-Co and TiC-Ni grades, the special corrosion-resistant grades are used. These always result in a sacrifice in strength, hardness, and/or abrasion resistance, as shown in Table 2. On the other hand, the corrosion-resistant grades do offer significant benefits in corrosion resistance in many media (Table 7). These grades include the WC + Ni binder, the WC + Co-Cr binder, and the so-called binderless WC, which generally contains about 10% TaC and between 1 and 2% Co. In addition, there are other special grades, such as the 0.1 to 1.0% Pt addition patented as an improvement toward ink corrosion resistance in ballpoint pen balls (Ref 26).

Sintered cemented carbide compositions based on more than 50% Cr_2C_3, for corrosion resistance are also mentioned in patents (Ref 27) and the literature (Ref 3, 4, 5). These are generally not commercially viable and are brittle materials; therefore, they cannot compete with the ceramic materials, such as silicon carbide, silicon nitride, aluminum oxide, boron nitride, and the whisker-reinforced ceramics, which have superb corrosion resistance. Where impact and chipping are not

problems, these ceramic materials are a better choice than the cemented carbides. The cemented carbides have the advantage, however, in strength, impact resistance, thermal conductivity, and often greater ease of manufacture.

The best recent work showing the performance of the special corrosion-resistant compositions compared to the standard compositions and even some experimental compositions is that done at Metallwerk Plansee (Ref 7, 28). Table 9 lists the properties of these grades; for convenience, the proprietary designations are given, and the grades are also noted by composition, such as WC-10Co-4Cr. Grades are also listed by a grade number that can be used when referring to Fig. 7, 8, 9, 10, 11, 12, 13, and 14.

Table 9 Properties of corrosion-resistant cemented carbide grades

See Fig. 7, 8, 9, 10, 11, 12, 13, and 14 for the corrosion resistance of 12 of these grades in various media.

Figure 7 shows the corrosion of the 12 different compositions listed in Table 9 in 22% HCl at room temperature. Grades 1 to 3 (WC-3Co, WC-6Co, and WC-9Co, respectively) illustrate the increase in corrosion rate that results from increasing cobalt binder content. The nickel binders (grades 5 and 6; WC-6Ni and WC-9Ni, respectively) are an improvement, but again, the increase in binder content increases the corrosion rate. Of the more exotic compositions, grades 4 (WC-10Co-4Cr) and 7 (WC-6NiCr) are viable choices for limited use in HCl at room temperature. The best of the experimental compositions is grade 9 (WC-40TaC-3NiCoCr); it has greater strength and higher hardness. If additional strength is needed above grade 9, grade 11 (WC-40TaC-9NiCoCr) is a good choice with the increases binder content, but as is generally the case, this results in a loss of corrosion resistance.

Figure 8 shows the same type of information for 38% HNO_3 at room temperature. In general, corrosion is lower, but again, the higher-cobalt WC-Co compositions (grades 2 and 3) are not suitable, nor is the WC-9Ni composition (grade 6). Grade 5 (WC-6Ni) is marginal in HNO_3, but grades 1 and 4 are still better. On the other hand, the commercially available grades 7 and 8 (WC-6NiCr and WC-9NiCr, respectively) show very limited corrosion attack that is virtually equal to that of three of the four experimental grades; the commercial alloys in this case have better strength.

The basic cemented carbides are attacked most severely by H_2SO_4 (Fig. 9). Some of the WC-Ni or WC-NiCr commercial compositions can tolerate limited use. However, the experimental grade 7 (WC-40TaC-3NiCoCr) provides exceptional corrosion resistance.

Figure 10 shows that many compositions are available for use in acetic acid with little corrosion. Attack in $H_3PO_4$is relatively only on the WC-Co compositions(Fig. 11).

Figures 12 and 13 show the suitability of all of the compositions listed in Table 9 in sodium hydroxide (NaOH) and sodium chloride (NaCl). In NaCl, there is significant benefit in choosing a nickel binder cemented carbide (for example, grade 5, WC-6Ni) if the loss in strength can be tolerated.

Figure 14 shows the resistance to erosion-corrosion of different cemented carbide compositions in a slurry of artificial seawater and sand. It follows the pattern of benefit for the use of nickel binders in saline applications. The best of the WC-Co compositions is obviously the one with the lowest binder content (WC-3Co; grade 1). It shows a rate, however, more than 10 times greater than the experimental grade 9 (WC-40TaC-3NiCoCr), and both have the same transverse

rupture strength and equivalent hardness. For a commercial composition, the grade 9 (WC-9NiCr) cemented carbide shows excellent performance, with one-half the rate of attack of the low-cobalt composition (grade 1, WC-3Co) and much higher transverse rupture strength.

Some of the same data are shown in Fig. 15 and 16 to compare the relative corrosion of the different compositions in various media. These tests were performed at room temperature, and solution concentrations are the same as those in Fig. 7, 8, 9, 10, 11, 12, 13, 14. In Fig. 16, the cemented carbides are also compared to an Fe-20Cr-32Ni alloy; the superiority of the experimental WC-40TaC-3NiCoCr cemented carbide is evident. As with corrosion test data, care must be taken not to extrapolate these to different solution concentrations and temperatures. It would be logical to assume, for example, that the WC-40TaC-3NiCoCr alloy would always outperform WC-3Co in these media at different concentrations and temperatures, but the validity of this assumption must be verified through further testing.

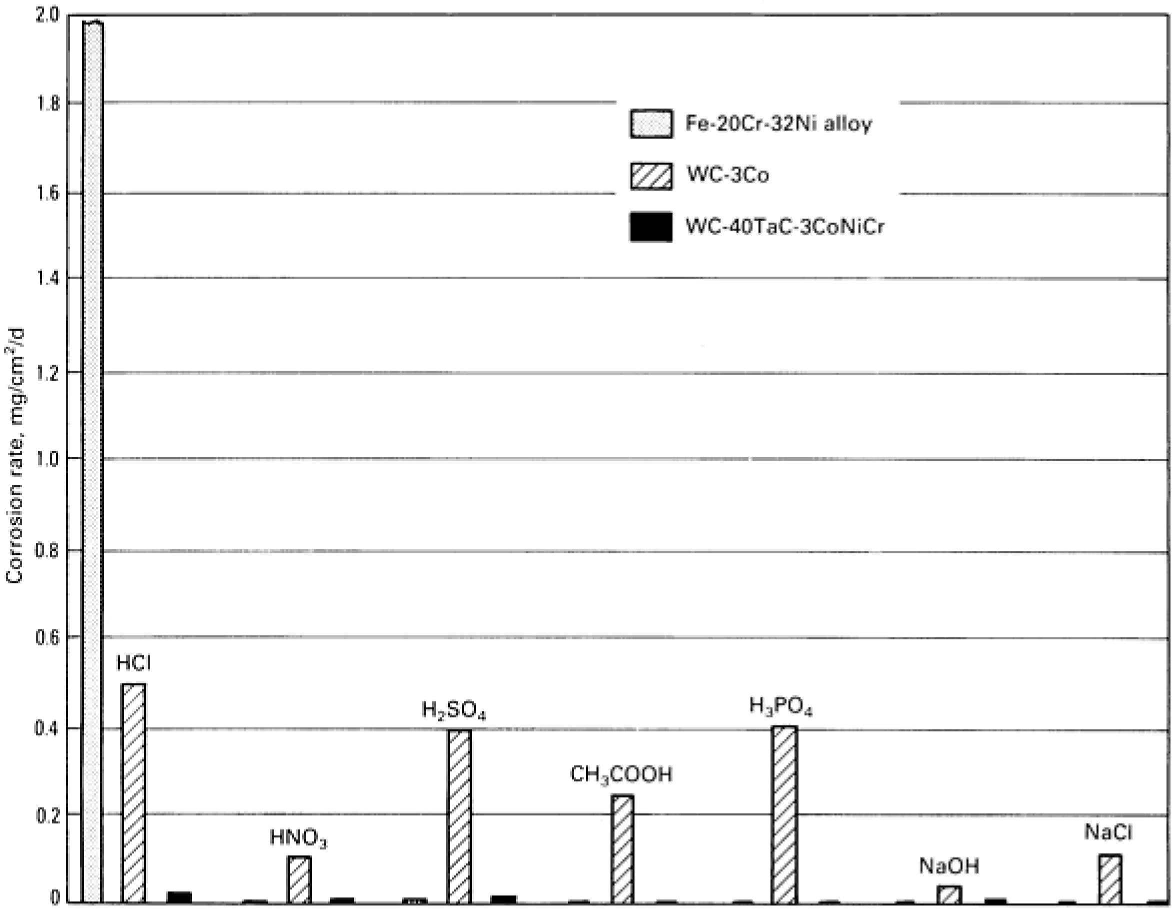

Fig. 16 Comparison of the corrosion resistance of a commercial WC-3Co cemented carbide and two experimental compositions in aqueous media. Source: Ref 28

Corrosion in Warm Acids and Bases. The corrosion rate of various cemented carbide compositions in warm (50 °C, or 120 °F) acids is shown in Table 10. The straight WC-Co compositions show rapid attack in dilute $H_2SO_4$and HNO_3, and little attack in those concentrated acids. Although the corrosion rate is lower in HCl, it is obvious that these compositions are not suitable for use in warm or hot acid solutions. The TiC-6.5Ni-5Mo composition is quite good in H_2SO_4, moderately good in HCl, and very poor in HNO_3. Several of the binderless compositions and the TaC-base cemented carbide show very acceptable corrosion resistance in these warm acids. These results are to be expected, because the cobalt and nickel binders are completely soluble in these acids.

Source: Ref 29

The corrosion rates of various cemented carbides in basic solutions at 50 °C (120 °F) is quite a different matter, as shown in Table 11. Although corrosion does proceed, it is slow enough to demonstrate the utility of even the WC-Co compositions in such applications as seal rings in these basic solutions.

Galvanic Corrosion. The resistance to galvanic corrosion of various cemented carbides coupled to AISI type 316 stainless steel has been investigated (Ref 30). Immersion testing of uncoupled specimens was also performed for comparison. Compositions of the materials tested are given in Table 12.

Table 12 Compositions and properties of galvanic corrosion test specimens

Specimen	Composition, wt%	Hardness, HRA	Transverse rupture strength	
			MPa	**ksi**
WC-6Co	WC-6Co	91.0	2400	348
WC-3TiC-2TaC alloy	WC-3TiC-2TaC	92.9	1200	174
TiC-base cermet	TiC-10TiN-2.5Mo_2C-15Ni	91.5	1500	218
Sintered cobalt-base alloy	Co-Cr-W-C	85.5	1400	203
WC-NiCrMo alloy	WC-3TiC-1.5($Cr_3C_2Mo_2C$)-15Ni	89.0	2100	305

Source: Ref 30

The apparatus used for the galvanic-corrosion testing is shown in Fig. 17. Figure 18 shows the corrosion rates of the materials in the immersion test. The binderless WC-3TiC-2TaC alloy performed the best, followed by the TiC-base cermet, the WC-Ni-CrMo alloy, the sintered cobalt-base alloy, and the WC-6Co alloy. The logarithm of weight loss plotted against the logarithm of time yielded the linear weight loss curves in this test. Based on this, it was postulated that the movement of electrons between cemented carbide and stainless steel is the rate-determining factor in galvanic corrosion. Table 13 compares the corrosion rates of the materials in the immersion and galvanic tests. For most of the alloy tested, the rate of galvanic corrosion is greater than the corrosion rate in the simple immersion test. It is thought that the larger the potential difference between the cemented carbide and the stainless steel, the greater the difference between the corrosion rates obtained in the immersion test and in the galvanic-corrosion test.

Table 13 Corrosion rates of immersion and galvanic corrosion test specimens

Specimen	Weight loss, $g/m^2/d$	
	Immersion test	**Galvanic test**
WC-6Co alloy	4.2	16.67

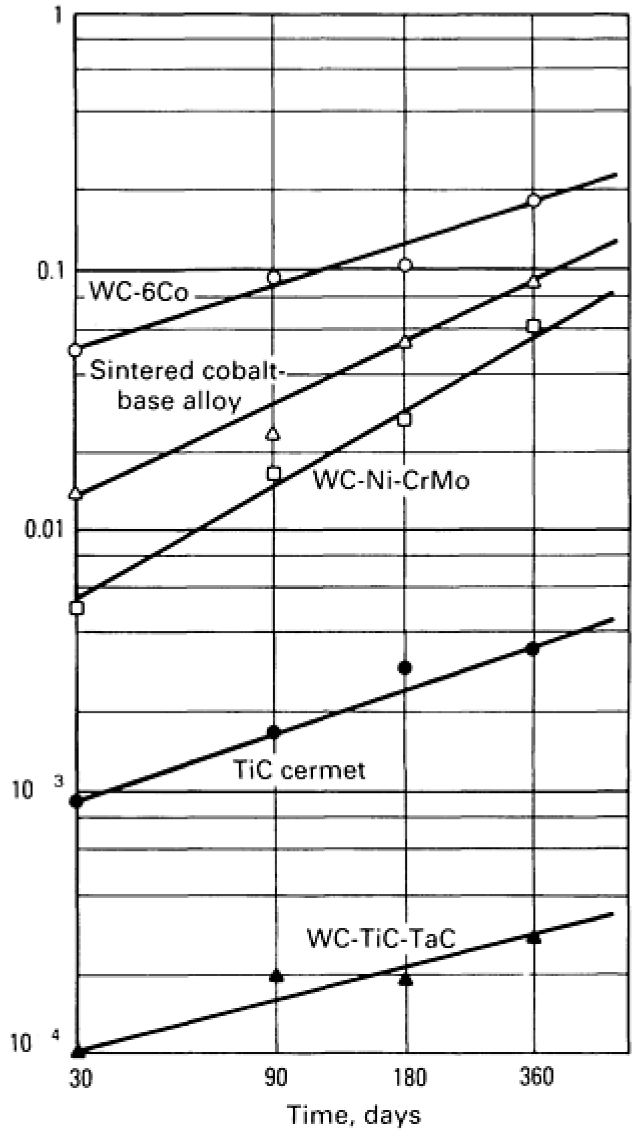

Fig. 18 Corrosion weight loss as a function of time for uncoupled test specimens from Ref 30

Figure 19 shows cross sections of specimen rings after the galvanic corrosion test. Corrosion proceeded inward from the surface that contacted the seawater in the WC-6Co alloy (Fig. 19a). The investigators postulated that the electrode potential is large and that electrons would move smoothly between the cemented carbide and the contacting stainless steel; therefore, attack proceeded according to the galvanic-corrosion mechanism. In the case of the binderless WC-3TiC-2TaC alloy (Fig. 19b), corrosion is very slight even after 1 year. The TiC-base cermet (Fig. 19c) shows corrosion only on the inner side surface (the side contacting the teflon; see Fig. 17). In the sintered cobalt-base alloy and the WC-Ni-CrMo alloy (Fig. 19c and d), corrosion proceeded from the corner that contacted both the seawater and the stainless steel. It was postulated that the electrode potential and the distance of electron movement were smaller than those for the WC-6Co alloy. Based on the results of these tests, either the binderless alloy or the TiC-base alloy should be acceptable for this type of application.

Crevice Corrosion. The same investigators also reported on the crevice-corrosion resistance of cemented carbides in seawater with specimens of type 316 stainless steel, teflon, and silicon carbide adjacent to the cemented carbide specimens (Ref 30). Of the five compositions tested, only the WC-6Co specimen showed any significant attack after 1 year. The attack was moderate and progressed the least against the silicon carbide and the most against the stainless steel (Ref 30).

Oxidation Resistance of Cemented Carbides

The ordinary WC-Co cemented carbides are reasonably resistant to oxidation in air up to about 650 to 700 °C (1200 to 1290 °F). The constituent affected the faster is WC, which will oxidize to WO_3. In oxygen, the temperature limit is lower, and rapid deterioration will occur at about 500 °C (930 °F). Even in air, however, the practical temperature limit for WC-Co compositions for any length of time is 500 to 600 °C (930 to 1110 °F). Nonetheless, these compositions do stand up, for example, in cutting tools in which localized higher temperatures at the cutting tip will be encountered. The addition of both or either TiC or TaC to the WC-Co compositions increases the oxidation resistance somewhat and is undoubtedly also related to the improvement found for these additions for machining steel. In applications in which oxidation resistance combined with wear resistance is required, as in hot glass forming and shearing tools, the addition of TiC and/or TaC to the basic WC-Co is of little benefit. The TiC-Mo_2C-Ni compositions have clearly superior oxidation resistance and can be used at temperatures up to 900 °C (1650 °F), at which point they start to oxidize fairly rapidly. At the lower temperature, the TiC-base compositions form a tight adherent oxide film that tends to resist rapid attack. This behavior difference is analogous to the behavior difference between cobalt and nickel alone, but WC is also more readily oxidized that TiC.

Saw Tips and Corrosion

Cemented carbides are in widespread use in slitter saws, which are used to saw all types of metals, composites, lumber, and many other materials. Small saw blades are sometimes manufactured from a single piece of carbide; larger blades, which may run up to 2 m (6 ft) in diameter, more commonly use cemented carbide tips brazed onto the steel saw body. The heavy-duty chain saws used in the lumber industry also have carbide teeth. Selection of cemented carbides for these

applications is invariably based on the need for excellent wear resistance and toughness. Basic WC-Co compositions are almost always used.

The rapid dulling of saws in such applications, however, is attributable to corrosive as well as abrasive conditions. For example, on investigation studied the corrosion of WC cutting tools used to cut western red cedar (Ref 31). Tests were performed to determine the relative rates of attack of WC and cobalt in substance extracted from western red cedar, which has a higher content of such substances than other commercial lumber species. Because the WC was not attacked, it was concluded that the cobalt binder content should be reduced to minimize attack. Alternatively, the cobalt binder could be replaced with another binder material, such as nickel; however, such a substitution would result in a serious loss of strength. Thus, the solution to this particular problem is not a simple one, and western red cedar is still being sawed primarily with WC-Co cemented carbide compositions.

It was also suggested that the carbide be coated with TiC, TiN, or Al_2O_3 (or a combination of these). To date, these coatings are not used in such applications because of the need for resharpening and because of the difficulties of brazing a coated tip.

Coating of Cemented Carbides

This widely used process has been primarily applied to metal cutting tools. Certain special applications can be cited, such as the coating of cemented WC watch cases with TiN to form a hard, corrosion-resistant gold-colored watch case (bezel). Clearly, the potential exists to utilize these thin (2 to 10 μm, or 0.08 to 0.4 mil) coatings on wear- and corrosion-resistant parts. The limitation is that the coating must be very thin to avoid spalling or chipping. In addition, because the use of a cemented carbide in a corrosion application will only be in a very high-integrity, relatively costly application, the potential danger of a coating failing or being locally breached rules out consideration in most applications. Despite this, coating of cemented carbides is an important state of the art that must be considered in special applications.

Coating is most commonly done by chemical vapor deposition (CVD), and this process gives a wide range of possible coating materials. In addition to the common TiN, TiC, Al_2O_3, perfectly feasible coating materials include hafnium carbide (HfC), hafnium nitride (HfN), zirconium carbide (ZrC), zirconium nitride (ZrN), TaC, and NbC. The state of the art includes all combinations of TiC, TiN, Al_2O_3, and titanium carbonitride (TiCN), with limited commercial use of HfN and TaC as coating materials. Chemical vapor deposition is generally performed at 900 to 1100 °C (1650 to 2010 °F). Titanium nitride is coated at lower temperatures, down to perhaps 700 °C (1290 °F), in less used commercial apparatus.

Physical vapor deposition (PVD) has the advantage of being done at lower temperatures, down to perhaps 500 °C (930 °F), but it is a line-of-sight process that generally requires rotation of the parts being coated. Deposition rates for PVD are much lower than those of CVD, and PVD equipment is more expensive. Physical vapor deposited coatings have also been limited commercially to TiN, usually at thicknesses of 3 μm (0.12 mil) or less. More information on the corrosion and wear resistance of coatings applied by these methods is available in the article "CVD/PVD Coatings" in this Volume.

Although there are few applications in which cemented carbides are used solely for corrosion resistance, it is essential to recognize the availability of the coated carbides. Coatings of TiN, TiC, or Al_2O_3 can impart important corrosion and oxidation resistance to cemented carbides.

Special Surface Treatments

Considerable work has been done to enhance the surface properties of cemented carbides (Ref 32, 33, 34), but it generally has been derived from surface modification processes developed for other metals. These surface treatments include boriding, nitriding, and ion implantation. Most of the treatments have been used to enhance resistance to wear, abrasion, or erosion. The benefits, if any, of such treatments in increasing resistance to oxidation and corrosion are not yet well documented. Nevertheless, these processes may have potential in special applications. The article "Surface Modification" in this Volume contains information on the ion implantation and laser surface modification processes and their effects on the surface properties of metals.

Corrosion of Metal Matrix Composites

Denise M. Aylor, David Taylor Naval Ship Research and Development Center

Introduction

METAL MATRIX COMPOSITE (MMC) materials have developed substantially over the past 20 years. Developmental efforts have involved aluminum-, copper-, magnesium-, titanium-, and lead-base MMCs, but the primary emphasis has been on aluminum-base materials. Interest in the use of these composites is due to the higher attainable strength and stiffness properties as compared to materials prepared by conventional alloying. However, successful application of MMCs in the marine environment requires adequate corrosion resistance.

This article will discuss the ambient-temperature corrosion characteristics of MMCs that have potential application in marine environments, with primary emphasis on aluminum-base composites. Structural characteristics, design criteria, and coatings for optimum protection of MMCs will also be discussed. More information on various types of MMCs is available in Volume 1 of the 1st Edition of the *Engineered Materials Handbook.*

Structural Characteristics

Metal matrix composites basically consist of a nonmetallic reinforcement incorporated into a metallic matrix. Reinforcements, characterized as either continuous or discontinuous fibers, typically constitute 20 vol% or more of the composite. Reinforcements in continuous-fiber composites include graphite (Gr), silicon carbide (SiC), boron (B), or aluminum oxide (Al_2O_3). Fabrication techniques for these composites vary from chemical vapor deposition (CVD) coating of the fibers, liquid-metal infiltration, and diffusion bonding to liquid-metal infiltration and direct casting to near-net shape. Discontinuous-fiber composites consist almost exclusively of SiC in whisker (w) or particulate (p) form. These MMCs are produced by using modified powder metallurgy techniques (Ref 1). Figure 1 shows cross sections of typical continuous and discontinuous reinforced MMCs.

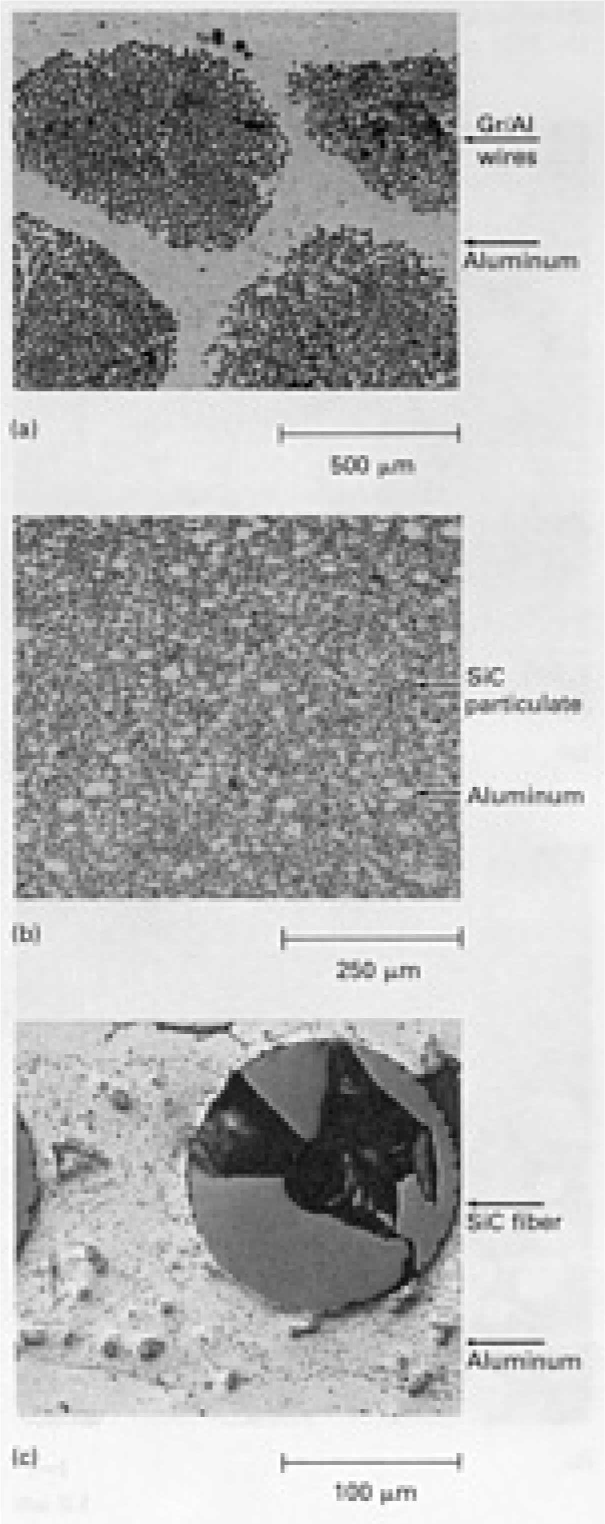

Fig. 1 Cross sections of typical fiber-reinforced MMCs. (a) Continuous-fiber reinforced graphite/aluminum composite. (b) Discontinuous silicon carbide(p)/aluminum composite. (c) Continuous-fiber silicon carbide/aluminum composite

Corrosion Behavior of Aluminum-Base MMCs

Graphite/aluminum composites exhibit accelerated corrosion in marine environments when graphite fibers and aluminum are simultaneously exposed. Assuming that the edges of the graphite/aluminum composite are masked off to prevent exposure of both the graphite and the aluminum, only the aluminum surface foils will initially be exposed to the environment. The aluminum surface foils will pit at an average rate of 0.025 to 0.035 mm/yr (1.0 to 1.4 mils/yr) in seawater and at 0.5 to 0.76 μm/yr (0.02 to 0.03 mils/yr) in the marine atmosphere (1100, 6061, and 5000 series aluminum

alloys). Pits may also be present with depths much greater than the average rates reported (Ref 2). Crevice corrosion of the aluminum foils may also occur at the edges because of the crevice formed between the aluminum surface foil and the masking material.

The pitting and crevice corrosion processes eventually penetrate the foils and result in exposure of the graphite/aluminum composite matrix below, at which point the corrosion rate becomes extremely accelerated. Corrosion has been shown to proceed preferentially along foil/foil, wire/wire, and wire/foil interfaces in the composite (Ref 3). Severe exfoliation occurs because of wedging of the hydrated alumina ($Al_2(OH)_3$) corrosion products within the composite. Figure 2 shows an example of severe graphite/aluminum corrosion (known as catastrophic failure). This catastrophic condition can occur within 30 days in seawater after exposure of the graphite-aluminum matrix. Catastrophic failure in the marine atmosphere and in splash/spray environments is less rapid than in seawater, but can occur within 6 months (Ref 4). This accelerated corrosion is believed to result from the aluminum carbides that are formed at the reinforcement/matrix interface during fabrication, which alter the properties of the aluminum surface film at these locations and render the composite more susceptible to breakdown (Ref 3, 5).

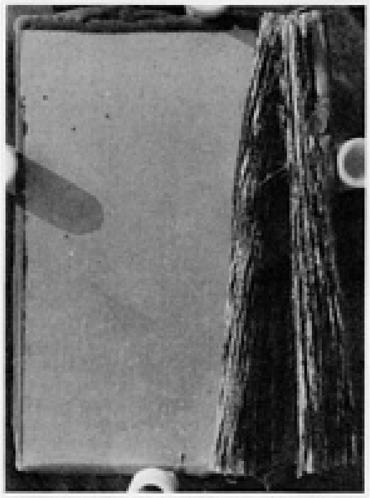

Fig. 2 Catastrophic failure of a graphite/aluminum MMC after 6 months in a marine atmosphere

The aluminum surface foils alone provide reasonably good corrosion protection to the composites. Marine exposure tests of graphite/aluminum MMCs with 6061, 5056, and 1100 aluminum alloy surface foils (graphite/aluminum edges masked) revealed no pitting penetration through the foils to expose the graphite/aluminum composite wires below during a 20-month exposure (Ref 4). Pitting of the foils, which occurred on most of the graphite/aluminum panels, ranked as light pitting in the splash/spray zone and marine atmosphere and as localized pitting in filtered seawater.

In summary, graphite/aluminum composites undergo extremely severe corrosion in marine environments when the graphite and the aluminum are mutually exposed. Aluminum surface foils have provided 20 months of protection to MMCs, assuming there is no graphite-aluminum exposure. However, the composite will start to fail upon foil penetration by the deepest pit. Service life can be extended by applying corrosion-resistant coatings. Primary emphasis should be placed on preventing exposure of both the graphite and the aluminum, and the graphite/ aluminum composite should be frequently inspected while the component is in service.

Silicon Carbide/Aluminum Composites. Marine corrosion of silicon carbide/aluminum composites is much less severe than that observed on graphite/aluminum MMCs. Discontinuous silicon carbide/aluminum MMCs, however, are susceptible to localized corrosion. Mild-to-moderate pitting has been reported on SiC whisker- and particulate-reinforced composites containing 6061 and 5000 series aluminum matrices exposed for a maximum of 42 months in splash/spray and marine atmospheric environments. The degree of corrosion present on the composites is slightly accelerated compared to that on unreinforced aluminum alloys.

Silicon carbide/aluminum composites immersed in natural seawater are susceptible to significantly more severe corrosion than is typical for silicon carbide/aluminum MMCs in the aforementioned environments (splash/spray and atmosphere). Silicon carbide/aluminum panels in seawater undergo pitting, both localized at the edges and distributed uniformly across

the surface. The extent of pitting varies from minimal attack through 33 months of exposure to extensive corrosion that is equivalent to a rate as high as 0.25 mm/yr (9.8 mils/yr).

Corrosion rates for silicon carbide/aluminum MMCs in seawater are also generally higher than is typical for unreinforced aluminum alloys. This was documented in Ref 4 for discontinuous SiC in 6061 and 5000 series aluminum matrices and in Ref 6, which reports than silicon carbide/2024 aluminum corroded approximately 40% faster than 2024 aluminum in sodium chloride (NaCl) solution. Contrary to these findings, in another study, little difference in weight loss measurements was noted between silicon carbide/6061 aluminum and 6061 aluminum in NaCl (Ref 7).

Discontinuous silicon carbide/aluminum MMCs are believed to corrode at the silicon carbide/aluminum interfaces (Ref 4, 6, 7). Concentration of the corrosion at these interfaces is presumably due to the crevices formed there, which are preferential sites for pitting. Evidence of the pitting concentrated at the silicon carbide/aluminum interfaces in both whisker and particulate composites is shown in Fig. 3.

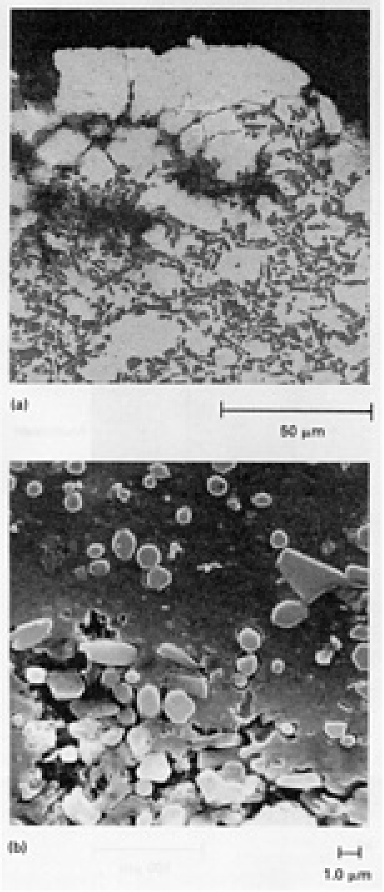

Fig. 3 Cross sections of discontinuous silicon carbide/aluminum MMC panels. (a) Silicon carbide(p)/6061 aluminum MMC after a 230-day, tidal-immersion exposure. (b) Silicon carbide(w)/6061 aluminum MMC after a 60-day filtered-seawater exposure

Electrochemical studies of discontinuous silicon carbide/aluminum MMCs containing 6061 and 5000 series aluminum alloy matrices demonstrated that the presence of the SiC does not increase the susceptibility of the composite to pit initiation (Ref 5, 8). Research on silicon carbide/2024 aluminum did show a more electropositive pitting potential for the composite relative to the 2024 aluminum (Ref 8); however, this difference in pitting potential may be due to difference in microstructure between the composite matrix and the 2024 aluminum (Ref 1).

Continuous-fiber silicon carbide/aluminum composites also undergo localized corrosion (Ref 4). These composites are susceptible to both crevice corrosion and pitting. Seawater entry into the silicon carbide/aluminum composite matrix will result in crevice corrosion at the fiber/matrix interfaces, which accelerates the corrosion rate and eventually results in delamination of the aluminum surface foils. However, the rate of silicon carbide/aluminum corrosion is much less severe

than is typical for graphite/aluminum. Figure 4 contrasts the extent of corrosion evident on the silicon carbide/aluminum panels described above.

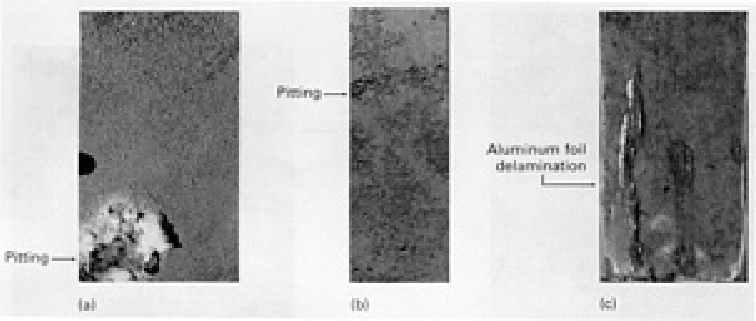

Fig. 4 Silicon carbide/aluminum, MMC panels after exposure to filtered seawater. (a) Silicon carbide(w)/6061 aluminum after a 4-month exposure. (b) Silicon carbide(p)/6061 aluminum after a 24-month exposure. (c) Silicon carbide (continuous fiber)/6061 aluminum after a 33-month exposure

In summary, silicon carbide/aluminum MMCs are susceptible to localized corrosion in marine environments. Generally, the susceptibility to pit initiation is similar for composites and unreinforced alloys; however, the rate of pit propagation is higher for composites. Silicon carbide/aluminum corrosion in seawater is increasingly more severe that in the other marine environments. Corrosion-resistant coatings are recommended for these composites to enhance their service lives.

Boron/Aluminum Composites. The corrosion properties of boron/aluminum composites are extensively reviewed in Ref 1. This section will summarize the significant findings.

Boron/aluminum MMCs experience severe corrosion in chloride environments and are significantly less corrosion resistant than unreinforced aluminum alloys. The concentration of corrosion in these composites has been found at fiber/matrix interfaces and at the bonds between foils (Ref 9, 10). The accelerated corrosion at these sites has been attributed to imperfect bonding and fissures in the composite and emphasizes the need for eliminating fabrication flaws to reduce corrosion of boron/aluminum MMCs in chloride environments (Ref 9). Corrosion at the fiber/matrix interfaces has also been attributed to the presence of aluminum boride formed during fabrication (Ref 10).

Aluminum Oxide/Aluminum Composites. The Corrosion properties of aluminum oxide/aluminum composites are reviewed in Ref 1. The significant findings are summarized below.

To obtain good wettability and bonding in aluminum oxide/aluminum MMCs, the aluminum matrix is alloyed to form a bonding compound between the fiber and the matrix. Corrosion studies of Al_2O_3/Al-2Li MMCs (containing a Li_2O-$5Al_2O_3$ bond layer) in NaCl solutions indicated no severe attack at the fiber/matrix interfaces. The corrosion rate of the MMCs (based on weight loss measurements) was only slightly higher than for aluminum alloy 6061-T6 (Ref 11).

Corrosion evaluations of Al_2O_3/Al-2Mg MMCs identified pitting at the fiber/matrix interfaces, presumably due to the Mg_5Al_8 precipitated there during fabrication (Ref 12). Research on aluminum oxide/6061 aluminum MMCs also reported preferential corrosion at the fiber/matrix interface (Ref 1). These findings suggest that the corrosion resistance of aluminum oxide/aluminum composites is highly dependent on the bonding compound formed at the fiber/matrix interface. To date, no severe corrosion problems have been identified with Al_2O_3/Al-Li composite.

The stress-corrosion cracking (SCC) properties of graphite/aluminum MMCs are discussed in Ref 13 and 14. Based on evaluation of a limited number of specimens, an initial stress-dependent corrosion mechanism was reported for graphite/aluminum, aluminum, which then shifted to a corrosion-dominated failure as the exposure in seawater increased (>100 h) (Ref 13). In another study, a corrosion-dominated mechanism was also noted at longer exposure times, but it was suggested that the failures were creep related as well (Ref 14).

Stress-corrosion cracking testing of boron/aluminum MMCs at lower stress intensities (<80% of overload fracture toughness) identified no failures within the 1000-h test limit (Ref 14). Delayed-time failures were reported at high stress

intensities for boron/aluminum MMCs evaluated in air and seawater. It was suggested that the failures resulted from room-temperature creep.

Corrosion Fatigue. The seawater and air fatigue properties of graphite/6061 aluminum MMCs are superior to those of aluminum alloy 6061-T6; however, composites and unreinforced aluminum alloys both exhibit a degradation in seawater fatigue properties as compared to the corresponding air fatigue properties (Ref 13). Discontinuous silicon carbide/6061 aluminum MMCs also retain improved fatigue properties over unreinforced aluminum alloy 6061 in chloride environments (Fig. 5) (Ref 15). It has been suggested that the improved corrosion fatigue properties of silicon carbide/aluminum MMCs are due to an increased resistance to crack initiation (Ref 16).

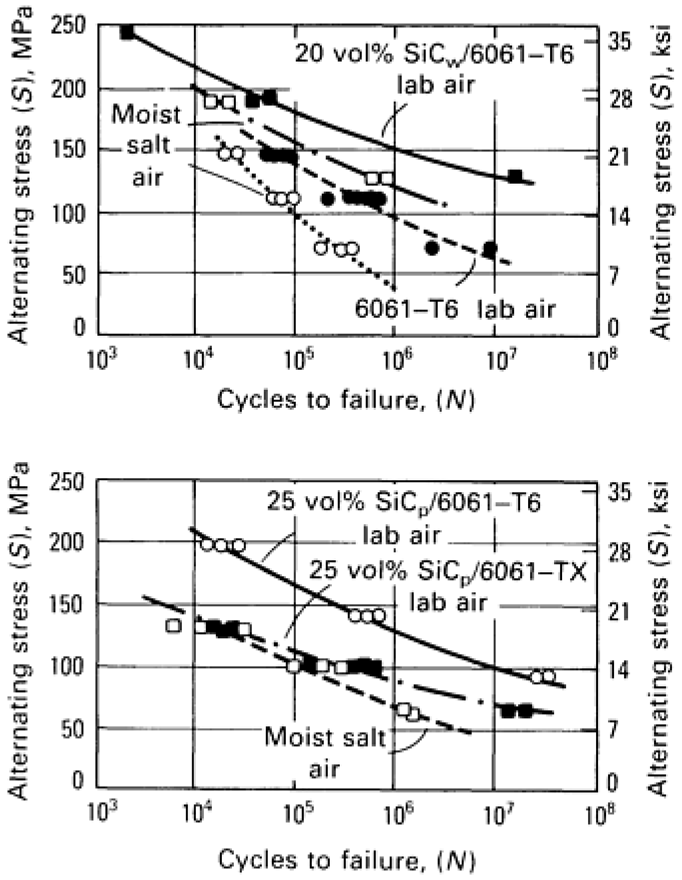

Fig. 5 Corrosion fatigue of discontinuous silicon carbide/aluminum in moist salt air. Source: Ref 15

Corrosion Behavior of Copper-Base MMCs

To date, very limited corrosion research has been conducted on copper-base MMCs. These composites offer substantial in marine applications because of their antifouling characteristics as well as their potentially higher strength and stiffness and lower density than that attainable in conventional copper alloys.

A corrosion evaluation of copper-base MMCs was recently completed by the author. The composites evaluated were some of the first copper MMCs ever produced and were not optimized materials. Many of them contained porosity, inconsistent sizes of reinforcement, and an uneven reinforcement distribution. The specific composites evaluated included continuous-fiber graphite/copper, silicon carbide/copper-tin, and silicon carbide/copper-titanium as well as discontinuous titanium carbide(p)/copper, titanium carbide(p)/copper-aluminum, silicon nitride(w)/copper, boron carbide(w)/copper, silicon carbide(w)/copper, and aluminum oxide (chopped fiber)/copper-titanium.

Overall, copper MMCs displayed minimal evidence of corrosive attack. Filtered-seawater specimens developed a green corrosion product film on their surfaces, which presumably was copper hydroxide chloride ($Cu_2(OH)_3Cl$) (Ref 17). Localized corrosion was commonly present on edges, surfaces, and adjacent to crevice sites. Localized corrosion outside the crevice area is typical for copper alloys (Ref 2). The localized corrosion present on the surfaces and edges was

possibly due to porosity in the as-fabricated composites, which provide continuing corrosion paths during seawater exposure. Figure 6 shows the typical corrosion found on copper-base MMCs and controls in filtered seawater.

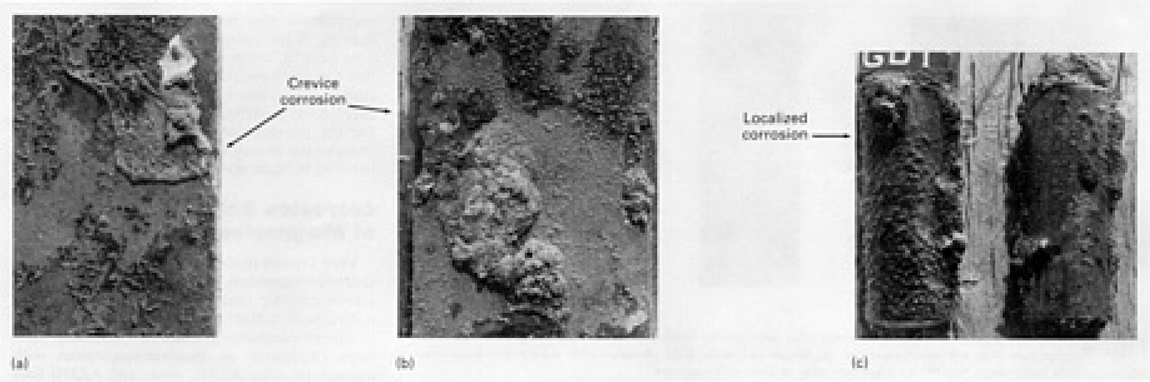

Fig. 6 Copper-base MMC and control specimens after exposure to filtered seawater. (a) Unreinforced 99.95% Cu after a 24-month exposure. (b) Titanium carbide(p)/copper MMC after a 21-month exposure. (c) Silicon nitride(w)/copper MMC after a 21-month exposure

In the marine, atmosphere, copper-base MMCs developed a thin, green corrosion product film on their surfaces. This film was much thinner than the film formed in seawater, and in developed more slowly. Graphite/copper MMCs showed evidence of surface foil blistering within 4 months of exposure in this environment; however, this degradation may have been due to imperfect bonding of the composite.

In general, copper-base MMCs display a marine corrosion resistance that is similar to that of copper alloys. Porosity in some of the composites could have contributed to increased corrosion. Further developmental efforts are required to improve the overall structure and the fiber-matrix bonding in these materials.

Corrosion Behavior of Magnesium-Base MMCs

Very limited research has been conducted on graphite/magnesium composites because of the known extreme reactivity of magnesium; graphite/magnesium MMCs are susceptible to extremely severe corrosion in chloride-containing solutions. Research on graphite/magnesium with magnesium alloy AZ91C wires and AZ31B foils identified severe corrosion after only 5 days of immersion (Ref 18). Corrosion was especially severe in areas where both the graphite fibers and the magnesium matrix were exposed; this can be attributed to galvanic-corrosion processes.

As the volume percentage of graphite is increased, the MMC corrosion rate also increases. The corrosion rate of composites containing only 10 vol% graphite (1.8 mg/cm^2 day, or 4×10^{-4} oz/in.^{2} day) is still unacceptable for component applications. Therefore, to use graphite/magnesium MMCs effectively in chloride environments, graphite fiber exposure to the environment must be eliminated and the corrosion resistance of the magnesium matrix improved. Use of low impurity magnesium alloys, and a fiber surface treatment have been suggested to improve corrosion resistance (Ref 19).

Coatings for Corrosion Control

The coatings recommended in this section are applicable to aluminum-base MMCs. To date, no research has been published on protective coatings for copper magnesium-base MMCs. Figures 7 and 8 show photographs illustrating the corrosion evident on select coated continuous-and discontinuous-fiber MMCs.

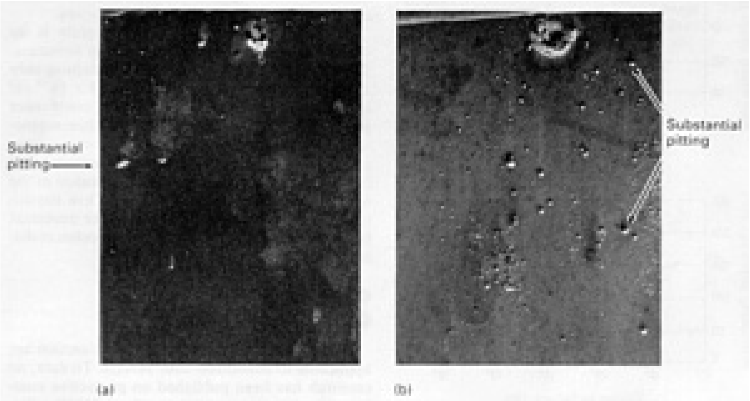

Fig. 7 Coated continuous-fiber graphite/aluminum MMCs after 1 month in filtered seawater. (a) Chromate/phosphate conversion coating. (b) Electrodeposited aluminum/manganese coating

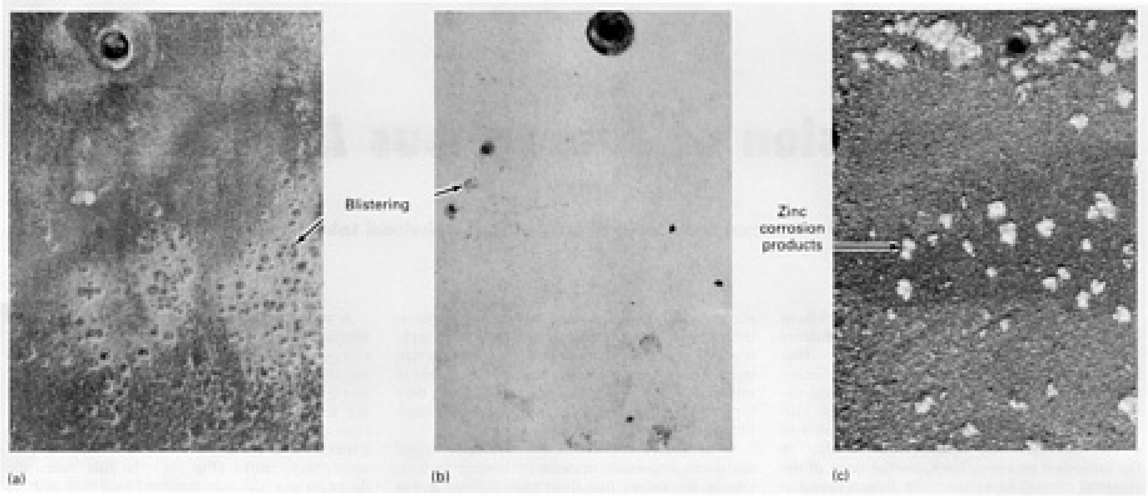

Fig. 8 Coated discontinuous silicon carbide(p)/aluminum MMCs after seawater exposure. (a) Coated with ion vapor deposited aluminum; 4-month exposure. (b) Coated with plasma-sprayed aluminum oxide; 18-month exposure. (c) Coated with arc-sprayed zinc; 9-month exposure

Continuous-Fiber Composites. Various coatings have been evaluated for protecting continuous-fiber graphite/aluminum (Ref 4, 20). Organic coatings have been identified as providing excellent corrosion protection for graphite/aluminum MMCs. In service, composites protected with an organic coatings must be frequently inspected because this coating provides only barrier protection and any coating holiday are potential sites for corrosion attack of the composite.

Noble metal coatings, such as nickel and titanium, applied by CVD, physical vapor deposition (PVD), and electroplating methods also provide barrier protection; however, graphite/aluminum corrosion at coating flaw sites is much worse for these coatings than for an organic coating. This is due to the highly unfavorable anodic (aluminum): cathodic (noble coating) area ratio formed at a flaw site. Consequently, noble metal coatings are not recommended for protecting aluminum-base MMCs.

Sulfuric acid (H_2SO_4) anodizing offers good marine corrosion protection for graphite/aluminum MMCs. Earlier studies in filtered seawater have shown that the anodized layer thins as a function of exposure time (Ref 21). However, current results indicate that anodizing has provided at least 28 months of protection for graphite/aluminum MMCs. Chromate/phosphate conversion and electrodeposited aluminum/manganese coatings on graphite/aluminum are less corrosion resistant than H_2SO_4 anodizing. Graphite/aluminum MMCs with these coatings are susceptible to substantial pitting and/or blistering within the first 3 months of marine exposure.

Aluminum are spray coatings exhibit excellent corrosion resistance in marine environments, but are not recommended for use on conventional graphite/aluminum MMCs. The reduced thickness of the surface foils on these composites (0.13 to 0.18 mm, or 5 to 7 mils) prohibits grit blast surface preparation without the occurrence of severe warpage. Thermal spraying can be used for protecting graphite/aluminum only if the surface foils are thick enough ($\geq$0.51 mm, or 20 mils) to prevent warpage.

In summary, sulfuric acid anodizing (0.025 mm, or 1 mil, thick), organic coatings, (0.13 mm, or 5 mils, thick), or preferably a combination of both are recommended for corrosion protection of continuous-fiber graphite/aluminum MMCs. These coatings will provide a minimum of 28 to 33 months of protection in the marine environment, assuming there are no substantial coating defects to expose the graphite/aluminum MMC. These coatings should also provide a similar degree of protection for continuous-fiber silicon carbide/aluminum, boron/aluminum, and aluminum oxide/aluminum MMCs.

Discontinuous-Fiber Composites. Both metallic and ceramic coatings have been investigated for protecting discontinuous silicon carbide/aluminum MMCs (Ref 4). Aluminum flame- and arc-sprayed coatings exhibit excellent corrosion resistance for a minimum of 33 months. Zinc arc-sprayed coatings are less corrosion resistant than aluminum thermal-sprayed coatings. Zinc coatings protect the silicon carbide/aluminum substrate by zinc dissolution. Although zinc coatings can provide more effective cathodic protection than aluminum, their mechanism of protection restricts their useful life. Zinc-coated composites immersed in seawater have exhibited pitting of the silicon carbide/aluminum substrate between 4 and 9 months of exposure, indicating a loss of protection by the zinc coating.

Aluminum oxide plasma-sprayed coatings applied to silicon carbide/aluminum MMCs exhibited varied results in the marine environment. The performance variations were attributable to differences in the quality of coating application rather than to poor corrosion resistance of the coating. Aluminum oxide coating performance ranged from excellent after 33 months of exposure to coating blistering that was extensive enough to expose the substrate after 4 months.

Aluminum oxide coatings will provide only barrier protection to the silicon carbide/aluminum composites. Aluminum thermal-sprayed coatings, on the other hand, do have some sacrificial-protection capabilities. The aluminum coatings will protect exposed silicon carbide/aluminum areas to a greater extent than a barrier coating.

Ion vapor deposited aluminum provides good corrosion protection to silicon carbide/aluminum MMCs in the marine atmosphere. This same coating tends to blister within 1 month of exposure in filtered seawater. The blistering is assumed to occur at silicon carbide particle sites because these particles project from the surface and interfere with a uniform surface for coating.

Aluminum, applied by flame or arc spraying, is recommended for protection of silicon carbide/aluminum MMCs in the marine environment. A coating thickness of 0.13 to 0.20 mm (5 to 8 mils) is optimum. Organic topcoats may also be applied for added protection. Proper thermal-spray and organic-coating surface preparation and application procedures must be followed to avoid premature failure in service.

Design for Corrosion Prevention

For long-term use of MMC components in service, effective coating protection must be employed. Consequently, MMC design should take into consideration the ease of initial coating application as well as coating maintenance (Ref 22). A simple component design is optimum for ensuring effective coating application; the more complicated the design, the more difficult it is to obtain an adherent, uniform coating. Areas that are difficult to coat, such as sharp edges and corners, overlaps, rivets, fasteners, and welds, should be eliminated as much as possible during design. Also, recesses or low spots should be avoided, because these areas will collect water and lessen the corrosion resistance of the coating. For maintenance considerations, it is imperative that all areas to be coated be readily accessible.

Corrosion of Amorphous Metals

N. Robert Sorensen and Ronald B. Diegle, Sandia National Laboratories

Introduction

AMORPHOUS, or glassy, metal systems have been extensively studied since their introduction for their unique structural, mechanical, electronic, magnetic, and corrosion properties. Glassy metals have seen practical applications that exploit many of these properties, but they are also interesting as a tool for probing the influence of atomic structure and chemical composition on the corrosion process. They contain none of the classical crystalline or chemical defects found in crystalline solids, such as grain boundaries and second-phase particles, and they are chemically and structurally homogeneous.

Glassy alloys can be produced from two or more transition metals, for example, copper-zirconium and nickel-niobium, or from a combination of metals and metalloids, such as iron, nickel, and chromium containing boron, phosphorus, silicon, or carbon. They are produced by such techniques as liquid quenching, molecular deposition, or external action, and they retain a disordered structure resembling the liquid. As such, they have no long-range order. There is, however, short-range

order over a few atomic distances (as found in the liquid state); this has prompted the use of the terms glassy or vitreous to distinguish them from materials that are truly amorphous on the atomic scale.

Very high cooling rates (>10^5 K/s) are required to retain the highly metastable glassy state. Although the temperature decrease in quenching from the liquid to the solid is not large, the rate of heat extraction is very high and requires at least one dimension of the resulting alloy to be very thin. Because of this requirement, glassy metals produced by liquid quenching are typically in the form of ribbons, wires, and filaments.

Techniques for producing glassy metals can be divided into three main groups (Ref 1). The first, which is termed quenching, involves rapid solidification from the melt under a set of conditions, such as cooling rate and sample dimensions, that precludes the formation of the stable equilibrium structure.

The second technique, termed atomic or molecular deposition, involves growth from the vapor phase, such as thermal evaporation and sputtering, or from a liquid phase, such as electroless deposition and electrodeposition, to form the desired alloy. These techniques have higher effective cooling rates than liquid quenching processes; therefore, they allow the formation of glassy alloys that cannot be produced by rapid liquid quenching.

The third set of techniques is classified as external action techniques, and they rely on such procedures as solid deformation and irradiation to form the metastable glassy alloy. Ion implantation and ion beam mixing, for example, can produce amorphous surface layers on bulk crystalline substrates. The latter two groups of techniques--molecular deposition and external action techniques--have the advantage of being able to produce considerably thicker alloys, but they typically require considerably more time for completion of the process.

Some glassy metals exhibit extremely good corrosion resistance because of several factors. Glassy metals are free from such defects as the grain boundaries and second-phase particles that are present in crystalline metals. Corrosion often occurs preferentially at such sites; therefore, glassy metals might be expected to exhibit better corrosion resistance than crystalline alloys. The galvanic corrosion associated with chemical inhomogeneities, such as secondphase particles, is also impossible in glassy metals. In addition, the passive films responsible for corrosion resistance in crystalline alloys also play a role in glassy metal corrosion. Thus, the effect of the amorphous structure, chemical homogeneity, and unique chemical composition on the formation and stability of the passive film must also be considered.

Any corrosion reaction involves two or more partial anodic and cathodic half-cell reactions (Fig. 1). Two sets of curves are shown in Fig. 1. The bottom curves represent metal dissolution and plating, and the top curves are for proton reduction and hydrogen oxidation. The reversible potential, E^o, represents equilibrium between the oxidized and reduced species. For the metal, the reaction is $M \rightarrow M^{n+} + ne^-$. The current density $M \rightarrow M^{n+} + ne^-$ at E^o is termed the exchange current density, i_o, and is a characteristic of the metal. The cathodic half cell in acid solutions is typically proton reduction, which is represented by the reaction $2H^+ + 2e^- \rightarrow H_2$. In the case of the cathodic reaction, i_o is a function of the surface on which the proton reduction reaction occurs. The corrosion rate of a metal in deaerated acid is represented by the intersection of the metal dissolution and hydrogen reduction curves. This intersection establishes the corrosion potential, E_{corr}, and the corrosion current, i_{corr}, because the anodic and cathodic partial currents are equal at that point. The net result is that the metal corrodes and hydrogen is evolved simultaneously at the metal surface.

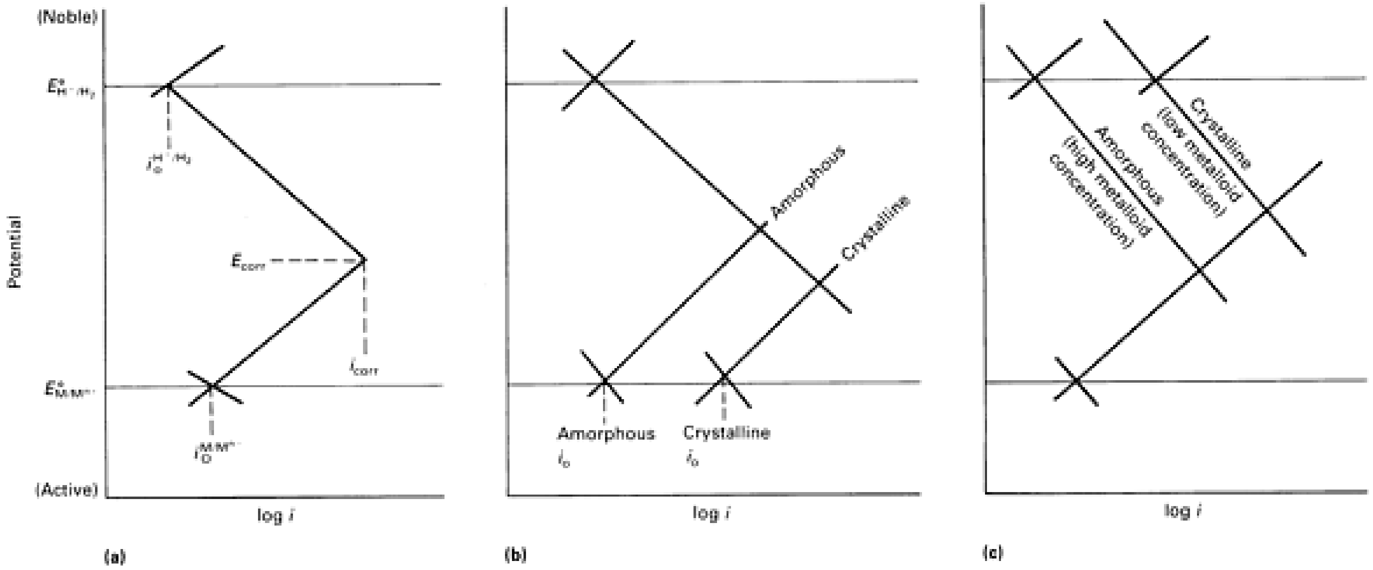

Fig. 1 Schematic Evans diagrams showing the possible influence of alloy structure and composition on the corrosion rate, i_{corr}, and corrosion potential, E_{corr}. See text for discussion. Source: Ref 2

There are several possibilities for explaining the difference in corrosion behavior between amorphous and crystalline metals. A metal-metalloid glassy metal typically contains of the order of 20 at.% metalloids. The exchange current density for the hydrogen reduction reaction may be lower on the metalloid surface than on the metal (Fig. 1b). If it is assumed that the anodic kinetics do not change, the Evans diagram predicts a decrease in i_{corr} and a more active E_{corr}.

A more likely possibility is that the anodic kinetics do in fact change with structure and composition. Because dissolution occurs preferentially at active sites, including kinks, ledges, steps, and grain boundaries, and because there are fewer long-range defects in an amorphous alloy, a lower exchange current density might be expected for metal dissolution in the case of amorphous alloys (Fig. 1c). In this case, the decrease in i_{corr} is accompanied by a shift in E_{corr} in the noble direction.

If amorphous alloys are compared with crystalline alloys with different chemical compositions (~20% metalloids for the glassy metal versus none for the conventional crystalline alloy), a shift in the reversible potential for metal oxidation would be expected. If this shift is in the noble direction and if all other factors remain constant, a decrease in i_{corr} would be expected, but a shift in the active direction would tend to increase the corrosion rate.

The above analysis is for a metal that is dissolving under activation control and at open-circuit potential. With systems containing film formers, the effect of the passive film and the interaction between metalloids and the film formers must be included, and the above analysis may not be appropriate.

Corrosion Behavior: A Historical Review

The first published information on the corrosion behavior of metallic glasses appeared in 1974 (Ref 3), and it concerned the Fe-Cr-P-C alloy system. Figure 2 shows the corrosion rates of $Fe_{70}Cr_{10}P_{13}C_7$ and $Fe_{65}Cr_{10}Ni_5P_{13}C_7$ metallic glasses and a typical AISI type 304 stainless steel in hydrochloric acid (HCl) of various concentrations at 30 °C (85 °F). It also includes data from Ref 4 obtained under similar test conditions. The corrosion rates, calculated from gravimetric measurements, were relatively large for the stainless steel because of pitting attack, but the rates for the metallic glasses were so low that they could not be detected even after immersion for 168 h. This early work illuminated the distinct differences in corrosion behavior between crystalline stainless steel and iron-base metal-metalloid glasses.

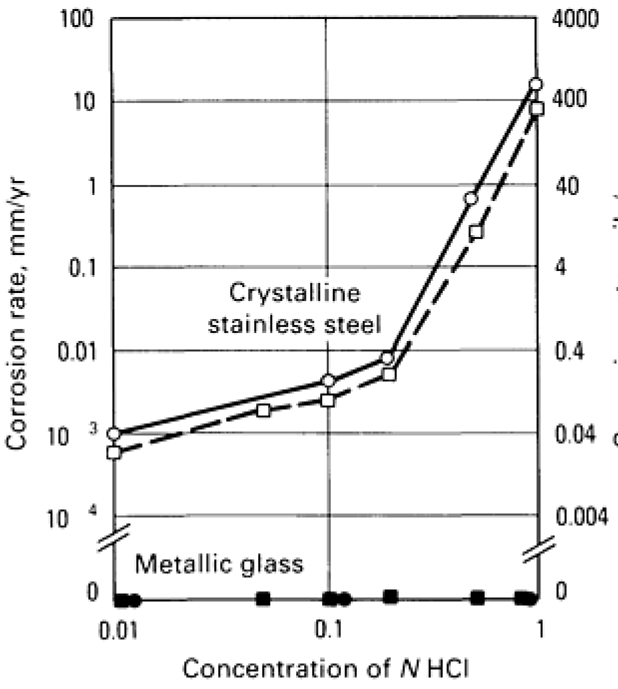

Fig. 2 Comparison of the corrosion rates of metallic glasses and crystalline stainless steel as a function of HCl concentration at 30 °C (85 °F). No weight changes of the metallic glasses of $Fe_{70}Cr_{10}P_{13}C_7$ were detected by a microbalance after immersion for 200 h. Open/closed circles (Ref 3); open/closed squares (Ref 4)

Other early research includes work that appeared in 1976 (Ref 5, 6). Figure 3 shows the relative corrosion rates in 1 *N* sodium chloride (NaCl) of crystalline iron-chromium alloys as compared to those of glassy Fe-$Cr_xP_{13}C_7$ alloys, where *x* ranges between 2 and 10 at.%. The corrosion rates of the crystalline alloys were about 0.6 mm/yr (24 mils/yr) and were largely unaffected by chromium content, which is the result of pitting corrosion. Conversely, the glassy alloys exhibited a sharp decrease in corrosion rate with increasing chromium content, with an undetectable rate occurring above 8 at.% Cr. Pitting did not occur on the glassy alloys, even those with only a few atomic percent of chromium.

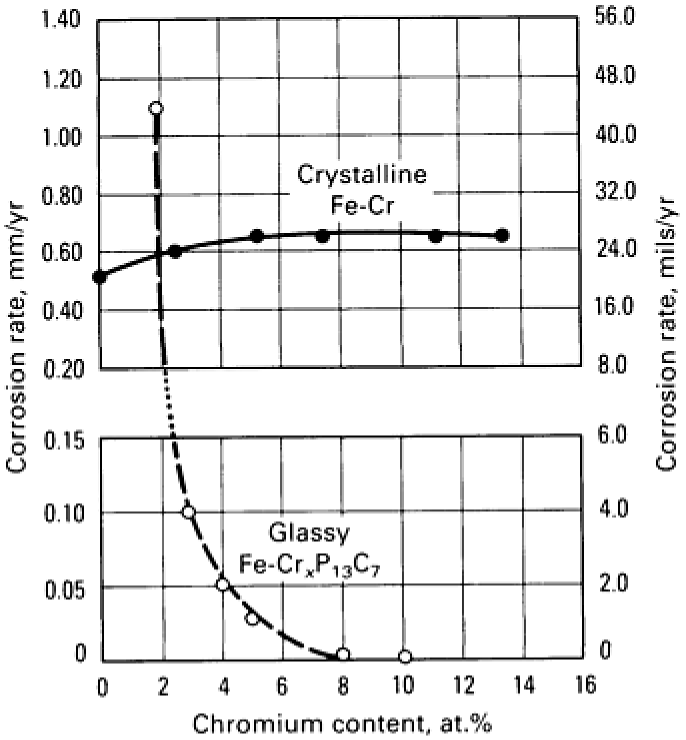

Fig. 3 Comparison of the corrosion rates of glassy Fe-$Cr_xP_{13}C_7$ alloys and crystalline iron-chromium alloys in 1 *N* NaCl solution at 30 °C (85 °F). Source: Ref 5

In another study, the anodic polarization behavior of glassy $Fe_{25}Ni_{40}Cr_{15}P_{16}B_4$ and $Fe_{40}Ni_{40}P_{16}B_4$ alloys was compared in sulfuric acid (H_2SO_4) with and without NaCl additions. The presence of chromium facilitated passivation over a broad potential range. Thermal crystallization of the metallic glasses caused the corrosion rates during anodic polarization to increase sharply, especially in the presence of chloride ion (Cl^-). It was concluded that crystallization probably decreased corrosion resistance by introducing chemical and structural heterogeneities into the alloys.

Studies such as those summarized above emphasized the excellent resistance to uniform and localized corrosion that could be obtained with certain types of metallic glasses. Results of these studies stimulated additional research into broader compositional ranges. Research during the late 1970s focused primarily on the transition metal-metalloid compositions, although some work was also initiated on metal-metal systems, such as copper-zirconium. Regarding the former compositional class of glassy alloys, research addressed the effects of phosphorus, boron, silicon, and carbon, which are added to stabilize the glassy structure.

These additive elements strongly influence the corrosion behavior of glassy alloys, as shown in Fig. 4 for $Fe_{70}Cr_{10}B_{13}X_7$ and $Fe_{70}Cr_{10}P_{13}X_7$ alloys. Specifically, in acidic solutions, the corrosion rates of the alloy system containing phosphorus as the major metalloid are two orders of magnitude lower than those of the alloy system with boron as the major metalloid. In addition, the corrosion rate of the glassy iron-chromium alloy progressively decreased by the addition of silicon, boron, carbon, and phosphorus in 0.1 *N* H_2SO_4. The addition of chromium without phosphorus to the glassy alloys is relatively ineffective in reducing corrosion rates, as evident from the $Fe_{70}Cr_{10}B_{13}C_7$ and $Fe_{70}Cr_{10}B_{13}Si_7$ alloys. Thus, phosphorus was identified as the single most effective metalloid element among phosphorus, carbon, silicon, and boron for improving the corrosion resistance of glassy iron-base alloys containing chromium. The combination of metalloids that is most effective in providing corrosion resistance in glassy iron-chromium alloys is phosphorus and carbon.

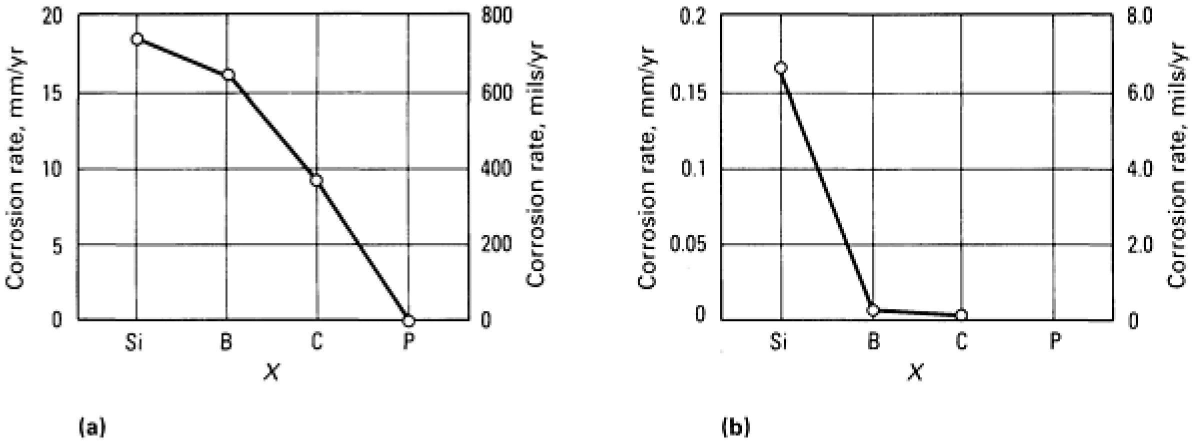

Fig. 4 Average corrosion rates estimated from the weight loss of amorphous $Fe_{70}Cr_{10}B_{13}X_7$ and $Fe_{70}Cr_{10}P_{13}X_7$ alloys in 0.1 *N* H_2SO_4 at 30 °C (85 °F), where (a) *X* is silicon, boron, carbon, and phosphorus, and (b) *X* is silicon, boron, and carbon. Source: Ref 7

It was also recognized that the corrosion behavior of glassy alloys is strongly influenced by additions of metallic elements, especially those that form films on the alloy surface, that is, film former additions. Figure 3 shows an early example of the strong beneficial effect of chromium additions to an iron-base glassy alloy. The effect of chromium content on the corrosion rates of glassy Ni-Cr-$P_{15}B_5$ alloys in 10% ferric chloride ($FeCl_3$) is apparent in Fig. 5, which shows that an undetectably small corrosion rate was attained with 7 at.% Cr. A large variety of other metal additions have also been investigated. For example, such elements as titanium, manganese, niobium, vanadium, tungsten, and molybdenum can benefit the corrosion resistance of Fe-$Cr_3P_{13}C_7X$ alloys in 1 *N* HCl (Ref 9).

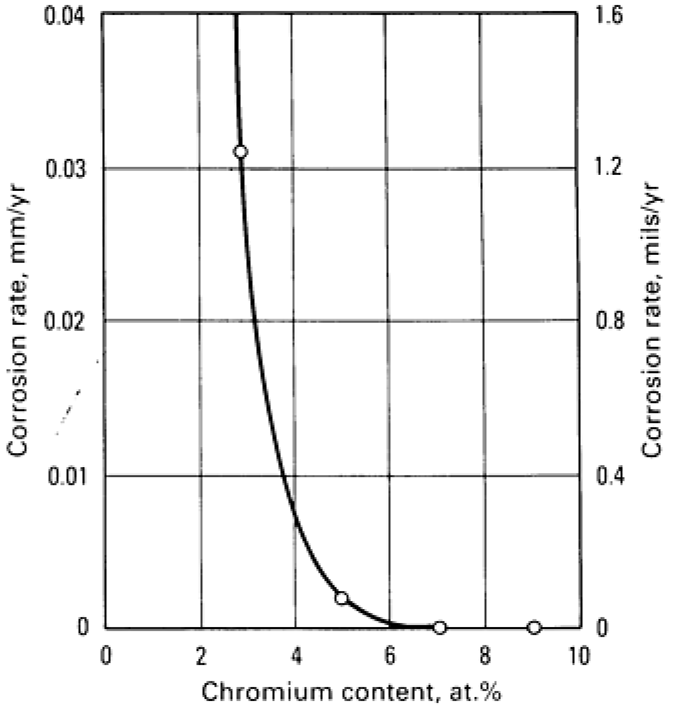

Fig. 5 Effect of the chromium content on the corrosion rates of amorphous Ni-Cr-$P_{15}B_5$ alloys in 10% $FeCl_3 \cdot 6H_2O$ at 30 ± 1 °C (85 ± 2 °F). The corrosion rate was estimated from weight loss during immersion for 168 h. Source: Ref 8

Corrosion research involving metal-metalloid system soon led to research with metal-metal glasses. One study characterized the corrosion behavior of copper-zirconium and copper-titanium alloys in H_2SO_4, HCl, nitric and (HNO_3), and sodium hydroxide (NaOH) (Ref 10). In all of the solutions except NaOH, the crystalline and glassy copper-titanium alloys exhibited corrosion rates lower than those of pure copper, and in all cases, the corrosion resistance of the glassy alloy was better than that of the crystalline alloy. The glassy alloys in these compositional systems are not unusually corrosion resistant; in fact, neither the crystalline nor glassy forms of the alloys were more corrosion resistant than pure titanium or pure zirconium. This fact suggests that the corrosion resistance of the glassy alloys is the result of the presence of the passivating element (titanium or zirconium), not the presence of the glassy state.

In another investigation, several alloys in the Cu-Zr system were examined in H_2SO_4 electrolyte (Ref 11). It was shown that the copper-zirconium alloys remained resistant to corrosion regardless of whether they were devitrified to a single-phase or a multiphase equilibrium microstructure; however, the glassy state was about 20% more corrosion resistant than the devitrified state.

Since the early work with iron-base metal-metalloid glasses, the field of study has been extended to include many alloy systems. Results with nickel-, titanium-, copper-, and cobalt-base alloy systems, among others, have been reported in the literature. The effect of metalloid additions on corrosion behavior is reasonably well characterized, and theories have been proposed to explain the beneficial effect of phosphorus on corrosion (Ref 7). The influence on corrosion behavior of a wide variety of elemental additions has been evaluated, and many such additions increase corrosion resistance; those with the strongest effect are the classical film formers, such as chromium, titanium, and molybdenum. Research on glassy alloy corrosion in the past few years has expanded to include developing means for using these alloys in practical applications. Therefore, research has accelerated in such areas as laser surface remelting, ion implantation, sputtering, electrodeposition, and chemical vapor deposition. See, for example, the articles "Surface Modification" (ion implantation and laser surface processing are discussed) and "CVD/PVD Coatings" in this Volume.

General Corrosion Behavior

Glassy alloys can be grouped into two major categories with intrinsically different corrosion behaviors. The first group includes the transition metal-metal binary alloy systems, such as Cu-Zr, Ni-Ti, W-Si, and Ni-Nb. The second class consists of transition metal-metalloid alloys. These alloys are usually iron-, nickel-, or cobalt-base systems, may contain film formers (such as chromium and titanium), and normally contain approximately 20 at.% P, B, Si, and/or C as the metalloid component.

Transition Metal-Metal Binary Alloys. Research in the transition metal-metal systems indicates that corrosion resistance is primarily determined by the behavior of the more corrosion-resistant component of the alloy. For example, in an investigation of the corrosion behavior of copper-zirconium alloys, the potentiodynamic polarization behavior of the alloys exhibited characteristics of both components, but it was not superior to the more passive material (zirconium) (Ref 2).

This work also examined the effect of alloy structure. By choosing the proper alloy composition ($Cu_{60}Zr_{40}$), the researchers devitrified the glassy alloy to a single-phase $Cu_{10}Zr_7$ and found a slight improvement in corrosion resistance when the material was in the glassy state. They worked with a series of copper-zirconium alloys and found that whether or not the alloy forms a single-phase or multiphase alloy upon devitrification has very little effect on corrosion resistance. This lead to the conclusion that, at least in this alloy system, structure plays a secondary role in establishing corrosion resistance.

Other alloys, including copper-titanium, copper-zirconium, and nickel-titanium, have demonstrated that the corrosion behavior of the transition metal-metal class of glassy metals is determined almost completely by the more corrosion-resistant component. Thus, the corrosion resistance in the transition metal-metal alloy systems is apparently the result of the presence of a passivating element, not the glassy structure.

Transition Metal-Metalloid Alloys. The second class of glassy alloys consists of transition metal-metalloid elements. This family includes iron-, nickel-, and cobalt-base alloys containing combinations of phosphorus, boron, carbon, and silicon as the metalloid constituents. These alloys can be formed as binary systems, such as Ni-P and Fe-B, or they may be considerably more complex, such as Fe-Ni-P-B quaternary systems. In addition to the base metal, they often contain appreciable concentrations of film formers to promote passivity--for example, the Fe-Ni-Cr-P-B system. They derive their corrosion resistance from the same type of processes as crystalline alloys, namely the development of a passive film. The

significant difference between corrosion-resistant glassy alloys and their crystalline counterparts, such as stainless steels, is that the level of chromium necessary to promote passivity can be considerably less in the glassy alloys.

Figure 3 shows a comparison between the corrosion rates of crystalline iron-chromium alloys and amorphous iron-chromium-phosphorus-carbon alloys as a function of chromium concentration. At low chromium levels, the amorphous alloy corrodes at a higher rate than the crystalline material. However, at slightly higher chromium levels (4 at.%), there is a significant decrease in the corrosion rate of the glassy alloy, but the crystalline material is essentially unchanged. At an intermediate level of 8 at.% Cr, no corrosion of the glassy alloy was detected by weight loss experiments after immersion for 168 h. It was also found that the concentration of HCl, which has a profound effect on corrosion behavior of crystalline, alloys, had no effect on corrosion of the glassy Fe-Cr-P-C or Fe-Ni-Cr-P-C alloy systems, which exhibited no weight loss after exposure for 168 h (Ref 5).

Figure 6 shows the effect of chromium concentration on the corrosion behavior of iron-, nickel-, and cobalt-base alloys. In all cases, the corrosion rate decreases with increasing chromium concentration and becomes vanishingly small at some level of chromium. In addition, the Fe-Cr-P-C alloy system, which exhibits the highest corrosion rate at low chromium contents, exhibits no weight loss in immersion tests with a chromium concentration of as little as 8 at.%. This behavior supports the theory that, when an alloy contains a strong film former, the higher the initial reactivity of the alloy, the more rapidly the film former can be accumulated at the interface and the more rapid the rate of passivation (Ref 9).

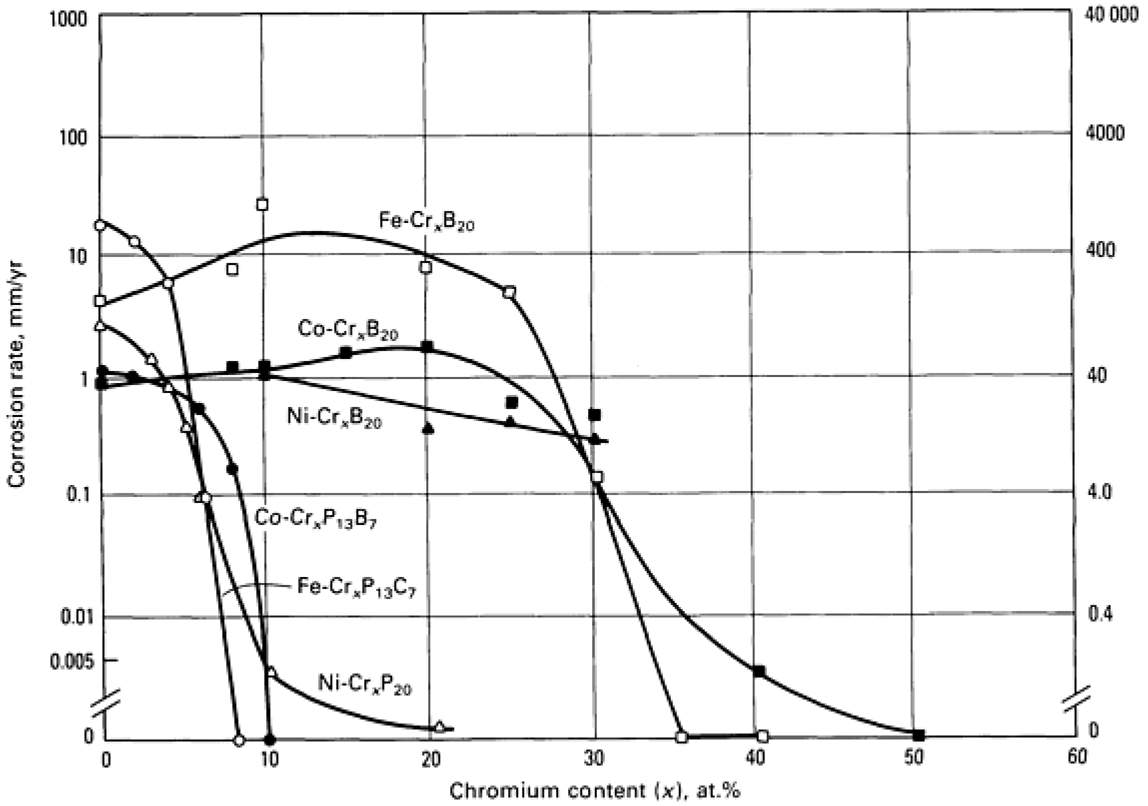

Fig. 6 The influence of chromium content on the corrosion rates of iron-, cobalt-, and nickel-base alloys in 1 *N* HCl. Source: Ref 12

The corrosion behavior of nickel-base (Ref 8) and cobalt-base (Ref 13) glassy alloys is very similar to that of the iron-base systems, and it is also a strong function of chromium concentration. Figure 7 shows the corrosion rate for a nickel-base glassy alloy as a function of chromium concentration. These data, which are very similar to the data for the iron-base system, show that at a concentration of about 7 at.% Cr the alloy is extremely resistant to corrosion in a $FeCl_3$ solution.

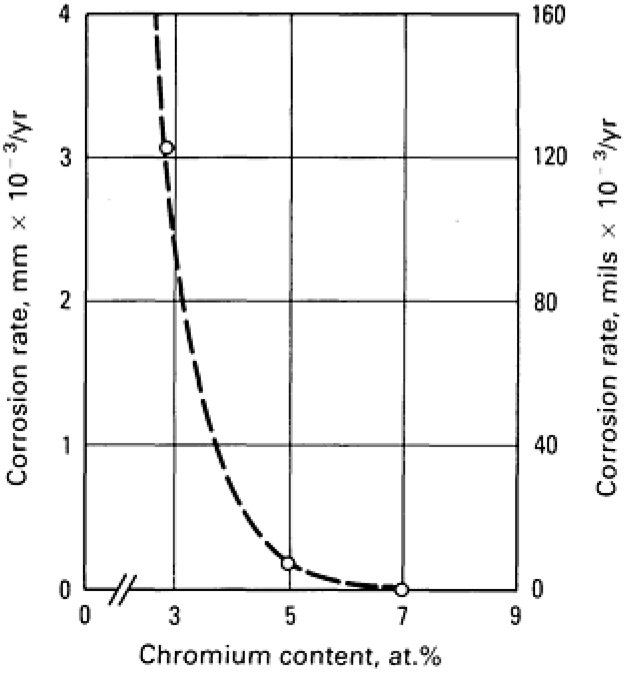

Fig. 7 Plot of corrosion rates of metallic glasses of Ni-Cr-$P_{15}B_5$ in 10 wt% $FeCl_3 \cdot 6H_2O$ at 30 °C (85 °F) versus chromium content

In one investigation, ion implantation was used to make glassy iron-chromium-phosphorus alloys in which the chromium level varies from 6 to 18 at.% (Ref 14). An interaction between chromium and phosphorus was observed, which suggests a mechanism for the passivation of these amorphous alloys. Specifically, at low chromium levels, phosphorus implantation degrades passivity and induces pitting. At high chromium concentrations, there is a slight improvement in passivation, although the crystalline and amorphous alloys are both spontaneously passive and exhibit current densities of the order of 1 uA/cm^2. However, at intermediate chromium levels (8 to 10 at.%), there is a profound benefit from the phosphorus implantation. At these intermediate levels, there is a decrease in current density relative to the unimplanted alloy, namely four orders of magnitude for the Fe-Cr_{10}P alloy. In fact, the Fe-Cr_{10}P alloy exhibits current decay characteristics similar to an Fe-18Cr crystalline alloy.

This research indicates that there is a critical chromium concentration required to provide passivity and that below this level the combination of phosphorus and the amorphous structure increases the initial dissolution rate. Also, below their critical chromium level, there is insufficient chromium for passivation; therefore, pitting is observed. Above this critical chromium concentration, phosphorus and the glassy structure increase the initial dissolution rate, cause a rapid accumulation of chromium in the passive film, and result in an increased rate of passivation.

One study examined the influence of alloying elements on the corrosion behavior of iron-chromium base alloys (Ref 12). Figure 8 shows current decay transients for glassy $Fe_{70}Cr_{10}B_{13}X_7$ alloys (X is silicon, carbon, or phosphorus) that were potentiostated in the passive region and abraded under potentiostatic control to produce the repassivation transients. The glassy alloy containing phosphorus exhibited the highest initial current, the most rapid repassivation kinetics, and the lowest passive current density.

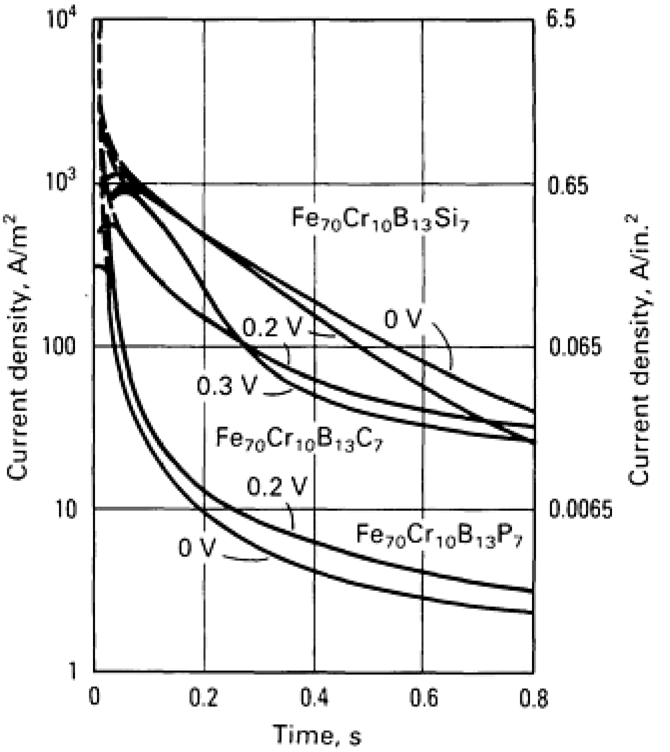

Fig. 8 Current density transients for glassy $Fe_{70}Cr_{10}B_{13}X_7$ alloys following mechanical abrasion of specimen surfaces during anodic polarization at constant potentials in 0.1 *N* H_2SO_4. *X* denotes minor metalloid content, and potentials (SCE) are indicated in the figure. Source: Ref 12

Thus, the most effective elements in providing corrosion resistance are chromium and phosphorus. Published concepts concerning and phosphorus appear to be consistent with existing data, but the relative effects of structure and composition on corrosion behavior remain to be quantified.

Localized Corrosion Behavior

One of the most outstanding characteristics regarding the corrosion behavior of certain metallic glasses is their ability to resist localized corrosion. In this article, the term localized corrosion refers to pitting and crevice attack (stress-assisted forms of corrosion, such as stress-corrosion cracking and hydrogen embrittlement, are discussed in the section "Environmental Cracking Behavior" in this article). In many cases, this resistance to localized attack extends over wide ranges of oxidizing potential and pH and to alloy compositions that would be considered lean in film former elements compared to conventional crystalline stainless steels.

Effect of Chromium on Pitting. The work summarized in Fig. 3 and described previously in this article indicates that iron-base glasses with only several atomic percent of chromium very effectively resist pitting in chloride-containing solutions. Polarization curves of glassy alloys obtained in 1 *N* NaCl do not show a characteristic pitting potential; rather, they exhibit stable passivity until the onset of transpassivity. In addition, results from the study discussed in Ref 6 with $Fe_{25}Ni_{40}Cr_{15}P_{16}B_4$ showed that the passive range in 1 *N* H_2SO_4 plus 0.1 *N* NaCl is not interrupted by pitting but extends to transpassivity.

In another study, increasing the chromium content from 0 to 16 at.% in a series of Fe-Ni-Cr-P-B alloy systems facilitated passivation in acidified 1 *N* NaCl, but pitting was not observed on any alloy polarized below the transpassive potential region (Ref 15). Polarization at transpassive potentials caused numerous pits to form that penetrated the filament and were noncrystallographic in shape.

Chromium was shown to be very effective in conferring pitting resistance, such as for the glassy alloys Fe-$Cr_xB_{13}C_7$ and Fe-$Cr_xB_{13}Si_7$ in 3% NaCl (Ref 16). With chromium levels of 2 and 5 at.%, both alloy types pitted at potentials slightly anodic to the free corrosion potential of about -0.6 V (saturated calomel electrode, SCE). The addition of 8 at.% Cr

extended the pitting resistance to about 1 V (SCE), which is an extremely aggressive condition for alloys containing such a low level of chromium. By contrast, type 304 stainless steel contains about 18 wt.% Cr, yet its pitting potential is several hundred millivolts less positive than that of these glassy alloys.

About 7 at.% Cr was sufficient to prevent pitting of Ni-Cr-P-B alloy systems in 10% $FeCl_3 \cdot H_2O$ at 30 °C (85 °F) (Ref 17). Glassy $Fe_{73}Cr_7P_{15}B_5$ passivated spontaneously in 1 *N* HCl. Surface analysis by x-ray photoelectron spectroscopy showed that chromium and phosphorus were enriched and that nickel depleted in the alloy substrate beneath the passive film. Figure 9 compares the effect on corrosion rate of adding chromium and titanium to Ni-X-P_{20} glasses. Chromium is more effective than titanium in conferring corrosion resistance, and the chromium-containing alloys exhibited a stronger tendency for spontaneous passivation. The corrosion rate decreased approximately logarithmically with increasing chromium or titanium up to about 10 to 7 at.%, respectively.

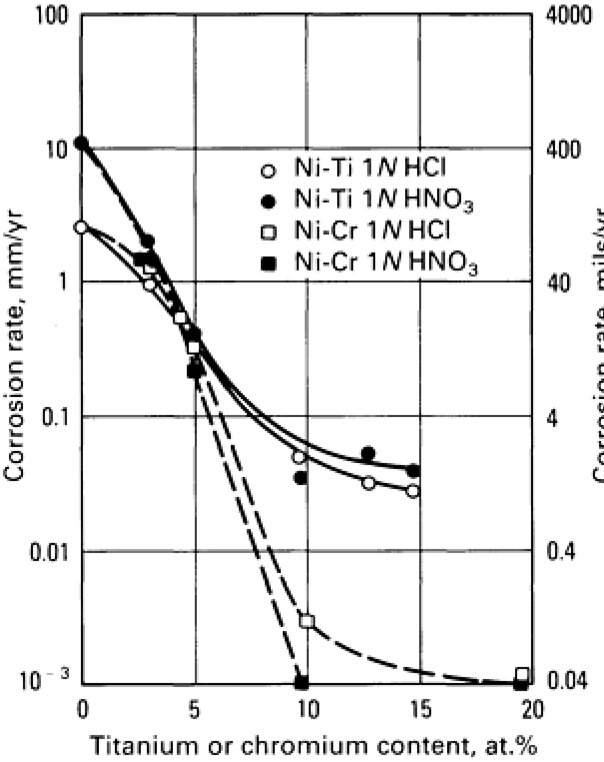

Fig. 9 Changes in corrosion rates of glassy Ni-Ti-P_{20} and Ni-Cr-P_{20} alloys measured in 1 *N* HCl and 1 *N* HNO_3 at 30 ± 1 °C (85 ± 2 °F) as a function of the titanium or chromium content. Source: Ref 18

Effect of Molybdenum on Pitting. Molybdenum benefits the pitting resistance of glassy alloys and crystalline steels. The addition of molybdenum to glassy Fe-$Mo_xP_{13}C_7$ alloys suppressed pitting and decreased the critical current density for passivation and the passive current density (Ref 19). As little as 4 at.% Mo prevented pitting in 1 *N* HCl, and small additions of molybdenum were more effective than chromium in decreasing corrosion rates. Molybdenum has been shown to facilitate the formation of a passive hydrated chromium or iron oxy-hydroxide film through its enrichment in the corrosion product layer during active dissolution (Ref 20). The enrichment assists the accumulation of the passivating species in the film by lowering the dissolution rate of the species; the molybdenum-rich product subsequently dissolves and thus leaves little molybdenum behind in the film.

Effect of Other Alloying Elements on Pitting. Titanium, tantalum, molybdenum, and tungsten were incorporated by high-rate sputter deposition into alloys of the general composition T_1-T_2 where T_1 = titanium, tantalum, molybdenum, or tungsten and T_2 = rhenium, iron, cobalt, nickel, or copper (Ref 21). Tungsten-iron and titanium-copper resisted pitting corrosion up to 2.5 V(SCE) in chloride solutions of pH 1 and 7. Addition of tungsten to Fe-$W_xP_{13}C_7$ increased the critical pitting potential, E_{crit}, to above 2 V(SCE) at x = 6 at.%, but x = 10 at.% caused transpassive dissolution at 1 V(SCE). Addition of tungsten to commercial type 304 stainless steel by sputtering stabilized the glassy structure and increased E_{crit} in chloride electrolyte (Ref 22).

One study investigated the effects of the alloying additions titanium, zirconium, vanadium, niobium, chromium, molybdenum, tungsten, manganese, cobalt, nickel, copper, ruthenium, rhodium, palladium, and platinum in the glassy alloy Fe-*X*-$P_{13}C_7$ (Ref 23). All elements except manganese decreased the corrosion rate in H_2SO_4, HCl, HNO_3, and NaCl solutions. Although the base alloy, Fe-$P_{13}C_7$, did not passivate, additions of any of the preceding elements at levels from 0.5 to several atomic percent enabled passivation to occur during anodic polarization in 0.1 *N* H_2SO_4. Chromium was most effective, and molybdenum and titanium also were very beneficial. Pitting was not observed in 3% NaCl for those alloys that passivated. The alloys that did not passivate, such as Fe-Co-$P_{13}C_7$, also did not pit, but they dissolved uniformly.

Passivation. It has been proposed that the excellent resistance of certain glassy alloys to uniform and localized corrosion results from their enhanced chemical reactivity relative to conventional stainless alloys (Ref 24). Transient repassivation experiments with glassy $Fe_{70}Cr_{10}P_{13}C_7$ and crystalline type 304 stainless steel in acidified chloride electrolyte showed a higher initial reactivity on the glassy alloy after abrasion and a more rapid rate of repassivation. These experiments demonstrated that there is a synergistic effect between chromium and phosphorus in transition metal-metalloid glasses such that maximum resistance to localized corrosion exists when these two elements are both present. The excellent resistance to localized corrosion may result from the rapid re-formation of a passive film at regions where it is damaged by mechanical or electrochemical means, combined with enrichment of Cr^{3+} species in the film.

Research cited earlier in this article concerning the use of ion implantation to make iron-chromium-phosphorus alloys (Ref 14) demonstrated that the synergistic effect of chromium and phosphorus is a strong function of the chromium concentration. Potentiostatic polarization experiments in acidic chloride solutions showed behavior that was a strong function of chromium concentration. At low chromium levels, phosphorus implantation induced pitting, but at high chromium levels (18 at.%), a slight improvement in passivation was observed. At intermediate levels (10 to 12 at.%), substantial improvement in the passive film was obtained through phosphorus implantation. It was proposed that when the alloy contains small amounts of chromium, there is not enough chromium to passivate the alloy, but when the phosphorus stimulates the initial dissolution, the alloy becomes susceptible to pitting. As the chromium concentration increases, there is sufficient chromium for passivation, and the phosphorus promotes the accumulation of chromium and a very protective passive film.

Crevice Corrosion Resistance. One investigation examined the resistance of glassy alloys to crevice corrosion in acidic solutions containing Cl^- ion. Crevice corrosion was studied as a means of circumventing the need for initiating localized corrosion; that is, crevice corrosion behavior was considered to represent more a measure of the resistance to propagation, rather than initiation, of localized corrosion (Ref 25). Introducing micro-cracks into Fe-Ni-Cr-P-B glassy alloy filaments by cold rolling (Ref 26) was found to cause susceptibility to a transient form of crevice attack; however, the crevices widened into pit-shaped cavities and then passivated spontaneously.

Subsequent research with an electrochemical cell consisting of a prepared crevice instrumented with microreference and pH electrodes showed that the glassy alloy possessed a strong tendency to passivate, even under the aggressive conditions of low pH, low dissolved oxygen concentration, and oxidizing potential that prevail within crevices (Ref 27). The conclusion was that the alloy resisted crevice attack because of its strong ability to passivate, which in turn stifled propagation. This resistance to crevice corrosion could be expected to extend to other glassy transition metal-metalloid compositions containing both a film former and phosphorus.

Glassy nickel-phosphorus is another alloy system that has been recently investigated and that appears to resist chloride-induced corrosion (Ref 27). In fact, the potentiodynamic polarization curves are virtually identical in both chloride-containing and chloride-free electrolytes. A form of chemical passivity has been proposed to explain the corrosion behavior. Passivation in this system is due to the formation of an ionic barrier layer, not to the formation of a classical passive oxide film. This barrier layer consists of hypophosphite ion adsorbed on the nickel-phosphorus surface, which may in turn be hydrogen bonded to an outer layer of water molecules. This barrier layer inhibits the transport of water to the surface and thus prevents hydration of nickel, which is the first step in the nickel dissolution process.

Environmental Cracking Behavior

The environmentally induced fracture of glassy alloys, namely hydrogen embrittlement and stress corrosion cracking (SCC), will be discussed in this section. Details on the mechanisms of these phenomena can be found in the article "Environmentally Induced Cracking" in this Volume.

Stress-Corrosion Cracking. One of the first reported experiments on the SCC of glassy alloys concerned $Ni_{49}Fe_{29}P_{14}B_6Al_2$ (Ref 28). Loading to 75% of the fracture stress in air in 3.5 *N* NaCl solution resulted in a slow, presumably SCC fracture region and a final, fast fracture region. However, another researcher suggested that the fracture of this alloy was actually induced by hydrogen (Ref 29).

In another case, the SCC behavior of a glassy $Fe_{32}Ni_{36}Cr_{14}P_{12}B_6$ alloy in boiling magnesium chloride ($MgCl_2$) at 125 °C (255 °F) was studied by means of constant extension rate tensile tests and constant strain tests (Ref 30). Stress-corrosion cracking occurred at the corrosion potential and anodic overpotentials, and slight cathodic polarization prevented SCC. Examination of the fracture surfaces led to the conclusion that localized corrosion enhances hydrogen entry and subsequent embrittlement.

The SCC behavior of glassy Fe-Cr-Ni-P-C alloy systems in acidic chloride solutions was investigated with constant extension rate tensile tests (Ref 31). Hydrogen embrittlement occurred at cathodic polarizations up to -300 mV relative to the corrosion potential. In the passive potential region, no cracking occurred in neutral NaCl solutions and in acidic solutions at low Cl^- concentrations. Fracture stress decreased only when the specimens were strained in strong acidic solutions containing Cl^-, and this phenomenon was also attributed to hydrogen embrittlement.

The tendency of glassy $Fe_{40}Ni_{40}P_{14}B_6$ to undergo SCC and hydrogen embrittlement in acidic electrolytes was also studied (Ref 32). Cathodic polarization of elastically stressed specimens in 1 *M* HCl resulted in failure by hydrogen embrittlement. Specimens immersed in aqueous $FeCl_3$ solution at the free corrosion potential failed by SCC, as did those that were anodically polarized in 1 *M* HCl. These specimens were covered by an iron oxide film, and selective leaching (dealloying of nickel from pits and cracks occurred.

Hydrogen Embrittlement. Although classical SCC (defined as cracking caused directly by anodic dissolution at the crack tip) of glassy alloys apparently occurs, hydrogen embrittlement is a more common mode of environmentally assisted failure in aqueous electrolytes. Hydrogen embrittlement of glassy alloys has been observed during bending or tensile tests during or after hydrogen charging in the following alloys:

- $Fe_{80}P_{13}C_7$ and $Fe_{70}Cr_{10}P_{13}C_7$ (Ref 33)
- $Fe_{32}Ni_{36}Cr_{14}P_{12}C_6$ (Ref 34)
- $Fe_{49.5}Cr_{7.5}Ni_{23}P_{13}C_7$ and $Fe_{53}Cr_7Ni_{20}P_{14}C_6$ (Ref 35)

As shown in Fig. 10, the stress-strain curve of an $Fe_{49.5}Cr_{7.5}Ni_{23}P_{13}C_7$ glassy alloy exhibits almost completely elastic behavior in air and in various acid chloride solutions. The fracture strain decreased to about 30% of that in air as a result of charging the specimen with hydrogen. It was proposed that local corrosion at the open-circuit and even passive potentials can produce hydrogen and thus create embrittlement; fractographic evidence and the return of ductility by baking after corrosion were cited as evidence for this claim (Ref 29).

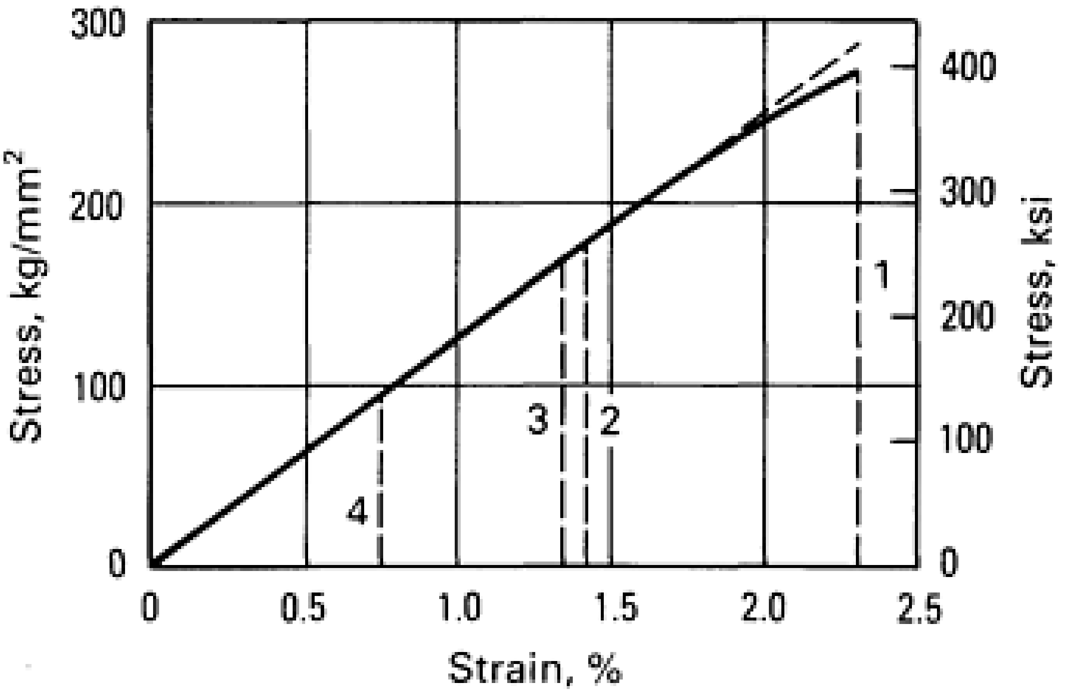

Fig. 10 Stress-strain behavior of a glassy $Fe_{49.5}Cr_{7.5}Ni_{23}P_{13}C_7$ alloy at various potentials in air and in solution at a strain rate of 4.2×10^{-6} s^{-1}. Line 1: in air; line 2: in 5 *N* H_2SO_4 + 0.1 *N* NaCl, E_{corr} = -20 mV; line 3: 5 *N* H_2SO_4 + 0.1 *N* NaCl, *E* = +500 mV; line 4: 5 *N* H_2SO_4 + 0.1 *N* NaCl, *E* = -500 mV. Source: Ref 31

Although it appears that hydrogen embrittlement is more common that SCC as the environmentally assisted failure mode for glassy alloys, the detailed mechanism of the hydrogen embrittlement of transition metal-metalloid alloys is uncertain. At cathodic potentials in deaerated solutions, the principal cathodic reaction produces hydrogen by the following reaction sequence: $2H^+ + 2e \rightarrow H_2$, which can be separated into a proton reduction step and a hydrogen adatom-adatom combination step. Elements such as phosphorus, sulfur, arsenic, and antimony poison the reaction $H_{ads} + H_{ads} \rightarrow H_2$; thus, they increase the concentration of adsorbed (ads) hydrogen on the electrode surface and consequently the flux of atomic hydrogen absorbed through the surface into the bulk alloy. Because phosphorus is commonly found in transition metal-metalloid glassy alloys, it would seem likely that these phosphorus-containing alloys might have a large tendency toward absorbing hydrogen from the electrolyte and consequently a significant tendency toward hydrogen embrittlement. Augmenting this tendency would be the very high strength and limited ductility characteristic of this compositional class of glassy alloys.

In this regard, an investigation of hydrogen permeation through glassy phosphorus-containing nickel-base alloys concluded that phosphorus increases the rate of hydrogen absorption relative to that for pure nickel (Ref 2). It was proposed that internal voids in the alloys act as traps for the atomic hydrogen and that this atomic hydrogen may subsequently combine to form molecular hydrogen, which ultimately produces internal pressure that can shatter the specimen.

Another researcher characterized the effects of metalloid additions on the susceptibility to hydrogen embrittlement of glassy Fe-$Cr_5Mo_{12}X$ and Fe-$Cr_{10}Mo_{12}X$ (*X* = 18C, 20B, or 13P-7C) in 1 *N* HCl, 0.5 *N* NaCl, and 1 *N* H_2SO_4 (Ref 29). Although phosphorus is an effective hydrogen recombination poison, alloys containing this element showed a lower susceptibility to hydrogen embrittlement. (The alloys containing carbon were the most susceptible.) This lower susceptibility was ascribed to the higher rate of repassivation of phosphorus-containing alloys; because the corrosion rate was decreased, the amount of hydrogen produced by the open-circuit corrosion reaction and that absorbed into the alloys should also be lowered.

The specific effects of each metalloid on hydrogen embrittlement susceptibility are still uncertain. However, the large concentrations of metalloids present in transition metal-metalloid alloys almost certainly influence the high susceptibility of these materials to hydrogen embrittlement.

Applications

Although metallic glasses are interesting from a research standpoint, there are several engineering applications in which their unique properties may be important. In considering possible applications of glassy metals, two obvious limitations are apparent. First, all alloys in this class of materials are metastable. If they are subjected to elevated temperatures, devitrification will occur, which normally results in loss of the properties of interest. The glass transition temperature is of course a function of the alloy composition; therefore, some alloys are suitable for use at temperatures substantially above ambient. The second limitation concerns the physical dimensions of the material produced. Because of the high cooling rate required, at least one dimension of the alloy must be very thin. Therefore, the most common forms of glassy metals include filaments, wires, and ribbons.

An obvious application of glassy alloys is that of corrosion-resistant coatings or barriers. In certain applications, a thin, highly corrosion-resistant coating may be sufficient, and these coatings permit the use of less-expensive base materials.

To make commercial use of glassy alloys, advances are required in several areas. Glassy coatings are very appealing in that they can be applied to engineering parts of complex geometry. However, most of the deposition processes used to make glassy alloys are slow, expensive, or both. Techniques are needed that enable the uniform and rapid coating of large areas. In addition, because most current used deposition techniques tend to be expensive, replacement of corrosion-resistant bulk alloys with glassy metal coatings must await the development of cost-competitive procedures. Additional information on the applications of amorphous materials, such as tool applications, aluminum die-casting mold inserts, metal-bonded abrasive wheels, and hardfacing coatings, can be found in *Powder Metal Technologies and Applications,* Volume 7 of the *ASM Handbook.*

Corrosion of Electroplated Hard Chromium

Allen R. Jones, M&T Chemicals, Inc.

Introduction

HARD CHROMIUM plated parts have more than about 1.2 μm (0.05 mils) of chromium. Parts that are plated with less than this amount are referred to as decorative applications. Electroplated chromium protects substrates by means of a barrier coating as opposed to a sacrificial coating, such as zinc. Chromium is more electrochemically active than steel; however, it forms a dense self-healing oxide layer on its surface. Chromium can be passivated, or the oxide layer can be formed by exposure to air or by immersion in room-temperature oxidizing acids. Electroplated chromium is chemically resistant to most compounds and offers excellent corrosion protection in various environments. It is especially useful in applications that also require wear resistance.

Electrodeposition Parameters

Chromium Plating Baths. Commercially, hard chromium is deposited from four types of baths; conventional, fluoride, and the two high-efficiency etch-free baths. All of the baths contain chromic acid (CrO_3) and sulfate (SO_4^{2-}). The (SO_4^{2-}) acts as catalyst. Chromium cannot be electrodeposited from an aqueous CrO_3 solution unless one or more catalysts are present. Depending on which catalysts are present and the plating parameters, between 10 and 45% of the cathodic current will be used to reduce hexavalent chromium (Cr^{6+}) to chromium metal. The properties of the electrodeposits are influenced by the ratio of CrO_3 to the catalysts, plating temperature, and current density.

Stress and Microcracks. The tensile stress in most electroplated chromium deposits increases until microcracks are formed (Ref 1, 2). The microcracks decrease the stress in the deposit as the thickness of the deposit increases. Stress is inversely proportional to the number of microcracks. The number of microcracks is more important in controlling stress than the type of bath chemistry. Crack-free deposits are highly stressed.

Microcracks are present in most electroplated hard chromium deposits. Figure 1 shows a typical microcrack structure. The density of microcracks in chromium deposits varies from 0 to more than 1200 cracks/cm (3000 cracks/in.), depending on bath chemistry, current density, and temperature. The number of microcracks increases with the concentration of catalyst in the plating bath. The depth of a microcrack is less than about 8 μm (0.3 mils) on a deposit and that is 130 μm (5 mils) thick with crack counts of about 800 cracks/cm (2000 cracks/in.).

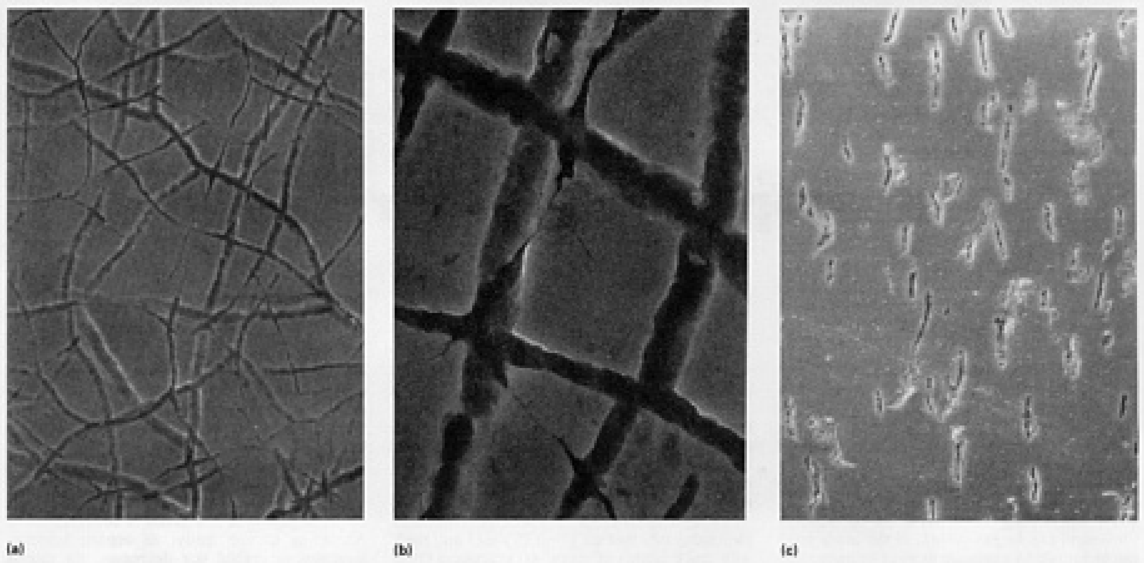

Fig. 1 Photomicrographs of chromium deposits (plated in a high-efficiency etch-free bath) after etching. (a) and (b) Deposit plated at 78 A/dm^2 (5 A/in.^{2}) and at 55 °C (130 °F). (a) 540×. (b) 2300×. (c) Cross section of a chromium deposit plated at 93 A/dm^2 (6 A/in.^{2}) and at 58 °C (135 °F). The specimen was polished before etching. 880×. Both deposits contain 800 microcracks/cm (2000 microcracks/in).

Because chromium protects substrates by forming a barrier, the coatings must be thicker than the microcracks to provide good corrosion resistance. Thin coatings may not form microcracks and can offer as much corrosion resistance as thicker coatings (see the section "Coating Thickness" in this article). Chromium electrodeposits that are about 25 μm (1 mil) thick with crack counts of about 400 cracks/cm (1000 cracks/in.) are as resistant to corrosion as deposits with crack counts of about 100 cracks/cm (250 cracks/in.). Deposits with very low crack counts have deeper microcracks than deposits with higher crack counts. Therefore, highly microcracked deposits are as resistant to corrosion as sparsely microcracked deposits.

Microcracks are not as detrimental to corrosion resistance as might be expected. There are two reasons for this. First, the microcracks are not voids, but are areas with a structure and composition that are different from those of the bulk. Second, because the microcracks are very narrow (about 0.1 μm wide) and because water does not wet chromium, the water does not readily enter the microcracks.

Microcrack-free thick chromium deposits can be plated from baths at low current densities and high temperatures. These microcrack-free deposits provide better corrosion protection than microcracked chromium. However, these deposits are highly stressed and are not as hard as microcracked chromium. Crack-free deposits can be used when corrosion protection is the only requirement for the deposit. Postplating grinding or cutting may cause pickout (chromium fracturing from chromium) in highly stressed deposits. The conditions under which some crack-free coatings are deposited will result in a deposition efficiency that is lower than that normally observed for the plating bath.

Additional Deposit Properties Influencing Corrosion. Hardness is related to microcracking, which is related to corrosion. Chromium coatings have hardnesses between 850 and 1050 HK (100-gf load). Microcrack-free deposits can have hardnesses as low as 600 or 300 HK (Ref 2). According to one study, as deposit hardness increases or crystal size decreases, the rate of attack by sulfuric acid (H_2SO_4), hydrochloric acid (HCl), and CrO_3 decreases (Ref 3).

Coating Thickness

Figure 2 shows that the corrosion resistance of hard chromium plated steel in salt spray undergoes a maximum and a minimum, then increases with the chromium thickness (Ref 4). Figure 2 also shows the average of two panels in a salt spray exposure. Maximum corrosion resistance occurred at a chromium thickness of about 5 μm (0.2 mils). As the thickness increased above 5 μm (0.2 mils), microcracking occurred and corrosion resistance decreased. When the chromium thickness increased to about 10 μm (0.4 mils), the initial cracks were covered by more chromium, there were fewer corrosion paths to the substrate, and the corrosion resistance of the deposit increased. These deposits were plated from a conventional bath containing 250 g/L of CrO_3 and 2.5 g/L of H_2SO_4 at 31 A/dm^2 (2 A/in.^{2}); no temperature was specified.

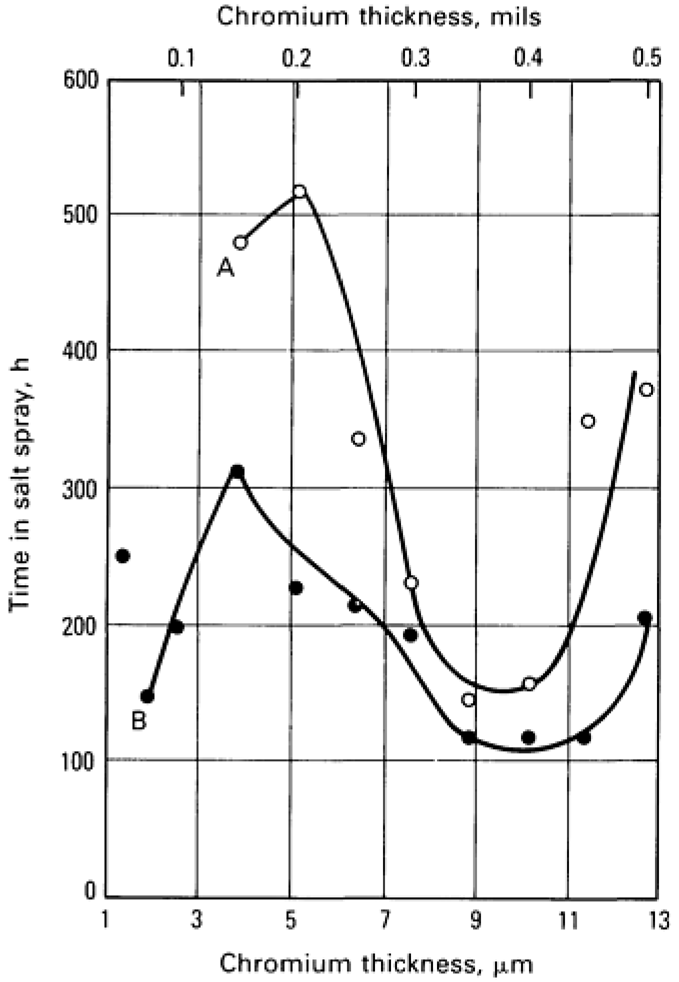

Fig. 2 Chromium corrosion in salt spray versus thickness of deposit. Curve A shows time to general rust; curve B is for time to initial corrosion. Parts were plated in a conventional bath (250 g/cL CrO_3 and 2.5 g/L SO_4^{2-} at 31 A/dm^2, or 2 A/in.^{2}). Source: Ref 4

Figure 3 shows additional data on corrosion resistance and chromium thickness. The electrodeposits were prepared from a conventional bath containing 295 g/L of CrO_3 and 3 g/L of H_2SO_4. Data are given for two plating conditions: 30 °C (85 °F) at 20 A/dm^2 (1.3 A/in.^{2}) and 60 °C (140 °F) at 43 A/dm^2 (2.8 A/in.^{2}). The first condition produced cold chromium that was crack free and soft. The second condition produced conventional microcracked hard chromium. The cold chromium deposit showed excellent corrosion resistance at thicknesses of 4.8, 9.1, and 12.4 μm (0.2, 0.36, and 0.49 mils), but the corrosion resistance was very poor at a thickness of 15.5 μm (0.6 mils). The 15.5-μm (0.6-mil) coating was not porous, and no reason was given for its poor corrosion resistance. The high stress in the coating and the poor adhesion of cold chromium may have resulted in coating failure. The thinner (<15 μm, or 0.59 mils) cold chromium coatings performed much better than the conventional chromium deposits.

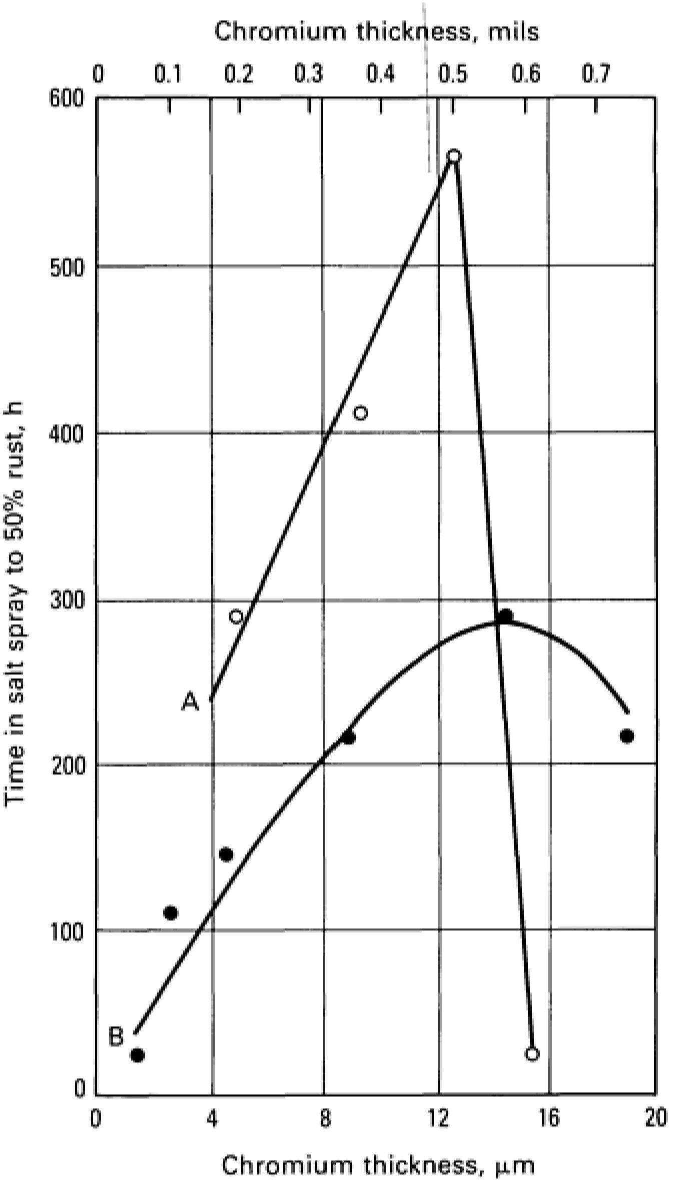

Fig. 3 Chromium corrosion in salt spray versus thickness of deposit. The electrodeposits were plated from a conventional bath (295 g/L CrO_3 and 3.0 g/L SO_4^{2-}) at two conditions: 20 A/dm^2 (1.3 A/in.^{2}) at 30 °C (85 °F) (curve A) and 43 A/dm^2 (2.8 A/in.^{2}) at 60 °C (140 °F) (curve B). Source: Ref 5

The conventional deposits shown in Fig. 2 do not exhibit the trend observed in Fig. 3. The thickest deposit (18.8 μm, or 0.74 mils) did show a slight decrease in corrosion resistance relative to the 14.4 μm (0.57 mil) deposit. Statistically, however, the corrosion resistance was the same for the two coating thicknesses.

Basis Metal Preparation

The importance of basis metal preparation and its effect on corrosion are discussed in Ref 4. Table 1 shows that corrosion resistance improves as the surface finish of the basis metal improves. The improvement is significant for both 24- and 150-h salt spray exposures. Superfinishing the parts before plating produces a smooth finish after plating that has fewer nodules. Large nodules are plated at a higher localized current density and may lead to the presence of local cells on the surface.

Table 1 Corrosion of chromium-plated parts in salt spray

Five different carburetor parts were plated with between 1.3 and 1.9 μm (0.05 and 0.075 mils) of chromium; four parts of each type were used in the test.

Condition of parts before plating	Average corrosion rating[(a)]	
	After 24 h	**After 150 h**
Unfinished	1.6	3.0
Roto-finished[(b)]	1.3	2.6

(a) Corrosion ratings: 0, none; 1, very light initial corrosion; 2, light localized corrosion; 3, light general corrosion.

(b) Parts were prepared by tumbling in a barrel containing granite chips for 1.5 h.

Defects in the basis metal that cause pits or atypical cracking expose the basis metal to corrosive media (Ref 6). Gas pits are usually caused by particles in or on the substrate surface that have a low hydrogen overvoltage. These pits can occur on overetched cast iron parts and on re-worked parts that have not been baked after stripping.

The composition of the basis metal will significantly improve the corrosion resistance of thin deposits if the basis metal is corrosion resistant. On thicker deposits, the substrate may affect corrosion by influencing adhesion or the stress of the deposit (microcracks).

Postplating Treatment

Chromium is often plated on hardened steel parts, and these parts will retain some of the hydrogen that is codeposited with the chromium. It is necessary to bake these parts after plating in order to reduce hydrogen embrittlement. Baking will affect corrosion in two ways. First, it will develop (open up) the microcracks. Immersion in boiling water is used to make cracks visible so that they can be counted after the part is reverse etched. Second, if the temperature is high enough, it will reduce the stress in the deposit (Ref 1). This reduced stress will decrease stress-corrosion cracking (SCC). Stress-corrosion cracking occurs at pits or grooves in the coating caused by differences in potentials at the bottom of the groove. The bottom of the groove will be dissolved anodically and will deepen the groove (Ref 7).

In one study, diamond (compacting) and baking in oil after plating improved the corrosion resistance of electrodeposited chromium (Ref 8). Diamond smoothing at forces of 10 and 15 kgf (22 and 33 lbf) after baking improved the corrosion resistance of 9- to 25-μm (0.35- to 1-mil) thick and 50- to 80-μm (2- to 3-mil) thick chromium coatings relative to samples that were not smoothed. Chromium-plated samples baked in oil were much more corrosion resistant than samples baked in air. Both methods sealed pores or cracks in the chromium, which improved the corrosion resistance. Superfinishing techniques may also seal pores and cracks and enhance corrosion resistance. In addition, mechanical recompression of electrodeposited chromium improves corrosion resistance (Ref 9).

Grinding of a chromium-plated part to finished dimensions should be performed with adequate cooling and lubrication. Excessive forces and heat may cause macrocracking of the chromium down to the basis metal. Coarse grinding will promote SCC.

The passivation of chromium by exposure to air or by immersion in oxidizing acid will significantly improve its corrosion resistance (Ref 10). In one study, nitrogen ion implantation of a chromium-plated molding tool improved the corrosion

resistance of the part to molding gases and fluids and increased its service life by more than four times (Ref 11). Postplating treatments are extensively discussed in Ref 12.

Corrosion Resistance Data

Corrosion of hard chromium deposits usually begins at microcracks or intersections of microcracks (Ref 10). After moderate acid attack, the corrosion reveals the microcrack pattern. Attack will continue on all of the chromium, and the microcrack pattern will no longer be visible. The corrosion of chromium in sodium chloride (NaCl) solutions will produce mounds of corrosion products. When these mounds are removed, concentric rings define the attacked area. The center and outside area are unattacked.

Chromium-plated steel with and without diffusion treatment at 1000 °C (1830 °F) resists corrosion by sodium polysulfides (Na_2S_4, Na_2S_5) and sulfur at temperatures to 440 °C (825 °F). In a 12-month static test, chromium-diffused samples (plating thickness: 50 to 200 μm, or 2 to 8 mils) performed better than the as-plated samples (Ref 13). Tables 2, 3, 4, and 5 provide detailed data on the corrosion of hard chromium in various media.

Applications

Electrodeposited chromium is used in a wide variety of applications and environments. Reference 15 includes a listing of 38 industrial categories with 315 specific applications of electroplated chromium. The corrosion resistance of electroplated chromium is important in wear applications. The wear resistance of a part will decrease if corrosion occurs on a wearing surface--for example, shocks and struts. Industrial applications in which chromium is not exposed directly to aggressive chemicals may expose chromium coatings to elevated temperature and corrosive environments, such as combustion products.

Electroplated chromium for atmospheric-corrosion applications should be between 20 and 30 μm (0.8 and 1 mil) thick. For corrosion resistance in chemical exposures, electroplated chromium should be 50 to 75 μm (2 to 3 mils) thick. Electroplated chromium is attacked at 58 °C (135 °F) in formic acid (HCOOH), hydrobromic acid (HBr), HCl, perchloric acid ($HClO_4$), H_2SO_4, and trichloroacetic acid (CCl_3COOH) and is attacked at 12 °C (55 °F) in hydrofluoric acid (HF). Hot (58 °C, or 135 °F) solutions of ferric chloride ($FeCl_3$), mercuric chloride ($HgCl_2$), and stannous chloride ($SnCl_2$) attack electroplated chromium more severely than most other salt solutions.

Corrosion of Brazed Joints

M.M. McDonald, Rockwell International

Introduction

CORROSION is a concern for many reasons when materials are brazed. Brazing involves the joining of dissimilar metals; therefore, galvanic corrosion or preferential attack is a possibility. Also, many of the fluxes used in brazing are corrosive; therefore, if improper cleaning does not remove all of the flux or if poor joint design results in flux entrapment, corrosion may result. Poor joint design may also contribute to corrosion by the introduction of stresses.

The corrosion behavior of brazed joints is a complicated phenomenon. The interacting factors include the brazing procedure, the materials, and the environment. The pertinent steps of the brazing procedure include joint design, heating process selection, flux selection, and cleaning. Material factors include selection of the base materials and the brazing alloy. The corrosiveness of an environment depends primarily on the relative concentration of water and impurities, the ability of electric currents to exist, and the presence or absence of oxidizing agents (Ref 1). The velocity and temperature of the environment are often important factors as well.

This article consists of four main sections. The first section provides background information on brazing. The second section briefly describes the major types of corrosion that are of importance in brazing, and the third section discusses the role of proper brazing procedures in minimizing corrosion. The fourth and major section reviews the work done to date on the corrosion behavior of the major classes of filler alloys. Additional information on brazing methods and practices can be found in *Welding, Brazing, and Soldering,* Volume 6 of the *ASM Handbook.*

Background on Brazing

The American Welding Society (AWS) defines brazing as a group of welding processes that produce coalescence of materials by heating them to a suitable temperature and using a filler metal having a liquidus above 450 °C (840 °F) and below the solidus of the base materials; the filler metal is distributed between closely fitted surfaces of the joint by capillary attraction (Ref 2). Brazing processes are generally classified according to the sources or methods of heating, such as torch, furnace, induction, dip, or infrared. The general procedure for brazing is discussed in the following section.

Brazing offers certain advantages over other joining processes. These advantages, which stem mainly from the lower heating temperatures (Ref 2, 3, 4), include the elimination of warping; increased joining speed; high production rates (due to simultaneous brazing); reduction of the effects of expansion, contraction, and distortion; reduced chance of locked-in stress; and reduced expense. The metals that are commonly brazed include aluminum, magnesium, copper, and their alloys; stainless steels; low-carbon and low-alloy steels; cast iron; nickel-base and cobalt-containing alloys; and alloys containing the reactive metals titanium, zirconium, and beryllium.

Major Types of Corrosion Important in Brazing

All types of corrosion can be observed in brazed joints. The types of corrosion that affect materials in a brazed joint are similar to those that affect the materials in service individually. Certain types of corrosion are seen more frequently in brazed joints because of conditions that are inherent in brazing. For example, because brazed joints are bonds of dissimilar metals, galvanic corrosion is always a concern. Interfacial corrosion is also of particular concern in brazed joints. In the following sections, the forms of corrosion will be briefly discussed as they pertain to brazed joints.

General Attack. All metals will exhibit general corrosion in some corrosive medium. Because two or three different types of metals are part of a brazed joint, the behavior of each different metal in the service environment must be considered with respect to the possibility of general attack. This type of corrosion is uniform; therefore, failure by this mechanism can be predicted on the basis of relatively simple tests in which the rate of dissolution is determined. Additional information is available in the articles "General Corrosion" and "Evaluation of Uniform Corrosion" in this Volume.

Galvanic Corrosion. A potential difference usually exists between two dissimilar metals immersed in an electrolyte. This potential difference produces electron flow between the metals, leading to increased attack of the less corrosion-resistant material and decreased attack of the more resistant material as compared to the behavior of these metals when they are not in contact (Ref 5). Because brazing is often performed when metallurgical incompatibility precludes the use of other welding processes, many dissimilar-metal combinations are brazed. Therefore, galvanic corrosion is always a concern, and the galvanic series for the service environment should be consulted. Table 1 is the galvanic series for seawater.

In determining the potential for galvanic corrosion in a brazed joint, environmental, distance, and area effects must be considered, as well as position in the galvanic series (Ref 5). In brazing, moisture is generally the most important environmental factor. Moisture enables the electrolyte to carry current between the two electrode areas; therefore, the corrosion rate generally increases with humidity (Ref 6), and keeping the materials dry inhibits corrosion. A critical humidity level exists for most metals above which corrosion proceeds rapidly--for example, 100% for copper, 85% for certain nickel alloys, and 65% for iron (Ref 7). Galvanic corrosion is readily recognized by the somewhat localized attack near the junction and by the decreasing evidence of attack with increasing distance from the junction. The distance over which galvanic corrosion is evident depends on the conductivity of the solution. An unfavorable area ratio consists of a large cathode (the more corrosion-resistant material) and a small anode (the less corrosion-resistant material); for a given current flow, the current density is greater for the smaller electrode than for the larger one.

Knowledge of the factors that influence galvanic corrosion enables determination of a practice that would minimize the occurrence of this phenomenon. Practices that accomplish this include selecting combinations of metals as close together as possible in the galvanic series, avoiding unfavorable area effects, and reducing moisture as much as possible. Additional information is available in the articles "General Corrosion" (in particular, the discussion of galvanic corrosion) and "Evaluation of Galvanic Corrosion" in this Volume.

Crevice Corrosion and Pitting. Within a crevice or other shielded area on a metal surface, stagnant solutions may lead to localized attack, or crevice corrosion (Ref 8). Lap brazed joints are a potential site for crevice corrosion. The geometry of lap joints creates conditions that are favorable for stagnant-solution buildup. The possibility of crevice corrosion can be minimized by making sure that the braze is continuous along the joint.

Pitting is an extremely localized form of corrosion. A pit may form at imperfections in the metal surface, such as grain boundaries, or at crevices or other areas of stagnant electrolyte (Ref 5). Additional information is provided in the articles "Localized Corrosion" (in particular, the discussions of crevice and pitting corrosion), "Evaluation of Crevice Corrosion," and "Evaluation of Pitting Corrosion" in this Volume.

Dealloying corrosion, or selective leaching, is the preferential removal of one component from an alloy. A classic example of selective leaching is the dezincification of brass. During dezincification, the brass actually dissolves, and the copper redeposits on the remaining brass (Ref 8). An example of dezincification of a brass tube soldered to a copper tube is shown in Fig. 1.

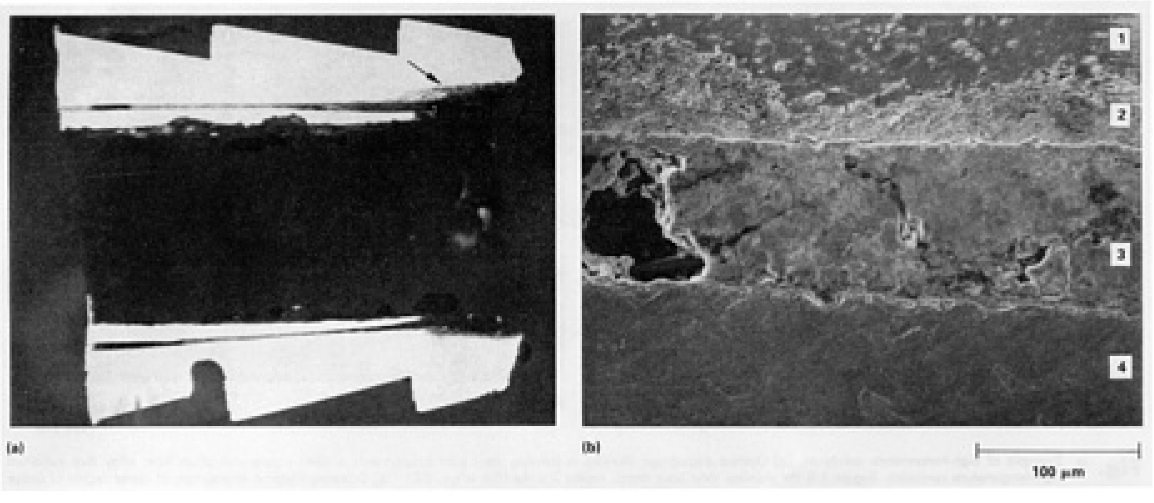

Fig. 1 Example of selective leaching. (a) Macrograph of a brass tube soldered to a copper tube. The arrow indicates the region of dezincification. 6.5×. (b) Scanning electron micrograph of the region of dezincification. Region 1, brass base metal; 2, dezincification zone; 3, lead-tin solder; 4, copper base metal. 275×. Source: Ref

Because selective leaching involves only one alloy, brazing does not increase the possibility of the occurrence of selective leaching. If an alloy susceptible to selective leaching is used in a brazed joint, however, the possibility of its occurrence should be considered. Additional information is available in the article "Metallurgically Influenced Corrosion" (in particular, the discussion of dealloying corrosion) in this Volume.

Interfacial Corrosion. Three conditions are necessary for interfacial corrosion (Ref 10). First, one member of the joint must be stainless steel. Second, the brazing alloy must be susceptible to this form of attack; that is, it must contain a copper-zinc rich phase. Third, the finished joint must be exposed to damp or wet conditions. The exact nature of this form of corrosion is under dispute. Several mechanisms have been proposed to explain the failure of brazed joints under these circumstances. Two of the more popular theories are (1) crevice corrosion based on an oxygen concentration and potential gradient across the brazing alloy and base metal (Ref 11, 12, 13, 14, 15) and (2) selective dissolution of the copper-zinc rich phase at the braze/steel interface and redeposition of the copper, that is, selective leaching or dezincification (Ref 16, 17, 18). Figure 2 schematically shows crevice formation and deposition of corrosion products on the metal surface. Other proposed mechanisms include oxygen deficiency (Ref 19), electrochemical action between the base and filler materials in the electrolyte (Ref 20), and chromium diffusion into the brazing alloy with the creation of a chromium-depleted zone at the base metal (Ref 21).

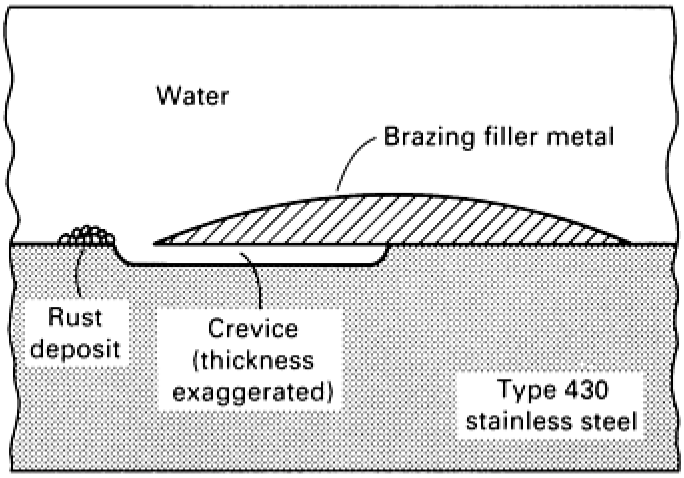

Fig. 2 Crevice formation and deposition of corrosion products on the stainless steel surface

The susceptibility of a brazed joint to interfacial corrosion depends on the type of filler alloy, the type of stainless steel, the service environment, and to some extent even the brazing technique (Ref 10). Polishing the finished joint has also been found to affect the likelihood of attack (Ref 10). Unfortunately, the most common brazing techniques, those using a silver-containing filler alloy and a flux, create the conditions under which joints are most susceptible to failure. Table 2 lists the available information related to the susceptibility of various alloys and base metal combinations to interfacial corrosion.

Table 2 Susceptibility of brazing alloy/stainless steel types to interfacial corrosion

Brazing alloy type	Susceptibility of steel type[a]	
	Ferritic	**Austenitic**
Ag-Cu-Zn-Cd	C	D
Ag-Cu-Zn	C	D
Ag-Cu-Zn-Cd-Ni	D	B
Ag-Cu-Zn-Ni	D	B
Ag-Cu-Zn-Ni-Mn	D	B
Ag-Cu-Zn-Sn	D	B
Ag-Cu-In-Ni	A	A
Ag-Cu-Sn-Ni	A	A
Ag-Cu (silver copper eutectic)	C	C
Ag-Mn(15% Mn-Ag)	C	C
Palladium-containing alloys	A	A
Gold-containing alloys	A	A
Nickel-base alloys	A	A
High-copper alloy	A	A

Source: Ref 10

(a) The designations are as follows: A, should be resistant under most conditions; B, may offer limited or complete protection, depending on conditions; C, rapid joint failure can be expected in a very short period; D, joint failure likely to occur after some time (less rapid than above).

All types of stainless steel are susceptible to attack by interfacial corrosion. Low-nickel ferritic and martensitic stainless steels are more susceptible to attack and suffer a more rapid rate of corrosion than the austenitic grades (Ref 10). In the case of such austenitic stainless steels as types 302, 304, and 316, the use of a brazing filler metal containing a small amount of nickel apparently eliminates interfacial corrosion completely (Ref 15). The use of a nickel-containing filler alloy also retards interfacial corrosion in type 430 stainless steel (Ref 15). The presence of nickel in the filler alloy is

beneficial because it is the major constituent of an interfacial layer that forms between the steel and filler alloy when these filler alloys are used (Ref 10).

Brazing in the absence of flux, that is, in dry hydrogen, inert gas, or vacuum, appears to eliminate interfacial corrosion in straight chromium stainless steels and chromium-nickel stainless steels (Ref 15). A notable exception is when certain brazing filler metals containing manganese are used (Ref 22). Evidently, manganese diffuses from the filler alloy into the surface of the stainless steel and produces a vulnerable manganese-rich layer.

Erosion-corrosion is the increase in rate of attack on a metal because of relative motion between a corrosive fluid and the metal surface. Impingement, fretting, and cavitation are the three most important types of erosion-corrosion. Erosion-corrosion may be equally detrimental to braze filler alloys and base metals because much of the effect is mechanical in nature (Ref 1). Inappropriate brazing practices, particularly designs that have rapid changes in section, have been shown to result in failure (perforation) at brazed joints due to erosion-corrosion (Ref 23). Additional information is available in the articles "Mechanically Assisted Degradation" (in particular, the discussion on erosion-corrosion) and "Evaluation of Erosion and Cavitation" in this Volume.

High-Temperature Corrosion. Corrosion may occur at elevated temperatures by mechanisms similar to those at lower temperatures. The most common type of high-temperature corrosion is oxidation. Oxidation can be defined as the loss of electrons by a constituent in a chemical reaction (Ref 24). Therefore, the phenomenon of oxidation includes attack by carbon oxides, sulfur compounds, nitrogen, and hydrogen, as well as oxygen. Corrosion testing of brazed joints often involves high-temperature exposure of the joints to various environments. The brazing filler alloys that are most resistant to oxidation are those containing a high percentage of noble elements and those that form tenacious protective films (Ref 1). Examples of such filler alloys are the gold- and nickel-base alloys. In addition, if the flux used during the brazing process is not completely removed from a joint, its presence may lead to corrosion of the joint at elevated temperatures.

An example, of high-temperature corrosion is given in Fig. 3. In this example, the copper in the silver-copper-palladium filler alloy oxidized. The alloy was used to braze stainless steel. Additional information is available in the articles "Fundamentals of Corrosion in Gases" and"General Corrosion" (in particular, the discussion of high-temperature oxidation/sulfidation) in this Volume.

Stress-Corrosion Cracking (SCC). Unfortunately, there is considerable confusion and controversy concerning the classification of SCC phenomena. In this context, SCC refers strictly to the situation in which a metal that is subject to a constant tensile stress and exposed simultaneously to a specific corrosive environment cracks immediately or after a given time (Ref 26). The stress may be residual in the metal or may be externally applied. Failure may be either intergranular or transgranular. Of particular interest in brazing is the susceptibility of copper-base alloys to SCC in the presence of ammonia.

Few documented failures of brazed joints have been attributed to SCC, probably because they were not identified as such (Ref 1). Some results of SCC tests on brazed joints have been reported in the literature. For example, one study examined the stress-corrosion behavior of Ti-6Al-4V butt joints brazed with aluminum-copper filler alloys and smooth Ti-6Al-4V base metal specimens in 3.5% sodium chloride (NaCl) at room temperature under a tensile stress of 714 MPa (102 ksi) (Ref 27). The joints and specimens were found to be essentially immune to SCC after 1000 h of exposure. In another study, all of the titanium joints tested were found to be unsusceptible to SCC in the environments to which they were exposed (Ref 28). These tests involved titanium joints brazed with aluminum-base filler alloys exposed to aqueous 3.5% NaCl at room temperature and to dry NaCl at 150 °C (300 °F) under a load of 91 to 105 MPa (13 to 15 ksi) for 500 h. Additional information is available in the articles "Environmentally Induced Cracking" (in particular, the discussion of SCC) and "Evaluation of Stress-Corrosion Cracking" in this Volume.

Liquid-Metal Embrittlement (LME). Many materials (including stainless steels, nickel alloys, and copper-nickel alloys, particularly age-hardenable ones) will crack during brazing if they are stressed while in contact with the molten brazing metal (Ref 2). The cracking occurs virtually instantaneously during the brazing operation, and the molten filler metal follows the fills in the cracks, making them easily visible. This type of failure is known as LME. Although LME is not, strictly speaking, a corrosion phenomenon, it is often discussed in the context of SCC. This is presumably because both mechanisms are often categorized as forms of stress cracking.

An example of LME of TZM (Mo-0.5Ti-0.08Zr-0.015C) brazed with a gold-base filler alloy is shown in Fig. 4. The backscattered electron micrograph taken in the scanning electron microscope highlights the filler alloy present in the cracks of the base metal. Similar behavior has been observed in molybdenum brazed with goldbase filler alloys (Ref 30).

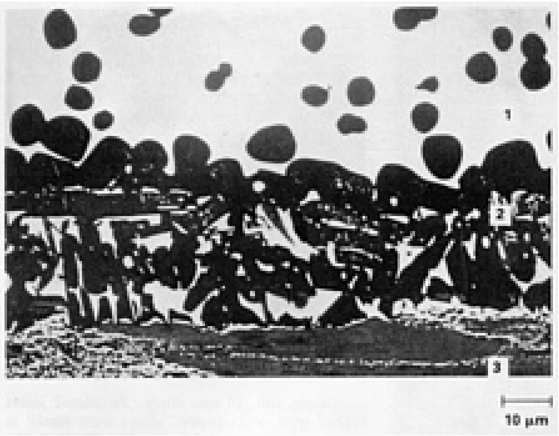

Fig. 4 Backscattered electron micrograph of TZM molybdenum-base metal that exhibited stress cracking due to thermal stresses and the presence of molten gold-base filler alloy. Region 1 is the filler alloy, region 2 is an intermetallic phase formed by interaction between base metal and braze alloy, and region 3 is the TZM base metal. The cracks in the base metal are quite evident because of the penetration of the filler alloy. Source: Ref 29

Liquid-metal embrittlement is generally believed to be specific; that is, a particular solid will be significantly embrittled only by certain specific liquid metals (Ref 26, 31). The problem of determining which solid metal/liquid metal combinations will exhibit LME is complicated by the fact that this phenomenon is strongly dependent on temperature and strain rate. The solid iron-base alloys/liquid copper combination has received considerable attention. Many investigators have shown that this combination is susceptible to embrittlement (Ref 32, 33, 34, 35, 36, 37). In a series of studies, the mechanism of cracking in a number of stainless steels, steels, and superalloys was identified as LME by molten copper (Ref 38, 39, 40). Another investigation showed that the austenitic stainless steels are severely embrittled by copper and high-copper braze alloys and that the base metals are nearly unaffected by silver-base braze alloys (Ref 31). In addition, it was found that a type 430 ferritic stainless steel was not embrittled by any of the several liquid braze alloys to which it was exposed, namely copper and several copper-base alloys, several silver-base alloys, aluminum, and gold (Ref 31). Liquid-metal embrittlement has been eliminated by (Ref 2):

- Removing the source of an externally applied stress as determined from a critical analysis of the brazing

process

- Redesigning parts or revising joint design
- Selecting a brazing filler metal that is less likely to cause LME in the substrate

Solid-phase embrittlement refers to the phenomenon of brittle-phase formation in the region of the brazing alloy/base metal interface. The presence of this brittle phase can lead to cracking. Like SCC, solid-phase is not, strictly speaking, a corrosion phenomenon. However, it is discussed here because it is also often categorized as a stress-cracking phenomenon. Embrittlement of base metals containing more than a few percent nickel or iron is known to occur when filler alloys containing free phosphorus are used for brazing (Ref 41). Another example of solid-phase embrittlement is sulfide formation in nickel-base alloys by reaction of the base metal with a brazing atmosphere containing sulfur compounds or from contamination from sulfurized cutting oil (Ref 41).

Figure 5 shows the presence of β', a brittle beryllium-copper intermetallic phase that formed at the interface of beryllium and a silver-copper filler alloy in a braze between beryllium and Monel. In this case, the occurrence of the brittle intermetallic phase was suppressed by coating the beryllium with titanium hydride prior to brazing (Ref 43).

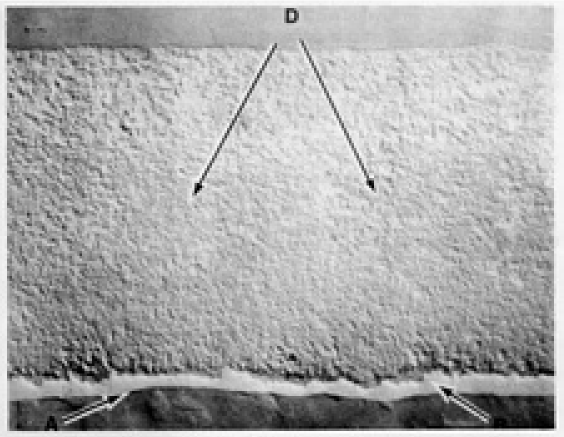

Fig. 5 Optical micrograph of a cross section of a beryllium-to-Monel joint brazed with a silver-copper filler alloy. Arrow A points to a beryllium-copper intermetallic phase, arrow B points to a copper-beryllium intermetallic phase, and arrow D points to the copper-nickel-beryllium reaction matrix. 330×. Source: Ref 42

Intergranular corrosion refers to the phenomenon of localized attack at and adjacent to grain boundaries, with relatively little corrosion of the grains. Sensitization of stainless steels is a classic example of intergranular corrosion. Sensitization occurs because of chromium depletion near the grain boundaries caused by precipitation of chromium carbides at the grain boundaries. The chromium-depleted zone near the grain boundaries may then corrode because it does not contain sufficient corrosion resistance to resist attack in many corrosive environments. Figure 6 shows sensitization of a stainless steel joint that was overheated during brazing with a silver-copper-palladium filler alloy (Ref 25). In general, sensitization is not a concern when brazing properly with silver-base filler alloys, because of the low brazing temperatures. When brazing stainless steels with copper-base filler alloys, however, care should be taken to cool quickly through the 510- to 790- °C (950- to 1450 °F) temperature range in which sensitization occurs. Additional information is available in the articles "Metallurgically Influenced Corrosion" (in particular, the discussion of intergranular corrosion) and "Evaluation of Intergranular Corrosion" in this Volume.

The Role of Proper Brazing Procedures In Minimizing Corrosion

Efforts to minimize the occurrence of corrosion can be made at each step of the brazing process. These steps include joint design, selection of materials, brazing process and flux, and final cleaning.

Joint Design. In designing a joint that is to be brazed, attention should be given to geometries that may make a joint more susceptible to corrosion. For example, if an assembly is to be pickled, the internal geometry of the entire assembly should allow complete exchange of pickling and cleaning solutions (Ref 41). If a lap joint is to be fabricated, the possibility of the geometry leading to the buildup of stagnant solution should be considered. If a butt joint is to be fabricated, the efficiency of the joint is maximized by making sure the joint has no defects, such as entrapped flux, voids, incomplete joining, and porosity (Ref 1, 44). These defects, in addition to impairing the structural integrity of the joint, may increase the susceptibility of the joint to corrosion. Entrapped flux may lead to high-temperature corrosion, and incomplete joining may lead to crevice corrosion.

The concept of distributing the stress in the joint as evenly as possible is also important in joint design. If the stress is concentrated, the conditions for SCC may exist. Reference 3 provides suggestions for distributing stress.

Materials Selection. In addition to the material properties normally considered, such as strength, the selection of the materials for a brazed joint should involve consideration of the potential for corrosion. In particular, the appropriate galvanic series should be consulted (Table 1). Also, attention should be paid to the susceptibility of certain alloys to other types of corrosion, such as selective leaching and general attack. The service environment often dictates the potential of corrosion. Alloy systems are discussed in more detail later in this article and in the Section "Specific Alloy Systems" in this Volume.

Brazing Process Selection. Brazing processes are generally classified according to the sources or methods of heating, such as torch, furnace, induction, dip, or infrared (Ref 2). Table 3 summarizes the major advantages and disadvantages of these common methods of brazing. The intensity of the heat source can play a role in the distribution of stress and the formation of phases. If the material is known to be susceptible to SCC, the distribution of thermal stresses should be considered. If an alloy system is susceptible to brittle-phase formation, the temperature and time at temperature the alloy is subjected to should be considered in choosing the brazing process. The susceptibility of alloy systems to brittle-phase formation may be determined by examining phase diagrams or consulting the literature.

Table 3 Advantages and disadvantages of some common brazing methods

Method	Advantages	Disadvantages
Torch	Inexpensive; lower temperature; small parts	Need flux; oxidation
Vacuum furnace	Fluxless; prevents oxidation; good temperature control	Higher temperature (because fluxless); expensive; slow heating
Induction	Localized heating; atmosphere or vacuum conditions; fast heating	Poorer temperature control
Dip	Good temperature control; small parts	Part cleanup
Infrared	Able to do large parts fluxless	Slow heating

Torch brazing is a method of brazing that may involve the use of a low-temperature, air-gas, large flame to minimize the possibility of localized overheating (Ref 41). Localized overheating may overstress a filler alloy as it solidifies if the metal is sufficiently restrained. Cracking may then result from the overstressing. Induction heating can be used to keep a uniform temperature distribution around the joint to prevent the stress concentrations from thermal expansion and contraction that may lead to stress cracking. Vacuum brazing has the advantage of thoroughly degasing the material and protecting the materials from oxidation and other forms of high-temperature corrosion. The cost of vacuum brazing, however, may preclude its use.

The Brazing Procedure. To achieve a good joint by any method of brazing, it is necessary to follow certain guidelines (Ref 2, 45). The parts must be properly cleaned before brazing, and they must be protected by fluxing or by the use of an inert atmosphere during the heating process to prevent excess oxidation or other forms of high-temperature corrosion. Also, as previously discussed, the proper filler alloy, flux, and joint design must be chosen, and a heating process must be selected that will provide the proper brazing temperature and heat distribution. Guidelines for the selection of filler alloy and flux are available in Ref 46 and in *Welding, Brazing, and Soldering,* Volume 6 of the *ASM Handbook.* Finally, the braze joint must be cleaned to remove flux residue and any oxide scale formed during the brazing process. Flux removal is particularly important because flux residues are often chemically corrosive and, if not removed, could possibly weaken certain joints. Figure 7 shows a copper to stainless steel joint that exhibited corrosion products as a result of improper flux removal.

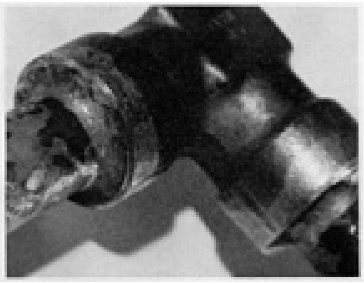

Fig. 7 Macrograph of a copper to stainless steel braze joint that exhibited corrosion products as a result of improper flux removal. 1×. Source: Ref 47

Corrosion Resistance of Brazed Joints

The corrosion resistance of brazed joints involves the individual and collective corrosion resistance of the base metals and the filler alloys. This section will summarize the work done to date on characterizing the behavior of the main categories of braze filler alloys in corrosive environments. A more detailed discussion of this topic is provided in Ref 1. The articles in this Volume on the corrosion of specific metals and alloys should also be consulted. American Welding Society designations for the classes of filler alloys discussed in this section are contained in Ref 2.

Silver-Base Filler Alloys. The class of silver-base filler alloys is used to braze most types of base metals. Examples of alloy systems brazed with silver-base alloys referred to in this section include titanium to titanium, zirconium to zirconium, aluminum to titanium, copper to copper, and stainless steel to stainless steel.

In general, the corrosion resistance of silver-base filler alloys is similar to that of other nonferrous metals used for their low-temperature corrosion-resistant properties (Ref 1). These brazing alloys are unsuitable for use with strong mineral acids, although the attack is slow enough to allow pickling in sulfuric (H_2SO_4) or hydrochloric (HCl) acids for cleaning (Ref 24).

Many corrosion tests involving silver-base filler alloys have been performed in saltwater environments. For example, titanium joints, brazed with silver-aluminum-manganese filler alloys, that were exposed to 50 h of salt spray and were flexure tested failed sooner if the filler alloy contained a lower amount or no manganese (Ref 48, 49). However, in another test, aluminum brazed to titanium with silver or silver-aluminum alloys exhibited very limited damage after salt spray exposure of over 250 days (Ref 50). In addition, a researcher found that the silver-copper-zinc filler alloy of stainless steel joints corroded out by interfacial corrosion after 1 month of exposure to a NaCl solution (Ref 21). Another researcher obtained similar results for exposure to NaCl solutions and related the decreased interfacial corrosion resistance to increasing zinc content of the filler alloy and increasing nickel plus chromium content of the base metal (Ref 51).

Many corrosion tests involving silver-base filler alloys have also been performed in water not containing salt. In one study, Zircaloy-2 joints brazed with silver-copper alloys were tested in pressurized water at 360 °C (680 °F) (Ref 52). Straight silver-copper alloys and silver-copper alloys with a small amount of silicon failed (separated) in 154 h or less. Silver-copper alloys containing 10% Sn did not fail in 1250 h; the filler alloy, however, was completely oxidized. Another researcher tested copper joints brazed with a silver-tin alloy for $1\frac{1}{2}$ to 2 years (Ref 53). The filler alloy with the highest amount of tin exhibited the least amount of corrosion, but the corrosion was heavy after 22 months for this alloy.

A problem with galvanic corrosion would be expected when aluminum is coupled with titanium. However, no evidence of galvanic corrosion was found in aluminum-to-titanium joints brazed with silver-base alloys tested in simulated and actual aircraft service environments (Ref 50). Another researcher tested aluminum brazed to titanium with silver-base (silver-aluminum) alloys under weathering conditions (Ref 54). Although no galvanic corrosion was found, there was appreciable corrosion of the filler alloy after 3 months and total disappearance of the filler after 1 year.

Silver-base filler alloys have also been tested in other environments. For example, stainless steel joints brazed with silver-copper-zinc alloys were found to exhibit rapid declines in shear strength in a matter of days with exposure to HNO_3, HCl, and H_2SO_4 (Ref 21). In another test, stainless steel joints brazed with silver-copper-palladium and silver-manganese filler alloys were exposed to carbon dioxide (CO_2) + 5% carbon monoxide (CO) at 900 °C (1650 °F) for 5000 h and steam at 700 °C (1290 °F) for 5000 h (Ref 55). In both environments, most of the filler alloy disappeared because of corrosion. A third investigation involved testing of type 410 stainless steel joints brazed with a silver-copper-palladium alloy for oxidation resistance at temperatures ranging from 315 to 650 °C (600 to 1200 °F) for 500 to 1000 h (Ref 56). The filler alloy exhibited less than 0.025 mm (1 mil) of penetration after exposure to 315 °C (600 °F) for 500 h, and it exhibited a completely oxidized filler after exposure to 540 °C (1000 °F) for 1000 h. Lastly, Inconel joints brazed with a silver-palladium-manganese alloy were exposed to air at elevated temperatures (Ref 57). At 815 °C (1500 °F), the oxidation penetrated more than 0.13 mm (5 mils) after 200 h, and the filler was completely destroyed after exposure at 925 °C (1700 °F) for 200 h.

Silver-base braze joints are generally discolored by sulfur-containing substances (Ref 24). However, some steel members brazed with silver-base brazing alloys have been successfully used in handling sulfite pulps in paper mills (Ref 58).

Tests have shown that joints brazed with silver-base filler alloys have good long-term oxidation resistance at temperatures to 425 °C (800 °F) (Ref 1). In fact, joints with silver-base filler alloys are being used successfully in engine components having service environments to 425 °C (800 °F) (Ref 56). Additional information on the corrosion of silver and silver alloys is available in the article "Corrosion of the Noble Metals" in this Volume.

Copper-Base Filler Alloys. As a brazing filler alloy, copper is stronger and less expensive than silver. Copper brazing is performed at higher temperatures (1100 °C, or 2000 °F) than silver brazing and therefore requires an exceptional high-temperature flux or controlled atmosphere to prevent oxidation (Ref 59).

As was the case with silver-base filler alloys, many of the studies of the corrosion resistance of copper-base filler alloys have been done on joints involving stainless steel. Copper filler alloys containing, significant amounts of zinc (such as RBCuZn) or phosphorus (such as BCuP) are not recommended for joining stainless steels, because brittle compounds tend to form at the braze/base metal interface when these filler alloys are used (Ref 60). As discussed in the section "Liquid-Metal Embrittlement" in this article, the combination of copper-base brazing alloys and stainless steel base metals is particularly susceptible to LME. The intergranular penetration of stainless steel base metals by copper-base brazing alloys has been investigated (Ref 61, 62). It was found that intergranular penetration could be avoided by using a Ni-13Cr-10P filler alloy (Ref 61). Also, as discussed previously, when copper-base alloys are used to braze stainless steel, care should be taken to cool quickly through the carbide sensitization range.

Many investigators have examined the condition of joints brazed with copper-base filler alloys exposed to water. One study found that copper pipes joined with a copper-phosphorus alloy exhibited no corrosion of the filler alloy after up to 2 years of exposure; the base metal, however, was heavily corroded after as little as 17 months of exposure (Ref 53). In a second investigation, Zircaloy-2 joints brazed with copper-phosphorus alloys exhibited failure after exposure to 360 °C (680 °F) water for as little as 86 h (Ref 52). Similar joints brazed with copper-silver-tin alloys failed after 1200 h of exposure, and a Cu-20Pd-3In alloy appeared virtually unattacked after over 1400 h of exposure. However, in another study, Zircaloy-3 joints brazed with this same filler alloy were tested in the same environment. A marked decrease in the tensile strength and the formation of a black corrosion product at the extremely brittle joint were found (Ref 63). Finally, an examination of copper and cupro-nickel joints brazed with a copper-silver-phosphorus alloy and a copper-zinc-tin alloy found that the copper-zinc-phosphorus joints were susceptible to interfacial corrosion and that the copper-zinc-tin joint exhibited severe corrosion of the β phase in the copper joint (Ref 64).

The behavior of joints brazed with copper-base filler alloys in other environments has also been investigated. For example, Ti-6Al-4V joint diffusion brazed with copper were exposed to air to 425 °C (800 °F) for 100 h, and no degradation of tensile strength of the joint was found (Ref 65). These joints were also examined for corrosion or stress corrosion after exposure at 703 MPa (102 ksi) in 3.5% NaCl for 1000 h; there was no evidence of corrosion. However, the base metal and joints were mildly susceptible to corrosion fatigue, with the joints showing somewhat higher susceptibility than the base metal. In another case, stainless steel joints brazed with copper-base filler alloys exposed to CO_2 + 5% CO at 480 °C (900 °F) for 5000 h exhibited depths of penetration in the filler alloy from 60 μm (2.5 mils) for the 82Cu-18Pd alloy to 0.6 mm (25 mils) for the 52.5Cu-38.5Mn-9Ni alloy (Ref 55). Lastly, a systematic investigation of the oxidation resistance of stainless steel joints brazed with a copper-manganese-cobalt alloy found less than 25 μm (1 mil) of penetration after 1000 h at 425 °C (800 °F), from 50 to 125 μm (2 to 5 mils) of penetration after 1000 h at 540 °C (1000 °F), and more than 125 μm (5 mils) of penetration after 500 h at 650 °C (1200 °F) (Ref 56). Additional information is available in the article "Corrosion of Copper and Copper Alloys" in this Volume.

Nickel-Base Filler Alloys. Brazed joints produced with nickel-base filler alloys are used at temperatures ranging from -200 to above 1200 °C (-330 to above 2190 °F) (Ref 1). The characteristics of nickel make it a good starting point for developing brazing alloys to withstand high service temperatures; it is ductile, and with proper alloying additions, such as chromium, it has excellent strength and oxidation resistant as well as corrosion resistance at elevated temperatures (Ref 61, 66, 67). One investigation involved examination of a series of nickel-chromium-silicon-boron-iron metallic glass filler alloys with varying amounts of chromium used to braze type 410 stainless steel after exposure to saltwater vapor at 540 °C (1000 °F) for 336 h (Ref 68). A strong influence of chromium content on corrosion resistance was found. The chromium-free filler alloy was severely corroded, with both general corrosion and pitting being evident; the high-chromium alloy exhibited only minimal evidence of corrosion. In another study, similar results were obtained for titanium-stabilized austenitic stainless steel brazed with nickel-chromium filler alloys (for example, BNi-2 and BNi-7) and exposed to air at 800 and 850 °C (1470 and 1500 °F) (Ref 69).

Much of the work on the corrosion behavior of nickel-base filler alloys has been done with nickel-base metal joints. One researcher examined the effect of air exposure at 815 °C (1500 °F) for 1 week on a series of 25 nickel-base filler alloys used to braze thin nickel sheet (Ref 70). The nickel-manganese alloys exhibited excellent oxidation resistance, and the nickel-phosphorus alloys exhibited poor-to-good resistance, with resistance increasing with decreasing manganese content. In another study, Inconel joints brazed with nickel-chromium-germanium-lithium, nickel-chromium-germanium-indium, and nickel-chromium-silicon-indium exhibited significant oxidation at 900 °C (1650 °F) after 500 h (Ref 71). In a

third investigation, a nickel-chromium-silicon alloy exhibited good resistance to hot corrosion and sufficiently good resistance to oxidation when used to braze nickel alloy vanes (Ref 72).

Lastly, nickel 201 joints that were vacuum brazed using a nickel-silicon-boron filler alloy according to two different vendor processes were compared (Ref 73). The processes resulted in significantly different thermal exposures, and field failures were found to be a function of the brazing process. The higher-temperature process caused rapid grain-boundary diffusion of boron from the brazing filler metal to the base metal, resulting in intergranular corrosion. The lower-temperature, faster cooling process resulted in less diffusion of the boron; therefore, failure was not intergranular. Crevice corrosion, involving attack of a needlelike nickel boride phase, led to failure.

The oxidation resistance of nickel-base filler alloys has received considerable attention. In addition to the influence of the chromium content of the filler alloy on corrosion, other factors in corrosion behavior have been examined. For example, in one study, there was no effect on austenitic/ferritic stainless steel joints brazed with a series of nickel-base filler alloys (BNi-2,3,6,7) exposed to air at 575 °C (1065 °F) for up to 10,000 h (Ref 74). Another researcher found a continuous oxide layer on the base metal of Inconel 718 joints, but there was no oxide penetration into the nickel-palladium filler alloy region after 200 h at 815 °C (1500 °F) (Ref 75). A third study found that a nickel-chromium-phosphorus and a nickel-chromium-palladium-silicon alloy had good oxidation resistance after 100 h at 800 °C (1470 °F) but that a nickel-manganese-palladium alloy had poor resistance under the same conditions (Ref 76). Finally, a nickel-tin alloy exhibited severe corrosion after exposure in air at 815 and 930 °C (1500 and 1700 °F) for up to 1300 h, but other nickel-base filler alloys, such as nickel-chromium-silicon-boron-iron alloys and nickel-chromium-germanium alloys, that were tested under these conditions exhibited only slight penetration (Ref 57).

Special tests are required for brazed joints that are put into service environments in which liquid-metal coolants, such as sodium or potassium, are used. One researcher recently examined the sodium compatibility of refractory metal alloy/type 304 stainless steel joints brazed with a series of nickel-base filler alloys (BNi-3,5,7) (Ref 77). No significant chemical corrosive attack was observed for any of the joints exposed to a sodium environment at 800 °C (1470 °F) for 130 h. Other researchers had previously conducted extensive studies of the corrosive behavior of nickel-base filler alloys in liquid sodium environments (Ref 57, 71, 78). In other studies, the corrosion behavior of nickel-base filler alloys used to join stainless steel was examined in potassium environments (Ref 79, 80). As shown in Fig. 8, the lower-melting filler alloys (for example, BNi-6,7) exhibited the least corrosion resistance in boiling potassium at 835 °C (1540 °F) for up to 6500 h, but the higher-melting filler alloys (for example, BNi-3,4) suffered minimal attack.

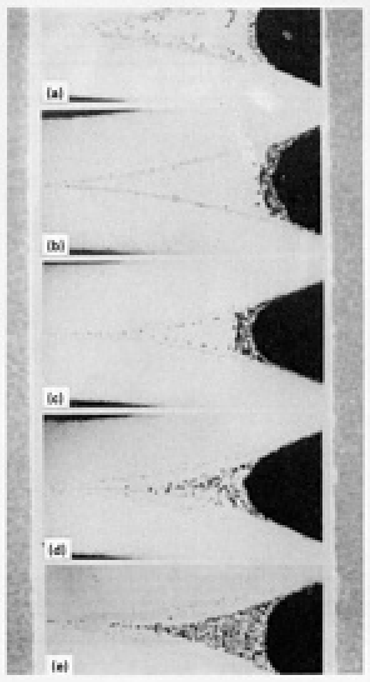

Fig. 8 Type 316 stainless steel brazed with (a) BNi-3, (b) BNi-5, (c) Ni-19Cr-10Si-10Mo, (d) BNi-7, (e) BNi-6, and exposed to potassium at 835 °C (1535 °F) for 6500 h. Source: Ref 79

The corrosion behavior of a series of nickel-chromium-phosphorus alloys used to join stainless steel, Hastelloy X, and a nickel-base alloy was investigated in mixtures of steam and CO_2-CO at ambient and elevated temperatures (Ref 81, 82). All of the filler alloys showed generally good corrosion resistance under all conditions. Additional information is given in the article "Corrosion of Nickel-Base Alloys" in this Volume.

Aluminum-Base Filler Alloys. Aluminum-based brazing alloys are primarily used to braze aluminum. Corrosion in an electrolyte is minimized when using aluminum-silicon filler alloys because the electrolytic potential between the base and braze materials is minimal (Ref 1). Aluminum filler alloys that contain significant levels of zinc or copper exhibit less corrosion resistance, but their resistance is often adequate for all but extremely harsh environments. In addition, when brazing with aluminum-base filler alloys, it is important to remove the flux thoroughly after brazing (Ref 1, 83) because the highly active nature of these fluxes may cause corrosion even by simply absorbing moisture from the air (additional information is available in the article "Brazing of Aluminum Alloys" in *Welding, Brazing, and Soldering,* Volume 6 of *ASM Handbook.*). Removal may be accomplished by immersion in boiling water (Ref 23) or concentrated acid solutions (Ref 2).

The work of one researcher indicated that penetration of the filler alloy into the base metal was a problem when aluminum-silicon-yttrium alloys were used to braze aluminum alloys (Ref 84). In another study, the susceptibility of several aluminum alloys (6951, 6061, 6063, 3003, 3004, 3105) to penetration of aluminum-silicon filler alloys was investigated (Ref 85). Only the alloys 6951 and 6061 were found to exhibit a tendency toward excessive grain-boundary penetration. In studying the pitting corrosion properties of vacuum-brazed 7072 clad A3003 aluminum alloy, it was found that the potential difference between clad and core materials maintained the corrosion resistance of the joint (Ref 86).

Aluminum-base filler alloys are also used to join aluminum to titanium or titanium to titanium. The galvanic potential between aluminum and titanium alloys indicates that galvanic corrosion should occur in an electrolyte (Ref 50), but electropotential studies have shown that the natural oxide passivation films on the titanium and aluminum surfaces greatly reduce the danger of that couple (Ref 1). In one study, no susceptibility to SCC was observed in titanium alloys brazed with aluminum-base filler alloys (Ref 28). These corrosion tests on titanium joints indicated adequate corrosion resistance when an aluminum-silicon filler alloy was exposed to aqueous 3.5% NaCl at room temperature, but there was inadequate corrosion resistance when aluminum-copper-silver filler alloy was exposed. Other researchers found that weathered titanium joints brazed with aluminum-zinc filler metals showed no visible corrosion after 1 year (Ref 54). Additional information is available in the article "Corrosion of Aluminum and Aluminum Alloys" in this Volume.

Other Filler Alloy Systems. In one study, the corrosion behavior of more than 150 candidate filler alloys (mostly zirconium-base) was evaluated for joining Zircaloy alloys (Ref 87). The results of these corrosion tests in 3-L stainless steel autoclaves with exposure to boron shim water at 360 °C (680 °F) and 18.6 MPa (2705 psi) for 500 h are presented in Table 4. Another investigation examined the corrosion resistance of Zircaloy brazements with a wide variety of filler alloys, including many zirconium-, palladium-, and silver-base alloys, exposed to 360- °C (680- °F) water (Ref 52). Test results are given in Table 5. Additional information on the corrosion of Zircaloy alloys can be found in the articles "Corrosion of Zirconium and Hafnium" and "Corrosion in the Nuclear Power Industry" (in particular the discussion of corrosion of Zircaloy-clad LWR fuel rods) in this Volume.

(a) The filler metal compositions are given in weight percent before arc melting. Some alterations in compositions may have resulted during melting and subsequent brazing.

(b) + = excellent; 0 = good; - = poor.

(c) Weight change of the brazing filler metal is computed by subtracting the $\Delta W/A$ of the braze coupon on the control specimen times the unbrazed area of the braze coupon from the total ΔW of the braze coupon and dividing the balance by the area of the brazing filler metal: $C_3 = \Delta W_1 - (\Delta W_2/A_2)(A_1 - A_3)/A_3$, where subscripts are 1, brazed specimen; 2, Zircaloy-2 control; and 3, brazing filler metal.

(d) Repeat runs.

(e) Later formulation did not melt at this temperature.

(f) Severely attacked Zircaloy-2 tab; test discontinued.

(g) These filler metals were evaluated by mixing particles of Zr-Be and Zr-Cu binary systems. The braze temperature does not necessarily represent 30 °C (85 °F) superheat for an actual ternary melt.

Table 5 Corrosion test results for Zircaloy specimens brazed without spacing shims, exposed to 360 °C (680 °F)

Filler metal composition (nominal), wt%	Total exposure time, h	Condition of specimen[(a)]
Ag-28Cu	154 failed	. . .
Ag-28Cu	24 failed	. . .
Ag-28Cu	29.5 failed	. . .
Ag-30Cu-10Si	29.5 failed	. . .
Ag-30Cu-10Sn	1250	Filler metal was completely oxidized.
Al-1Ni	1318	Center of filler metal was completely oxidized, although a corrosion-resistant alloy layer was found adjacent to the base metal.
Al (hot dip coating)	163 failed	. . .
Al-24Pd	113 failed	. . .
Al-12Si	1413	Considerable attack along centerline of filler metal
Cu-7P	86 failed	Was thick joint
Cu-7p	1318	Virtually complete failure
Cu-15Ag-5P-5Sn	1201	Failure virtually complete
Cu-15Ag-5P-10Sn	1201	Failure virtually complete
Cu-20Pd-3In	1413	Virtually unattacked
Ni-7P (Kanigen plate)	1367	Virtually unattacked
Ni-3.4P	1313	75% of joint destroyed
Ni-30Ge-13Cr	104 failed	. . .
Ni-20Pd-10Si	1367	Slight attack on filler metal

Ni-20Cr-10Si	1315	Extensive corrosion
Pd-6Si	1310	Very extensive attack of Zircaloy adjacent to filler metal
Pd-10Nb	1315	Very heavy attack of base metal
Pd-20Sn	1413	Extensive base metal attack extending into filler metal
Zr-21Cu	1311	80% of joint destroyed
Zr-17Ni	1200	Heavy attack
Zr-15Ni-10Sn	1200	Extensive attack throughout joint
Zr-5Be	1259	Unattacked
Zr-10Fe-10Sn	1200	50% of joint corroded
Zr-15Fe-15Mn	1200	20% of joint corroded
Gold	23 failed	. . .
Au-10Co	1450	Virtually complete failure

(a) Specimens were removed from test after a minimum of 1200 h and examined.

In a study of the corrosion resistance of a series of iron-base filler alloys for brazing molybdenum, the alloys were found to exhibit outstanding corrosion resistance when exposed to liquid sodium and molten fluoride salts at 600 to 700 °C (1110 to 1290 °F) (Ref 88). Also, a titanium-vanadium-beryllium filler alloy was tested in potassium and in vacuum; the alloy performed satisfactorily (Ref 89).

Several hundred binary and ternary alloys (mainly based on zirconium and/or titanium systems) were investigated in an effort to find a suitable filler alloy for joining niobium (Ref 90). The results of these shear tests on joints aged 100 h at 815 °C (1500 °F) are summarized in Table 6.

Table 6 Results of room-temperature shear tests on brazed niobium joints

Shear strength of the niobium specimen: 207 MPa (30 ksi)

Alloy, wt%	Brazement shear strength[a]			
	As-brazed		**Aged 100 h at 815 °C (1500 °F)**	
	MPa	**ksi**	**MPa**	**ksi**
48Ti-48Zr-4Be	230 (6)	33.3 (6)	169 (3)	24.5 (3)
46Ti-46Zr-4V-4Be	192 (6)	27.8 (6)	224 (4)	32.5 (4)
63Ti-27Fe-10V	187 (6)	27.088 (6)	155 (4)	22.5 (4)
68Ti-28V-4Be	185 (6)	26.8 (6)	154 (4)	22.3 (4)
63Ti-27Fe-10Mo	172 (5)	24.9 (5)	134 (4)	19.5 (4)
75Zr-19Nb-6Be	165 (6)	24.0 (6)	171 (4)	24.8 (4)
45Ti-40Zr-15Fe	155 (3)	22.5 (3)	121 (4)	17.5 (4)
60Zr-25V-15Nb	148 (4)	21.5 (4)	85 (3)	12.4 (3)
67Zr-29V-4Fe	139 (5)	20.2 (5)	101 (3)	14.6 (3)
80Zr-17Fe-3Be	117 (3)	16.2 (3)	[b]	[b]

Source: Ref 90

(a) Numbers in parentheses indicate number of specimens.

(b) Specimens broke during machining.

An extensive investigation was conducted on the galvanic corrosion of metals and coatings when coupled to uranium in severe environments (Ref 91). This report also contains a comprehensive bibliography on this subject. The materials that were investigated included brazing alloys, namely silver-copper and silver. The environments in which the galvanic series was determined were as follows:

- 0.05 *M* H_2SO_4, pH 1.0, 29 °C (84 °F)
- deionized water, pH 5.8, 29 °C (84 °F)
- 5.0 wt% NaCl, pH 6.8, 29 °C (84 °F)

- 0.5 *M* sodium carbonate (Na_2CO_3), pH 11.3, 29 °C (84 °F)

Many other braze alloy systems have been examined for their corrosion behavior in various environments. Reference 1 provides and extensive review of the literature on this subject.

Corrosion of Clad Metals

Robert Baboian and Gardner Haynes, Texas Instruments, Inc.

Introduction

CLAD METALS are metallurgical materials systems that are a part of a large group of materials termed composites. As shown in Fig. 1, clad metals are categorized as bonded metal metal laminar composite systems that can be fabricated by several processes. They are also referred to as sandwich metals, metal laminates, and multimetals. Clad metals can be provided in plate, strip, tube, rod, and wire form.

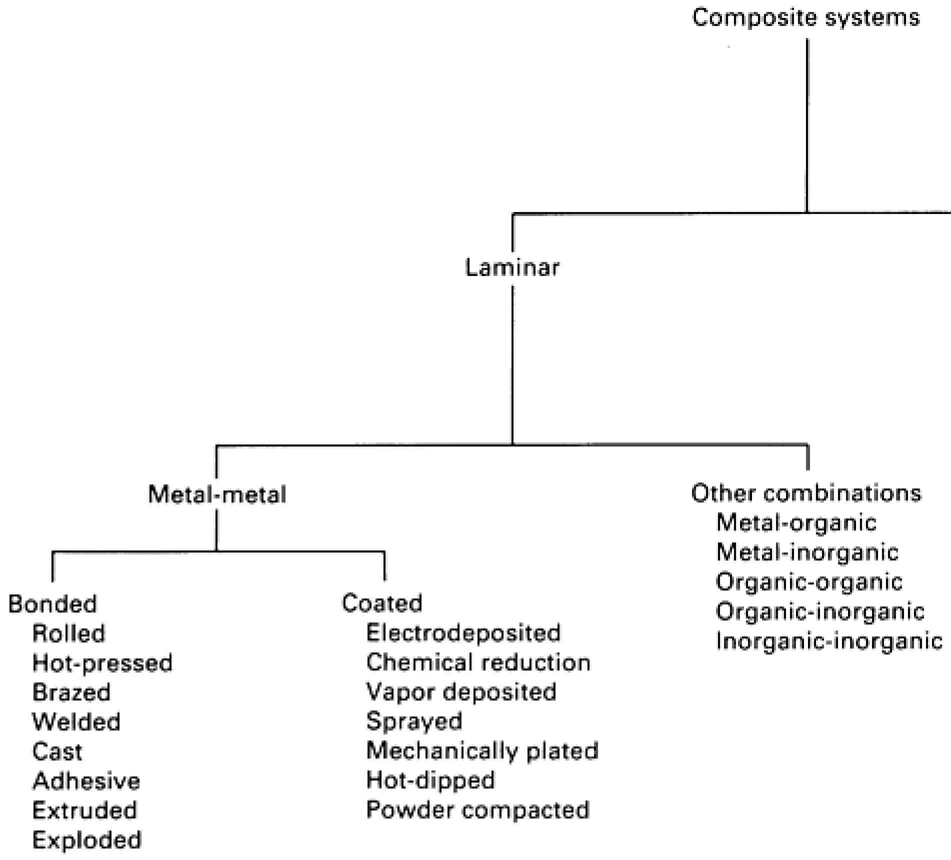

Fig. 1 Categorization of clad metals as bonded metal-metal laminar composite systems

The use of clad metal systems dates back to 3000 B.C., when gold was used to cover bronze. Hammering was the method usually used for cladding. Even today, clad metals--including platinum- and gold-clad (gold-filled) systems--are widely used in the jewelry industry. In about 300 B.C., laminated swords fabricated by hammer cladding were stronger, lighter, and more durable than the ones made with a monometal. Modern cladding processes originated in the early 1800s, when English craftsmen developed the Old Sheffield process for cladding silver (or gold) to another metal. This was the first use of the roll-bonding process.

The Cladding Process

The cladding process is generally differentiated from other bonding processes, such as brazing and welding, by the fact that none of the metals to be joined is molten when a metal-to-metal bond is achieved. Also, there are no intermediate layers, such as adhesives. The principle cladding techniques include cold roll bonding, hot roll bonding, hot pressing,

explosion bonding, and extrusion bonding (Fig. 1). Regardless of the technique used, the bond is achieved by forcing clean oxide-free metal surfaces into intimate contact; this causes a sharing of electrons between the metals. Gaseous impurities diffuse into the metals, and nondiffusible impurities consolidate by spheroidization. All the techniques involve some form of deformation to break up surface oxides, to create metal-to-metal contact, and to heat in order to accelerate diffusion. The techniques differ in the amount of deformation and heat used to form the bond and in the method of bringing the metals into intimate contact. Cold and hot roll bonding apply primarily to sheet (less than 5 mm, or 0.2 in., thick), but explosion bonding is usually restricted to thicker gages (up to several inches).

Most engineering metals and alloys can be clad by using one or more of these techniques. As many as 100 different metal combinations with up to 15 layers have been cold roll bonded. Clad combinations that have been commercially produced on a large scale are shown in Fig. 2.

	Aluminum	Carbon steel	Copper	Nickel	Magnesium	Austenitic stainless steel	Brass/bronze
Aluminum	○	○	○	●	●	○	●
Nickel	●	○	○	●	●	○	○

Titanium	○	○	○	○	●	●	●

○ Commercial

● Requires development

Fig. 2 High-volume commercially available clad metals

Certain combination are more difficult to bond. Table 1 categorizes a number of cladding combinations by degree of difficulty in bonding. Properties that affect the bonding process include ductility, nature of oxide films, and tendency to form intermetallic compounds. Because bonding processes commonly use large amounts of reduction, alloys with greater ductility are more easily clad. Metals and alloys with virtually no ductility, such as beryllium and chromium, are impossible to bond. Metals and alloys that form tenacious oxide films are more difficult to bond. These include stainless steels, aluminum alloys, and the refractory metals. Finally, some combinations of metals are thermally unstable and form brittle intermetallic compounds above a certain temperature. These combinations can be clad, but require stringent control of process variables to avoid the formation of intermetallic compounds.

Table 1 Categorization of clad metals by degree of difficult in bonding

In most cases, when a metal is named, alloys of that metal also apply.

Easy to bond
Copper/steel
Copper/nickel
Copper/silver
Copper/gold
Aluminum/aluminum alloys
Tin/copper
Tin/nickel
Gold/nickel
Difficult to bond
Copper/aluminum
Aluminum/carbon steel
Stainless steel/aluminum
Copper/tantalum, niobium, titanium
Titanium/carbon steel, stainless steel
Stainless steel/carbon steel
Aluminum/nickel
Nickel/steel
Copper/stainless steel
Manganese/nickel/copper

Copper/manganese
Silver/manganese
Silver/steel
Uranium/zirconium
Zirconium/copper, steel, stainless steel
Platinum/nickel, copper, steel
Tantalum/niobium
Impractical to bond
Gold/aluminum
Zirconium/aluminum
Cobalt/aluminum
Impossible to bond
Beryllium/anything
Chromium/anything

Designing With Clad Metals

The choice of a material for a particular application depends on such factors as cost, availability, appearance, strength, fabricability, electrical or thermal properties, mechanical properties, and corrosion resistance. Clad metals provide a means of designing into a composite material specific properties that cannot be obtained in a single material. The early use of clad metals in the jewelry industry combined the aesthetics of precious metals with the low-cost strength of base metals. These materials systems are currently being used for electrical and electronics applications, such as contacts and connectors with selectively clad (inlay) precious metals for low contact resistance and high reliability.

Clad metals can provide properties not available in a monolithic materia at any cost. The best example is thermostat bimetals. An ally with a high coefficient of thermal expansion is clad to an alloy with a low coefficient of thermal expansion. When heated, the resulting bimetal will bend about its neutral axis. Thermostat bimetals are used in various temperature-sensing devices, including motor protectors, circuit breakers, automotive chokes, vent dampers, and room thermostat.

Clad metals can be designed with unique coefficient of linear expansion by cladding two or more alloys in a symmetrical configuration. Specific examples are copper-clad invar (iron-nickel alloy) wire for glass-to-metal seals and copper-clad invar (Cu/invar/Cu), that matches the coefficient of expansion of ceramics for leadless semiconductor chip carriers. Different expansion rates can be obtained by varying the cladding ratio.

Self-brazing materials, such as copper-clad stainless steel (Cu/SS/Cu) and copper clad steel (Cu/steel/Cu), provide another example of the unique properties designed into a clad material. Multilayer heat exchangers are fabricated from these materials by simply stacking the layers of clad material and furnace brazing the entire assembly.

A final example of a unique clad system is the brass-clad steel used in bullet jackets. In this case, the brass cladding provides the drawability that allows steel to be used as a bullet jacket with improved strength and aerodynamics.

Equations for calculating the properties of clad systems are available in the literature. Basically, such properties as density, electrical conductivity, and thermal conductivity involve weighted averages of the components. Other properties, such as thermal expansion and modulus of elasticity, depend on the clad configuration, but can be calculated.

Designing Clad Metals for Corrosion Control

Clad metals designed for corrosion control can be categorized according to the following systems:

- Noble metal clad systems
- Corrosion barrier systems
- Sacrificial metal systems
- Transition metal systems
- Complex multilayer systems

Proper design is essential for providing maximum corrosion resistance with clad metals. This section will discuss the basis for designing clad metals for corrosion resistance.

Noble metal clad systems are materials having a relatively inexpensive base metal covered with a corrosion-resistant metal. Selection of the substrate metal is based on the properties required for a particular application. For example, when strength is required, steel is frequently chosen for its corrosion resistance in a particular environment, such as seawater, sour gas, high temperature, and automotive.

A wide range of corrosion-resistant alloys clad to steel substrates have been used in industrial applications. One example is type 304 stainless steel on steel. Figure 3 shows cross sections of this material. The uniformity of the bond inter-face is apparent in Fig. 3(a), and in the polished-and-etched condition (Fig. 3b), the metallographic structure of the stainless steel is clearly visible. The grain structure is analogous to that of annealed stainless steel strip.

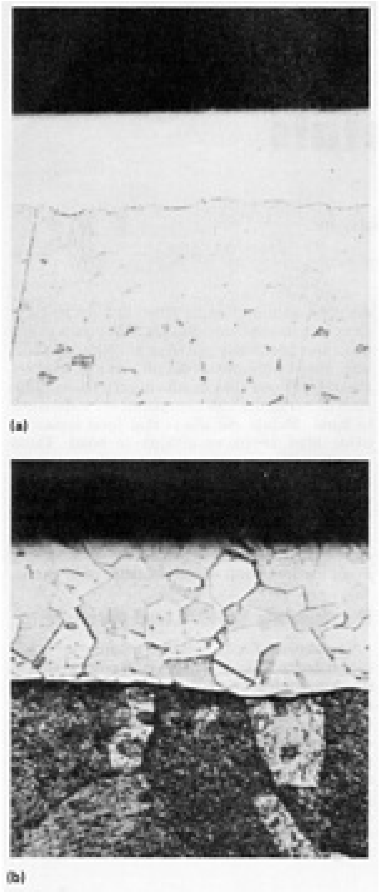

Fig. 3 Photomicrographs of cross sections of type 304 stainless steel clad carbon steel. (a) As-polished. 300×. (b) Polished and etched. 500×

Clad metals of this type are typically used in the form of strip, plate, and tubing. The noble metal cladding ranges from commonly used stainless steels, such as type 304, to high-nickel alloys, such as Inconel 625. These clad metals find various applications in the marine, chemical-processing, power, and pollution control industries. Specific uses include heat exchangers, reaction and pressure vessels, furnace tubes, tubes and tube elements for boilers, scrubbers, and other systems involved in the production of chemicals.

Another group of commonly used noble metal clad metals uses aluminum as a substrate. For example, in stainless steel clad aluminum truck bumpers (Fig. 4), the type 302 stainless steel cladding provides a bright corrosion-resistant surface that also resists the mechanical damage (stone impingement) encountered in service. The aluminum provides a substrate with a high strength-to-weight ratio.

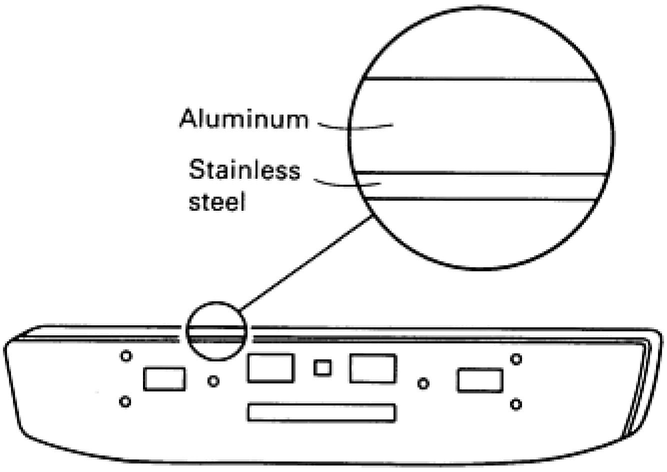

Fig. 4 Stainless steel clad aluminum truck bumper material that combines the corrosion resistance of stainless steel with lightweight aluminum

A wide range of precious metals are clad to lower-cost materials. Platinum-clad niobium consists of a thin layer of the precious metal bonded to a niobium substrate. This clad material, available in strip, wire, and rod form, is used as an anode for impressed-current cathodic protection (Fig. 5) and for such other application as electroplating and desalination. Gold that is clad to such substrate materials as brass is widely used in wire, strip, and tube form. The most familiar example is the gold-filled writing instrument, which consists of gold clad to brass.

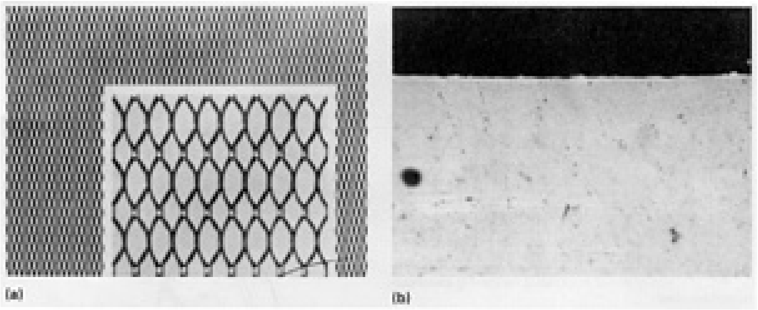

Fig. 5 Platinum-clad niobium, used widely as an anode material in electroplating and in impressed-current cathodic protection. (a) Expanded anode. (b) Cross section showing 1-μm (0.04-mil) thick platinum cladding on a niobium substrate. 500×

Corrosion Barrier Systems. The combination of two or more metals to form a corrosion barrier system is most widely used where perforation caused by corrosion must be avoided (Fig. 6). Low-carbon steel and stainless steel are susceptible to localized corrosion in chloride-containing environments and may perforate rapidly. When steel is clad over the stainless steel layer, the corrosion barrier mechanism prevents perforation. Localized corrosion of the stainless steel is prevented; the stainless steel is protected galvanically by the sacrificial corrosion of the steel in the metal laminate. Therefore, only a thin pore-free layer is required.

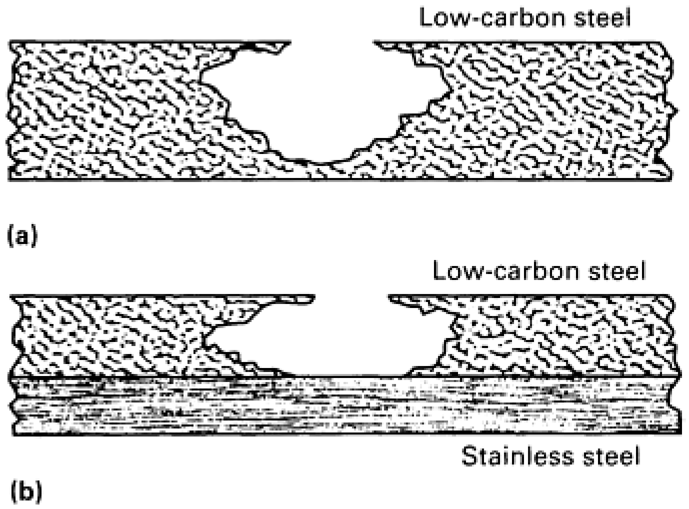

Fig. 6 Illustrations of the corrosion barrier principle. (a) Solid carbon steel. (b) Carbon steel clad stainless steel

The example shown in Fig. 7 of carbon steel clad to type 304 stainless steel demonstrates how perforation is avoided in seawater compared to solid type 304 stainless steel. This material can be used for tubing and for wire in applications requiring strength and corrosion resistance.

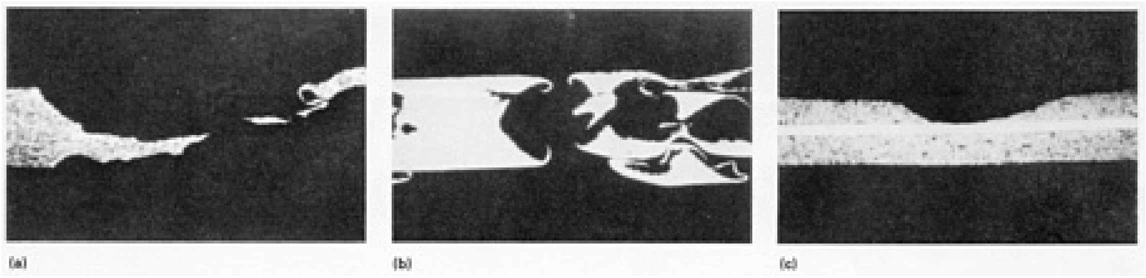

Fig. 7 Photomicrographs of cross sections of materials after 18 months of immersion in seawater at Duxbury, MA. (a) Low-carbon steel. (b) Type 304 stainless steel. (c) Carbon steel clad type 304 stainless steel

Carbon steel cannot be used when increased general corrosion resistance of the outer cladding is required. A low-grade stainless steel with good resistance to uniform corrosion but poor resistance to localized corrosion can be selected. In seawater service, type 304 stainless steel that is clad to a thin layer of Hastelloy C-276 provides a substitute for solid Hastelloy C-276. In this corrosion barrier system, localized corrosion of the type 304 stainless steel is arrested at the C-276 alloy interface (Fig. 6).

The most widely used clad metal corrosion barrier material is copper-clad stainless steel (Cu/430 SS/Cu) for telephone and fiber optic cable shielding. In environments in which the corrosion rate of copper is high, such as acidic or sulfide-containing soils, the stainless steel acts as a corrosion barrier and thus prevents perforation, while the inner copper layer maintains high electrical conductivity of the shield.

Sacrificial metals, such as magnesium, zinc, and aluminum, are in the active region of the galvanic series and are extensively used for corrosion protection. The location of the sacrificial metal in the galvanic couple is an important consideration in the design of a system. By cladding, the sacrificial metal may be located precisely for efficient cathodic protection.

The single largest application for cold roll bonded materials is stainless-steel-clad aluminum for automotive trim (Fig. 8). The stainless steel exterior surface provides corrosion resistance, high luster, and abrasion and dent resistance, and the aluminum on the inside provides sacrificial protection for the painted auto body steel and for the stainless steel.

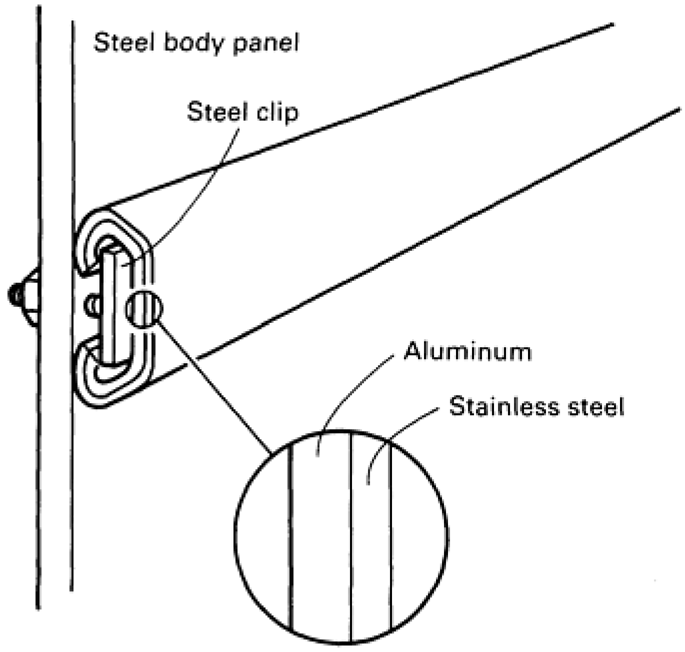

Fig. 8 Stainless steel clad aluminum automotive trim provides sacrificial corrosion protection to the auto body while maintaining a bright corrosion-resistant exterior surface.

The largest application for hot roll bonded materials--Alclad aluminum--also falls, into this category. In this case, a more active aluminum alloy is bonded to a more noble aluminum alloy. In service, the outer clad layer of aluminum corrodes sacrificially and protects the more noble aluminum substrate.

Transition Metal Systems. A clad transition metal system provides an interface between two incompatible metals. It not only reduces galvanic corrosion where dissimilar metals are joined but also allows welding techniques to be used when direct joining is not possible.

The principle of a clad transition metal is illustrated in Fig. 9. In this example, aluminum is jointed to low-carbon steel through a steel-clad aluminum transition metal. Steel and aluminum form brittle intermetallic compounds and are difficult to weld directly. The transition metal insert allows steel to be welded to steel and aluminum to aluminum; the actual bond between the steel and the aluminum occurs in the clad transition. In addition, the dissimilar-metal crevice is eliminated, which reduces susceptibility to galvanic corrosion.

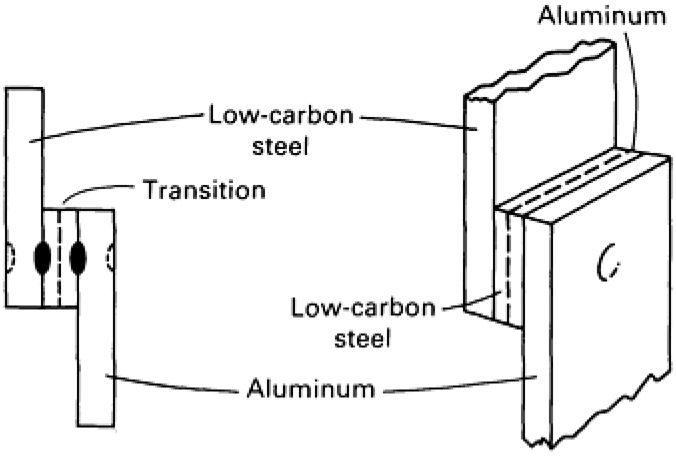

Fig. 9 Illustration of a steel-clad aluminum transition material insert used for joining aluminum to carbon steel

This concept has been applied commercially in a number of applications. Roll-bonded copper-clad aluminum has been deep drawn into transition tubes for joining aluminum and copper refrigeration tubing. Explosion-bonded steel-clad aluminum has been used to weld aluminum superstructures to steel ship hulls and aluminum bus bars to steel electrodes in aluminum smelting plants. Because of the increased use of aluminum on automobiles, steel-clad aluminum transition materials are being used for spot welding steel to aluminum in such applications as steering wheels and door components.

Complex Multilayer Systems. In many cases, materials are exposed to dual environments; that is, one side is exposed to one corrosive medium, and the other side is exposed to a different one. A single material may not be able to meet this requirement, or a critical material may be required in large quantity.

Clad metals provide an ideal solution to the materials, problem of dual environments. For example, in automobile windshield wiper sockets (Fig. 10), wear resistance is required on the mating surface, atmospheric-corrosion resistance is required on the external surface, and high strength is incorporated into the design. Multilayer phosphor-bronze-clad, steel-clad copper is used in this application. The phosphor bronze provides the required bearing surface, copper provides atmospheric-corrosion resistance, and steel provides the required strength.

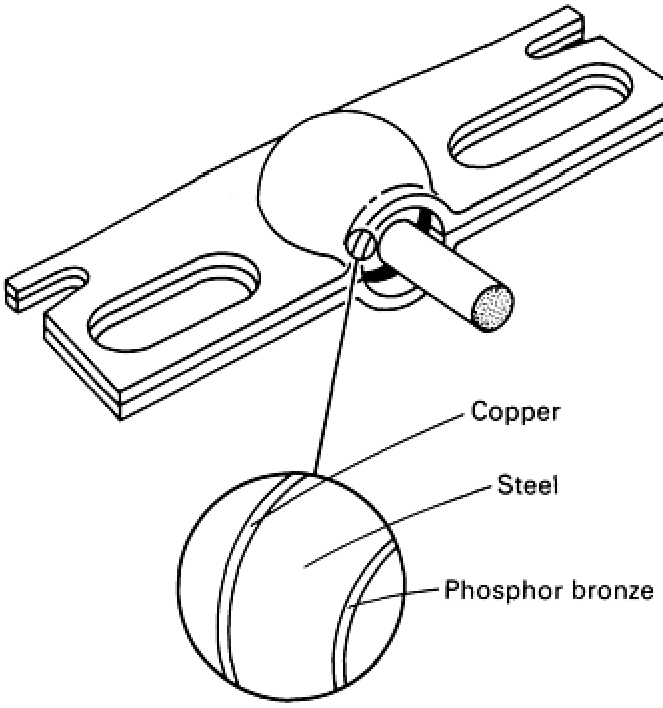

Fig. 10 Clad metal windshield wiper socket, which consists of copper-clad, steel-clad phosphor bronze

In the application of small battery cans and caps, copper-clad, stainless-steel-clad nickel (Cu/SS/Ni) is used where the external nickel layer provides atmospheric-corrosion resistance and low contact resistance. The copper layer on the inside provides the electrode contact surface as well as compatible cell chemistry. The stainless steel layer provides strength and resistance to perforation corrosion.

Other examples include the titanium-clad, copper-clad nickel (Ti/Cu/Ni) bipolar electrode used in fuel cells. Titanium is required on the anode side, nickel provides a hydrogen barrier on the cathode side, and copper provides electrical and thermal conductivity. Tantalum-clad, copper-clad nickel (Ta/Cu/Ni) is used for capacitor cans. Tantalum provides internal corrosion resistance, nickel provides external atmospheric-corrosion resistance and low contact resistance, and copper provides electrical and thermal conductivity.

Marine Corrosion

Chairman: Robert H. Heidersbach, Metallurgical Engineering Department, California Polytechnic State University

Introduction

MARINE CORROSION includes the deterioration of structures and vessels immersed in seawater, the corrosion of machinery and piping systems that use seawater for cooling and other industrial purposes, and corrosion in marine atmospheres. Although salt water is generally considered to be a corrosive environment, it is not widely understood how corrosive salt water is in comparison to other environments, such as fresh (salt-free) water.

Figure 1 shows the corrosion rate of iron in aqueous sodium chloride (NaCl) solutions of various concentrations. The maximum corrosion rate occurs near 3.5% NaCl--the approximate salt concentration of seawater.

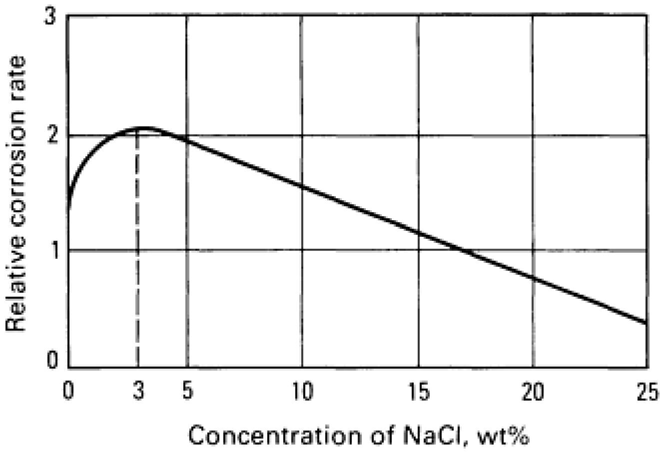

Fig. 1 Effect of NaCl concentration on the corrosion rate of iron in aerated room-temperature solutions. Data are complied from several investigations. Source: Ref 1

Other variables in seawater and in the marine environment affect corrosion rates in different ways; these variables are discussed in the sections "Seawater" and "Marine Atmospheres" in this article. The remainder of this article is devoted to corrosion protection in the marine environment (see the sections "Metallic Coatings," "Organic Coatings," and "Cathodic Protection"). Corrosion of specific metals and alloys in the marine environment is discussed in the articles in the articles in the Section "Specific Alloy Systems" in this Volume.

Seawater

Stephen C. Dexter, College of Marine Studies, University of Delaware

The general marine environment includes a great diversity of subenvironments, such as full-strength open ocean water, coastal seawater, brackish and estuarine waters, bottom sediments, and marine atmospheres. Exposure of structural materials to these environments can be continuous or intermittent, depending on the application. Structures in shallow coastal or estuarine waters are often exposed simultaneously to five zones of corrosion. Beginning with the marine atmosphere, the structure then passes down through the splash, tidal, continuously submerged (or subtidal), and subsoil (or mud) zones. The relative corrosion rates often experienced on a steel structure passing through all of these zones are illustrated in Fig. 2.

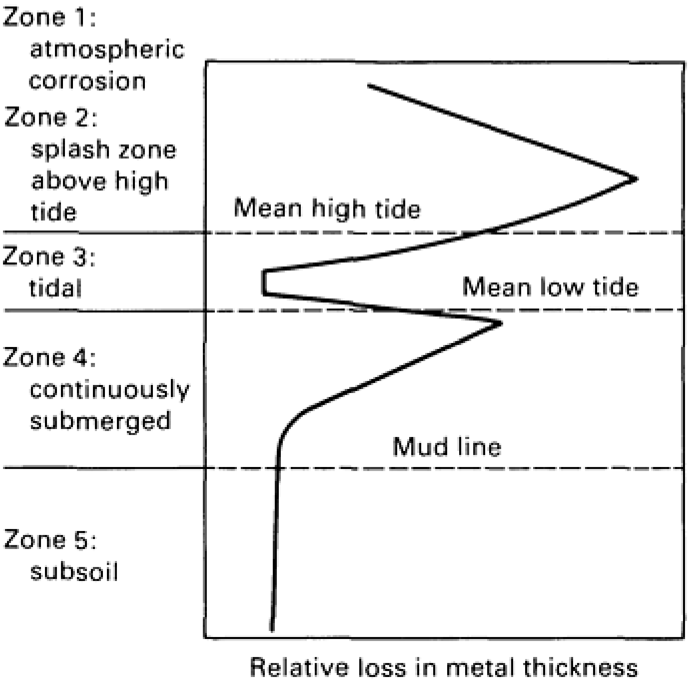

Fig. 2 Zones of corrosion for steel piling in seawater, and relative loss of metal thickness in each zone. Source: Ref 2

As will be discussed in this section, the major chemical constituents of seawater are consistent worldwide. The minor constituents, however, vary from site to site and with season, storms, and tidal cycles. These minor constituents include dissolved trace elements and dissolved gases. In addition, seawater contains dissolved organic materials and living microscopic organisms. Frequently, the minor chemical constituents of seawater, together with the organic materials and living organisms, are the rate-controlling factor in the corrosion of structural metals and alloys.

Because of its variability, seawater is not easily simulated in the laboratory for corrosion-testing purposes. Stored seawater is notorious for exhibiting behavior as a corrosive medium that is different from that of the water mass from which it was taken. This is due in part to the fact that the minor constituents, including the living organisms and their dissolved organic nutrients, are in delicate balance in the natural environment. This balance begins to change as soon as a seawater sample is isolated from the parent water mass, and these changes often have a large effect on the types of corrosion experienced and the corrosion rate.

Variations in the chemistry of open ocean seawater tend to take place slowly (over time periods of 3 to 6 months) and over horizontal and vertical distances that are large in comparison to the dimensions of most marine structures. Such gradual changes may produce an equally gradual change in the corrosion rate of structural materials with season and location, but they are unlikely to produce sharp changes in either corrosion mechanism or rate. Moreover, such gradual changes are relatively easy to measure and monitor.

On the other hand, changes that take place over periods of hours to days and over distances of centimeters to meters can occur as the result of point inputs of various chemical pollutants or the attachment of micro- and macroscopic marine plants and animals to the surface of a structure. The chemical changes produced by the attachment of biological fouling organisms take place directly at the metal/water interface where the corrosion occurs, not in the bulk water. This means that the chemical environment in which the corrosion reactions occur in the presence of a fouling film may bear little resemblance to that of the bulk water.

It is these types of effects, which can be produced quickly and can lead to sharp chemical gradients over short distances, that often result in the onset of localized corrosion. Crevice corrosion beginning under the base of an isolated barnacle on stainless steel is a good example of this type of influence. Whether the fouling film is composed of microscopic bacteria or large sedentary fouling organisms is often less important than whether the film provides complete or spotty coverage of

the metal surface. Almost invariably, a spotty film, or one that forms in discrete colonies of organisms with bare metal in between, will be more likely to induce structurally significant corrosion than a film that produces a continuous layer.

In this section, the general properties of ocean water and their effects on corrosion will be discussed. The major and minor features, including the effects of variability, pollutants, and fouling organisms, will be covered. Also included is a discussion of the factors that control the corrosivity of marine atmospheres.

Consistency and the Major Ions

The concentrations of the major constituents of full-strength seawater are shown in Table 1. Major constituents are considered to be those that have concentrations greater than 1 mg/L and are not greatly affected by biological processes. The behavior of these major ions and molecules is said to be conservative because their concentrations bear a relatively constant ratio to each other over a wide range of dilutions. Although most of the known elements can be found dissolved in seawater, the ions and molecules listed in Table 1 account for over 99.85% of the total dissolved solids. Moreover, the conservative nature of these major ions means that all of their concentrations can be calculated if the concentration of any one of them is measured.

Table 1 Concentrations of the most abundant ions and molecules in seawater of 35[permil] salinity

Density of seawater: 1.023 g/cm^3 at 25 °C (75 °F)

Ion or molecule	Concentration	
	m mol/kg of seawater	g/kg of seawater
Na^+	468.5	10.77
K^+	10.21	0.399
Mg^{2+}	53.08	1.290
Ca^{2+}	10.28	0.412
Sr^{2+}	0.09	0.008
Cl^-	545.9	19.354
Br^-	0.84	0.067
F^-	0.07	0.0013
HCO_3^-	2.30	0.140
SO_4^{2-}	28.23	2.712
$B(OH)_3$	0.416	0.0257

Salinity and Chlorinity. The most commonly measured property of seawater is its salinity. Historically, salinity, *S*, in parts per thousand ([permil]), has been defined as the total weight in grams of inorganic salts in 1 kg of seawater when all bromides and iodides are replaced by an equivalent quantity of chlorides and all carbonates are replaced by an equivalent quantity of oxides. Salinity is usually determined by measuring either then the chlorinity or the electrical conductivity of the seawater, Chlorinity, Cl, is defined as the mass in grams of silver required to precipitate the halogens in 0.3285234 kg of seawater. This is nearly equal to the mass of chloride in the seawater sample. Chlorinity is related to salinity by:

$$S = 1.80655\ \text{Cl} \quad \textbf{(Eq 1)}$$

where *S* and Cl are measured in parts per thousand.

If pure water is the only substance added to or removed from seawater, the concentration or any ion, χ, from Table 1 at a salinity other than 35[permil] can be calculated from the following relationship:

$$[\chi]\ \text{at salinity}\ S = [\chi]\ \text{at}\ 35‰\ \text{salinity} \times \frac{S}{35‰} \quad \textbf{(Eq 2)}$$

where the brackets denote concentration, and *S* is again given in parts per thousand. For example, using Eq 2 and Table 1, the concentration of sodium ion in seawater of 20[permil] salinity is:

$$[Na^+] \text{ at } 20‰ = (0.468 \text{ mol/kg of seawater}) \times \frac{20‰}{35‰} = 0.2667 \text{ mol } Na^+/\text{kg of seawater}$$

This relationship may break down at very low salinities (<10[permil] for Ca^{2+} and HCO_3^- and <5[permil] for the other major ions). The relationship may also break down in grossly polluted seawater. In this latter case, the concentration of the ion of interest must be known in both seawater and in the solution being added to it.

In the short term, the only processes that affect the concentrations of the major ions are evaporation, precipitation, and river discharge. Because water is the only substance added to or removed from seawater by the first two of these processes, they affect the absolute concentrations of each ion but have no affect on the concentration ratios.

Effect of River Discharge. River discharge does add constituents other than pure water. Therefore, the conservative behavior of the major ions may not hold in the low-salinity regions near river outlets. To a first approximation, river water is a 0.4 millimolar solution of calcium bicarbonate, as shown in Table 2. At a salinity of 10[permil], the calcium concentration calculated using Eq 2 and Table 1, but ignoring the river input, will be 10% too low. The error for bicarbonate ion will be even larger. Errors in concentrations of the other major ions calculated by ignoring the river input, however, will be much less because of their relatively high concentrations in seawater compared to those in river water.

Table 2 Concentrations of the most abundant ions and molecules in average river water

Ion or molecule	Concentration	
	m moles/L of river water	mg/L of river water
Na^+	0.274	**6.3**
K^+	0.059	**2.3**
Mg^{2+}	0.171	**4.1**
Ca^{2+}	0.375	**15.0**
Cl^-	0.220	**7.8**
HCO_3^-	0.958	**58.4**
SO_4^{2-}	0.117	**11.2**
NO_3^-	0.016	**1.0**
Fe^{2+}	0.012	**0.67**
$Si(OH)_4$	**0.218**	**20.9**

Salinity Variations. The total salt content of open ocean seawater varies from 32 to 36[permil]. It can rise above that range in the tropics or in enclosed waterways, such as the Red Sea, where evaporation exceeds freshwater input. It will be lower than that range in estuaries and bays, where there is appreciable dilution from river input. Salinity variations in the surface waters of the Pacific Ocean are shown in Fig. 3. The data for these figures, as well as the surface water data for other variables to follow, were taken from the *Russian Atlas of the Pacific Ocean.* Several additional sources of similar information are given in the Selected References at the end of this article. Salinity variations with depth at given locations in the Atlantic and Pacific Oceans are shown in Fig. 4. The locations from which these and other data on variations with depth were taken are illustrated in Fig. 5. It should be noted that the open ocean salinity variations with horizontal location and depth are quite small.

Effect of Salinity on Corrosion. The main effects of salinity on corrosion result from its influence on the conductivity of the water and from the influence of chloride ions on the breakdown of passive films. Specific conductance varies with temperature and chlorinity, as indicated in Table 3. The high conductivity of seawater means that the resistance of the electrolyte plays a minor role in determining the rate of corrosion reactions and that surface area relations play a major role.

Table 3 Specific conductance of seawater as a function of temperature and chlorinity

Conductance: $\Omega^{-1} \cdot cm^{-1}$

Chlorinity, [permil]	Temperature, °C (°F)

22	**0.032556**	**0.037508**	**0.042614**	**0.047948**	**0.053556**	**0.059321**

Two examples will serve to illustrate this point. First, galvanic corrosion in freshwater systems tends to be localized near the two-metal junction by the high resistivity of the electrolyte. In seawater, however, anodes and cathodes that are tens of meters apart can operate; therefore, the galvanic corrosion is much more spread out and is less intense at the junction. In the second example, a large area of cathodic metal, such as stainless steel, will produce more severe galvanic attack on an anodic metal in seawater than in freshwater, because high conductivity allows the entire area of stainless to participate in the reaction. Similarly, pitting corrosion tends to be more intense in seawater because large areas of boldly exposed cathode surface are available to support the relatively small anodic areas at which pitting takes place.

The second effect of salinity on corrosion in seawater is related to the role of chloride ions in the breakdown of passivity on active-passive metals such as stainless steels and aluminum alloys. The higher the salinity of the water, the more rapidly chloride ions succeed in penetrating the passive film and initiating pitting and crevice corrosion at localized sites on the metal surface.

The open ocean salinity changes shown in Fig. 4 and 5 have very little effect on the processes of galvanic, pitting, and crevice corrosion. The much larger salinity changes found in coastal and brackish waters can have a substantial effect on both the susceptibility to and the intensity of localized corrosion. These coastal salinity changes have undoubtedly contributed to the variability in reported pitting and crevice corrosion rates with season and location or with time at a given location. For alloys that corrode uniformly, variations in corrosion rate due to salinity changes are small compared to those caused by changes in oxygen concentration and temperature, as discussed in the following sections.

Variability and the Minor Ions

This section will consider how the variability of the minor constituents of seawater affects corrosion. Variabilities in seawater properties with horizontal location and depth will be presented for temperature, the dissolved gases oxygen and carbon dioxide, and pH. Each of these properties has a range over which it typically varies in the marine environment. The effect on corrosion of each property as it changes within this range will be considered.

Temperature. When all other factors are held constant, an increase in temperature increases the corrosivity of seawater. If the dissolved oxygen concentration is held constant, the corrosion rate of low-carbon steel in seawater will approximately double for each 30 °C (55 °F) increase in temperature.

Open ocean temperature variations are shown in Fig. 6 and 7. From these data alone, one would expect corrosion rates in tropical surface waters to be about twice those in the polar regions or in deep water. Corrosion rates are usually higher in warm surface waters than in cold deep waters, as illustrated in Fig. 8 and 9, but the picture is not nearly as simple as temperature alone would indicate. The saturation level of dissolved oxygen increases as the temperature decreases, and the effects of dissolved oxygen on the corrosion rate are often stronger than those of temperature, as will be discussed below. Short-term local temperature fluctuations and the effects of biofouling and scaling films must also be considered.

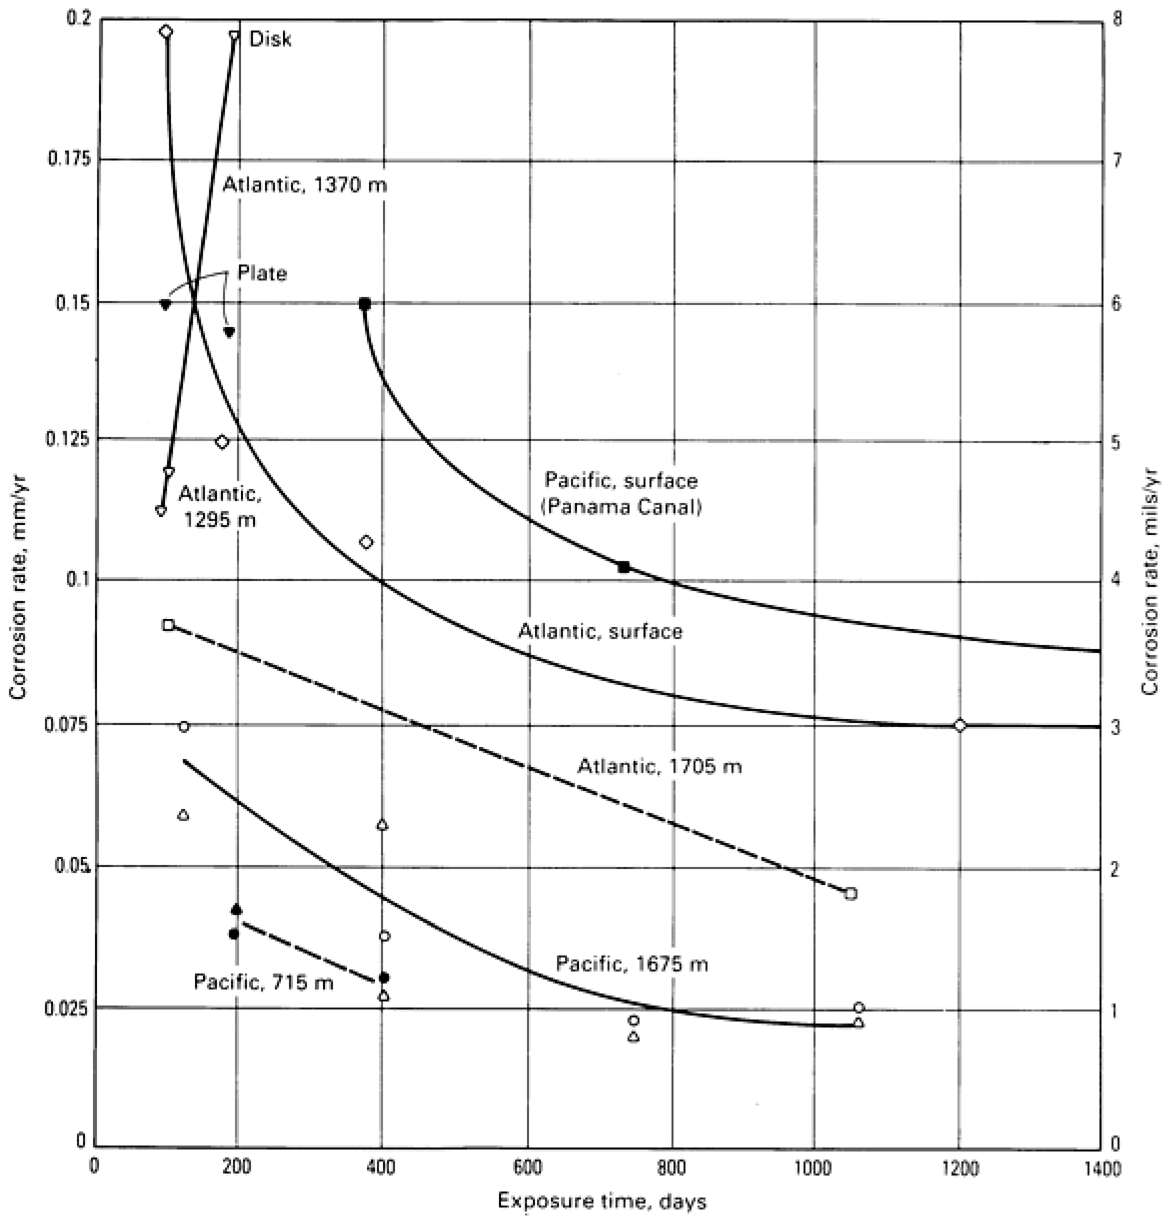

Fig. 9 Corrosion rates of low-carbon steels in the Atlantic and Pacific Oceans at various depths. Source: Ref 7

Data for the temperature and salinity variations with depth at the four coastal locations in Fig. 5 are shown in Fig. 10, 11, and 12, 13. The temperature and salinity profiles for Cook Inlet (station 1) and for the Oregon coast (station 3) given in Fig. 10 and 11(a), respectively, show only small differences with depth and season. No reliable data are available for the winter months at the Cook Inlet station. The differences shown here are inconsequential with regard to corrosion.

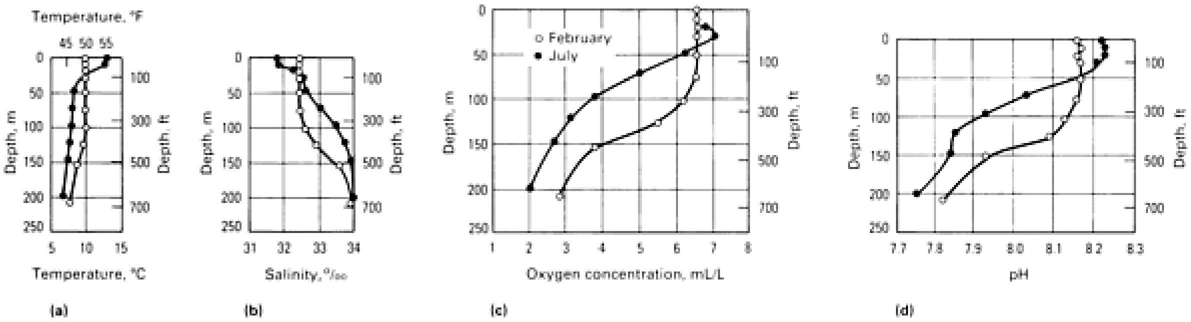

Fig. 11 Variation of temperature (a), salinity (b), dissolved oxygen (c), and pH (d) with depth and season off the Oregon coast (station 3, Fig. 5). Source: Ref 5

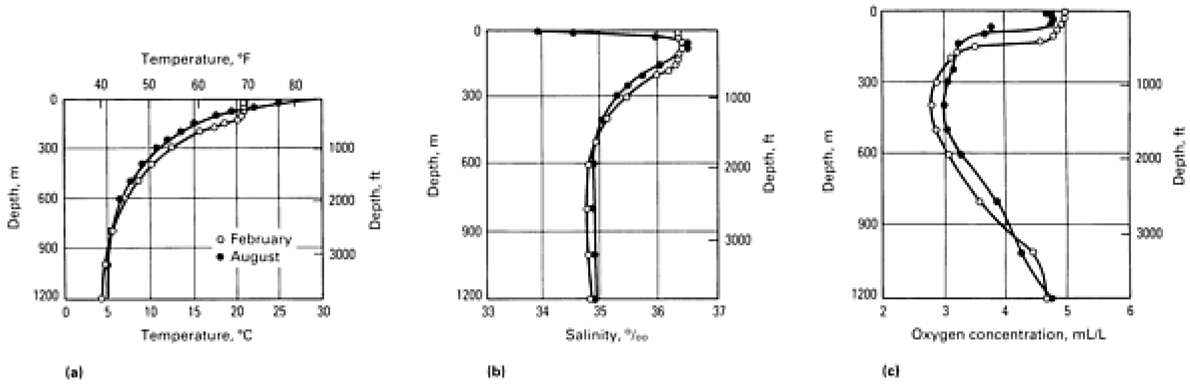

Fig. 12 Variation of temperature (a), salinity (b), and oxygen concentration (c) with depth and season in the Gulf of Mexico (station 4, Fig. 5). Source: Ref 5

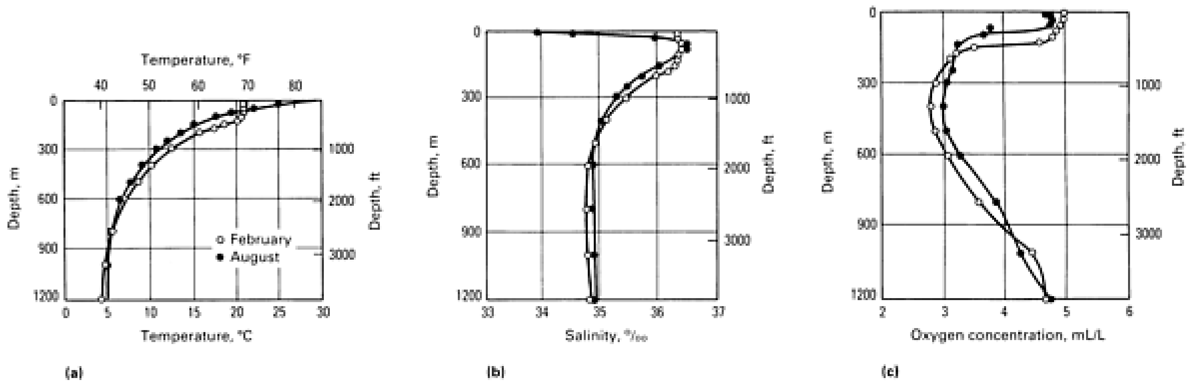

Fig. 13 Variation of temperature (a), salinity (b), dissolved oxygen (c), and pH (d) with depth and season off the New Jersey and Delaware coasts (station 5, Fig. 5). Source: Ref 5

Larger differences are shown for the Gulf of Mexico (station 4) and the New Jersey coast (station 5) in Fig. 12 and 13. The temperature differences with depth and season shown for these two locations will be large enough to influence both corrosion rate and calcareous deposition. The salinity changes shown will have little influence. The seasonal differences in the surface waters of the Gulf of Mexico disappear at greater depths, while those off the New Jersey coast persist all the way to the bottom.

Dissolved Oxygen. Many of the minor constituents that are important to corrosion processes are dissolved gases such as carbon dioxide and oxygen. Their concentrations are not conservative (that is, constant), because they are influenced by air-sea exchange as well as by biochemical processes. The concentration of dissolved oxygen in surface waters will usually be within a few percent of the equilibrium saturation value with atmospheric oxygen at a given temperature. The solubility of oxygen in seawater varies inversely with both temperature and salinity, but the effect of temperature is greater. If the absolute temperature T (°K) and salinity S ([permil]) are known, the solubility of oxygen can be calculated from the relationship:

$$\ln [O_2] = A_1 + A_2 \left(\frac{100}{T}\right) + A_3 \ln \left(\frac{T}{100}\right) + A_4 \left(\frac{T}{100}\right) + S \left[B_1 + B_2 \left(\frac{T}{100}\right) + B_3 \left(\frac{T}{100}\right)^2\right] \quad \text{(Eq 3)}$$

where oxygen concentration is given in milliliters per liter (mL/L), and salinity S is again in parts per thousand ([permil]). The constant A_1 through B_3 are given in Table 4. Table 5 lists the equilibrium oxygen saturation levels in milliliters per liter as a function of temperature and salinity calculated from Eq 3 and Table 4.

Table 4 Constants for use with Eq 3

These values can be used with Eq 3 to calculate oxygen concentration relative to air at 1 atm total pressure and 100% relative humidity.

Constant	Value
A_1	**-173.4292**
A_2	**249.6339**

Generally, the surface waters of the ocean are in equilibrium with the oxygen in the atmosphere at a specific temperature. Two sets of conditions, however, can lead to the waters becoming substantially supersaturated with oxygen. The first of these conditions is oxygen production due to photosynthesis by microscopic marine plants. During high growth periods, intense photosynthesis can produce concentrations as high as 200% saturation for periods of up to a few weeks. Such oxygen supersaturation is most often found in near-shore regions as a transient phenomenon.

The second condition that may cause oxygen supersaturation is the entertainment of air bubbles due to wave action. This factor usually will not cause supersaturations greater than about 10%, because vigorous wave action also promotes reequilibration with the atmosphere.

Oxygen Variability. The distribution of dissolved oxygen in the surface waters of the Pacific Ocean is shown in Fig. 14(a) for the months of January through March and in Fig. 14(b) for July through September. Comparison with Fig. 6 reveals that the highest concentrations of oxygen coincide with the lowest temperatures; this agrees with the oxygen solubility data given in Table 5.

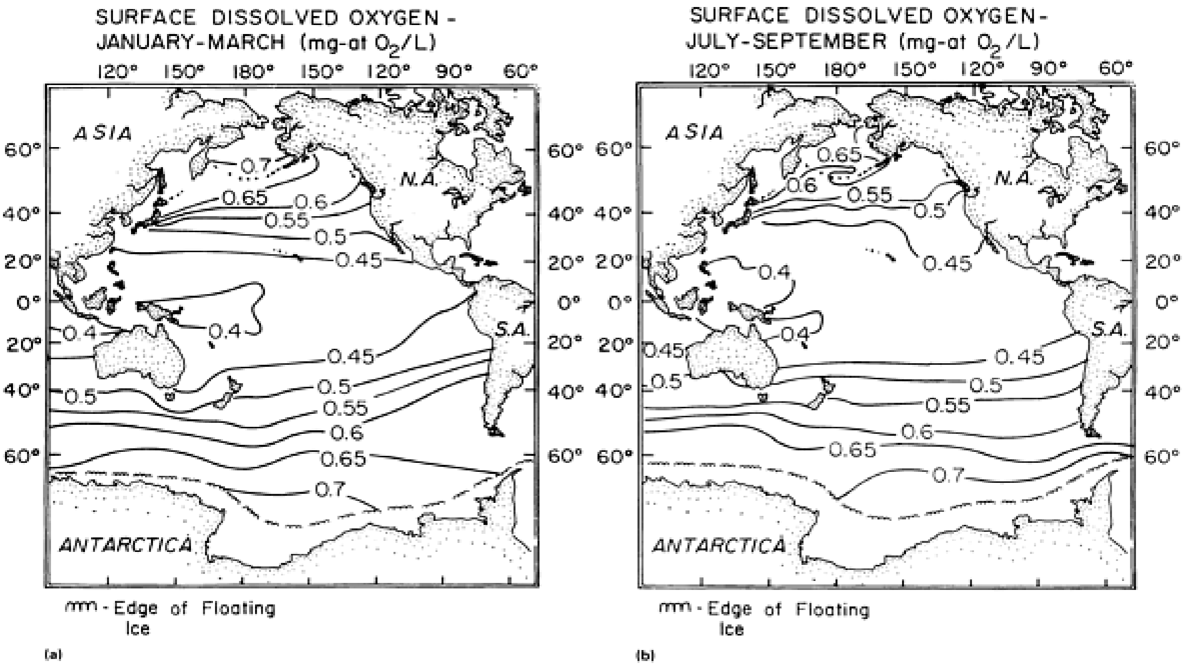

Fig. 14 Pacific Ocean surface dissolved oxygen (mg · atm/L) for January through March (a) and July through September (b). Source: Ref 5

As discussed previously, surface waters are either saturated or supersaturated with oxygen at atmospheric conditions. In contrast, deep waters are often undersaturated because of the consumption of oxygen during the biochemical oxidation of organic matter. Figure 15 shows horizontal maps of dissolved oxygen concentration in the Pacific Ocean at depths of 500 and 1000 m (1640 and 3280 ft). The level of oxygen is generally lower at these depths, especially in the northeastern Pacific.

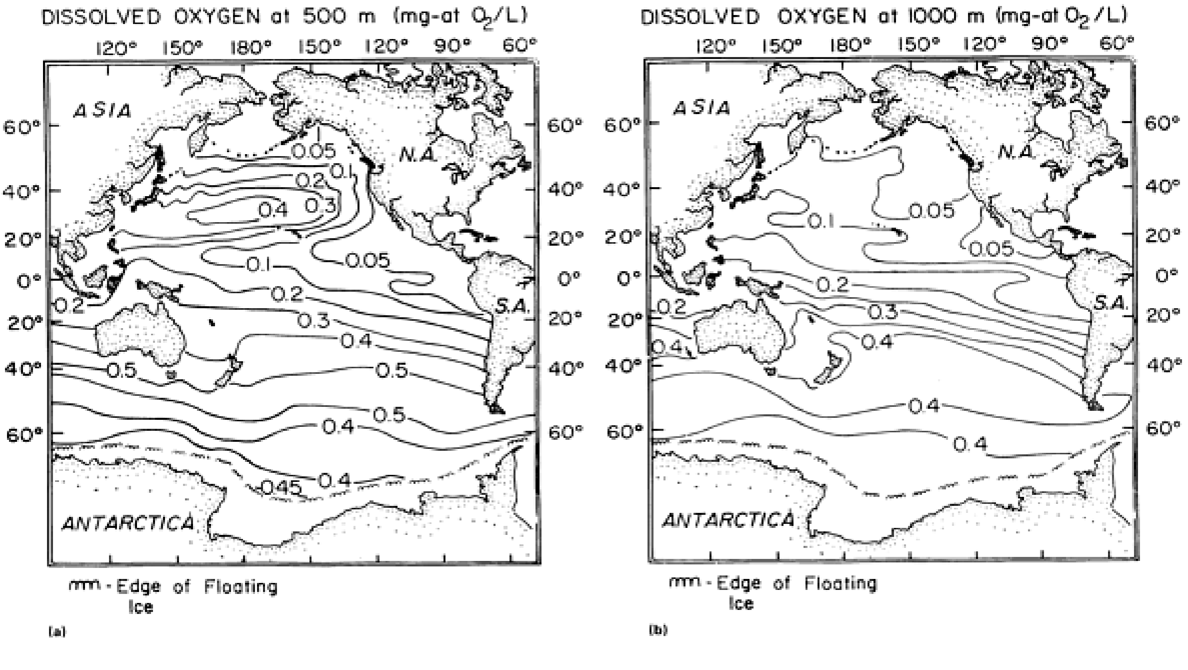

Fig. 15 Pacific Ocean dissolved oxygen (mg · atm/L) at depth of 500 m (a) and 1000 m (b). Source: Ref 5

This decrease in oxygen concentration with depth is shown more clearly in Fig. 16. The oxygen profiles for the open Atlantic and Pacific stations both go through a minimum at intermediate depths and increase again at great depths. In the Atlantic Ocean, the surface oxygen concentrations are usually lower, and the oxygen minimum is not as intense as in the Pacific. In addition, the oxygen concentrations in the deep Atlantic are higher than those in the deep Pacific, and they can be even higher than those in the Atlantic surface waters.

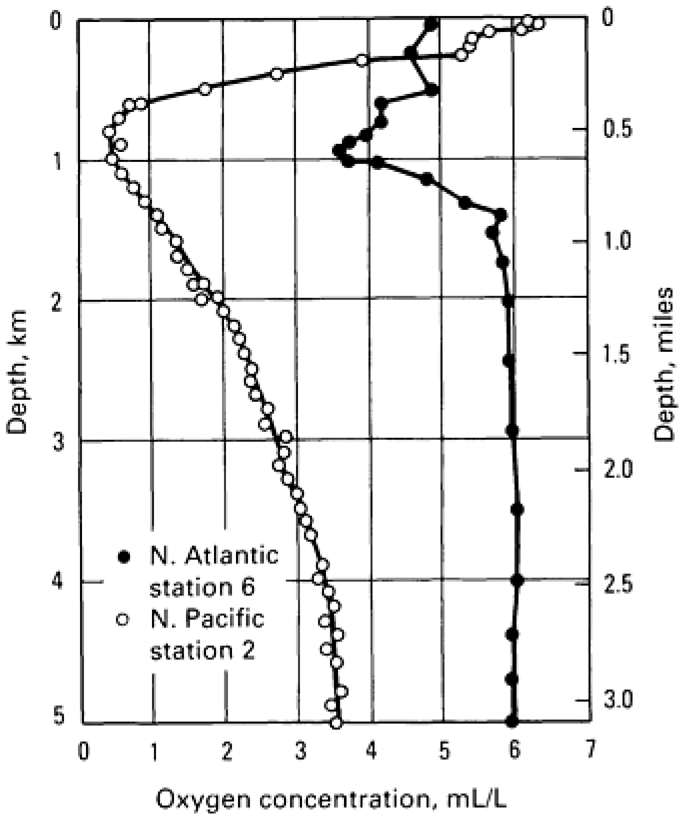

Fig. 16 Comparison of dissolved oxygen-depth profiles for open ocean stations 2 and 6 (see Fig. 5). Source: Ref 5

Figure 17 shows the depth of the dissolved oxygen minimum in the Pacific (solid contours) and the concentration of oxygen at that depth (dotted contours). The depth of the oxygen minimum ranges from 400 m (1310 ft) in the equatorial eastern Pacific to over 2400 m (7875 ft) in the central south Pacific. The concentration of oxygen at the depth of the minimum ranges from 0.01 to 0.40 mg · atm/L (1 mg · atm/L = 12.2 mL/L = 16 ppm at 25 °C or 75 °F). Oxygen profiles with depth for the four coastal stations are shown in Fig. 10, 11, 12, and 13.

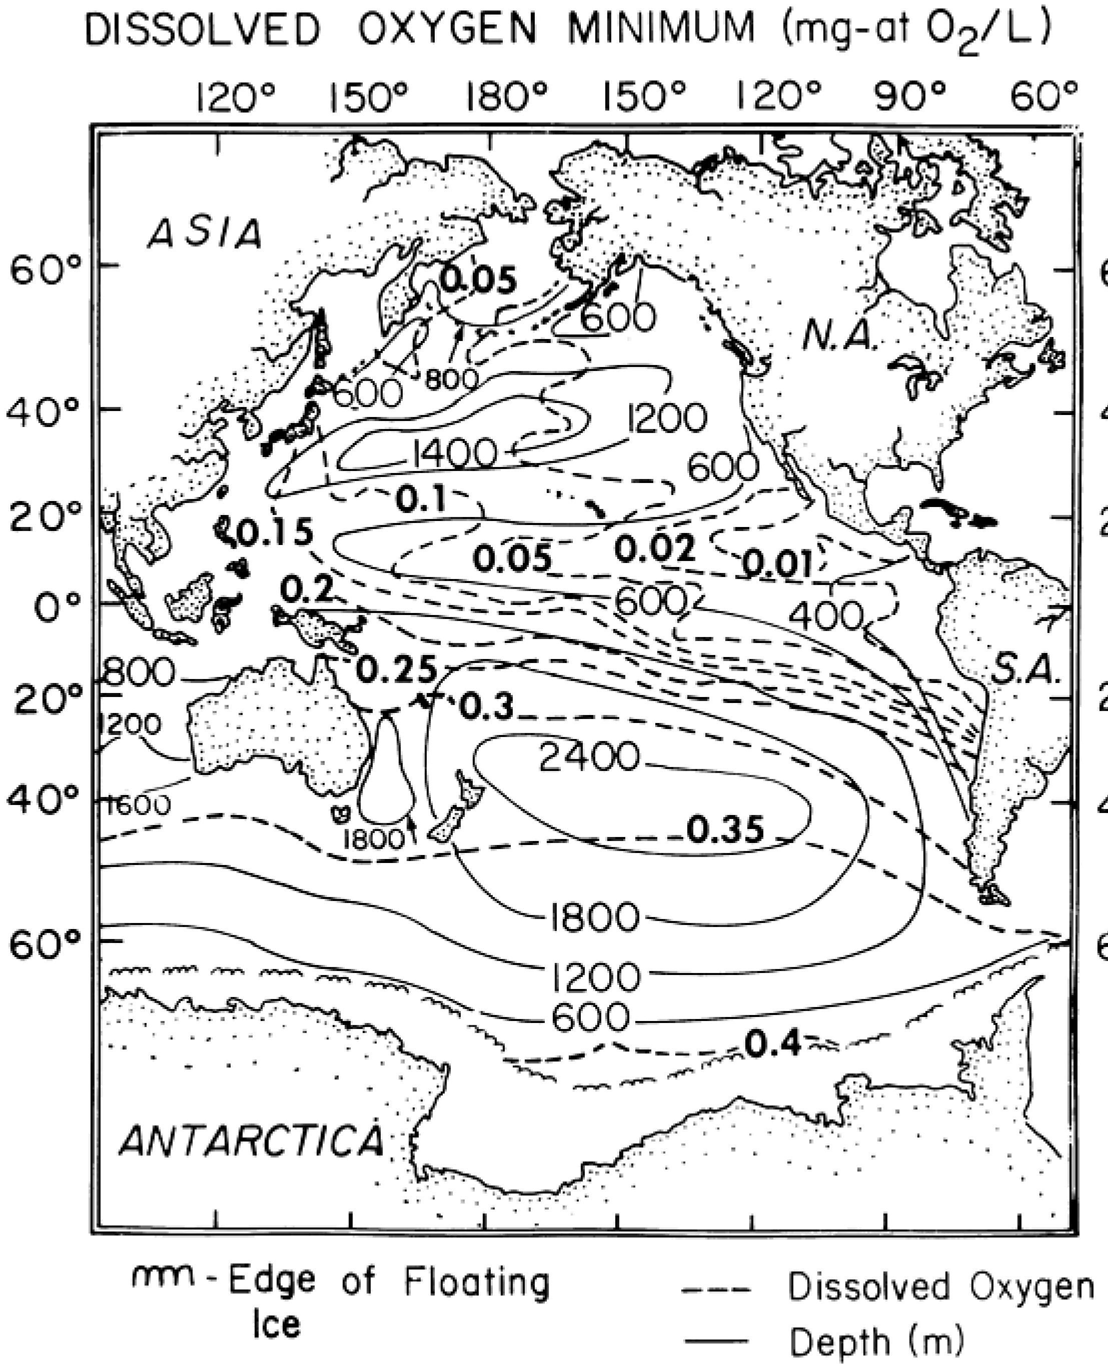

Fig. 17 Depth (meters) of the dissolved oxygen minimum in the Pacific (solid contours) and the value of the minimum in mg · atm/L (dashed contours). Source: Ref 5

Effect of Oxygen on Corrosion. The corrosion rate of active metals (for example, iron and steel) in aerated electrolytes such as seawater at constant temperature is a direct linear function of the dissolved oxygen concentration, as shown in Fig. 18. When oxygen and temperature vary together, as they do in the marine environment, the oxygen effect tends to predominate. This trend is illustrated by data for the corrosion rate of steel at various depths in the Pacific Ocean in Fig. 19. The corrosion rate decreases with dissolved oxygen down to the oxygen minimum, then increases again with oxygen at greater depths, despite a continuing decrease in temperature. The corrosion rates of nickel and nickel-copper alloys are somewhat less affected by oxygen concentration, as shown in Fig. 20. The effect of oxygen on copper alloys depends on the flow velocity. Figure 21 shows that there is very little effect of oxygen on copper alloys exposed in quiet open ocean water. At a flow velocity of 1.8 m/s (6 ft/s), however, increasing oxygen has a marked accelerating effect (Fig. 22).

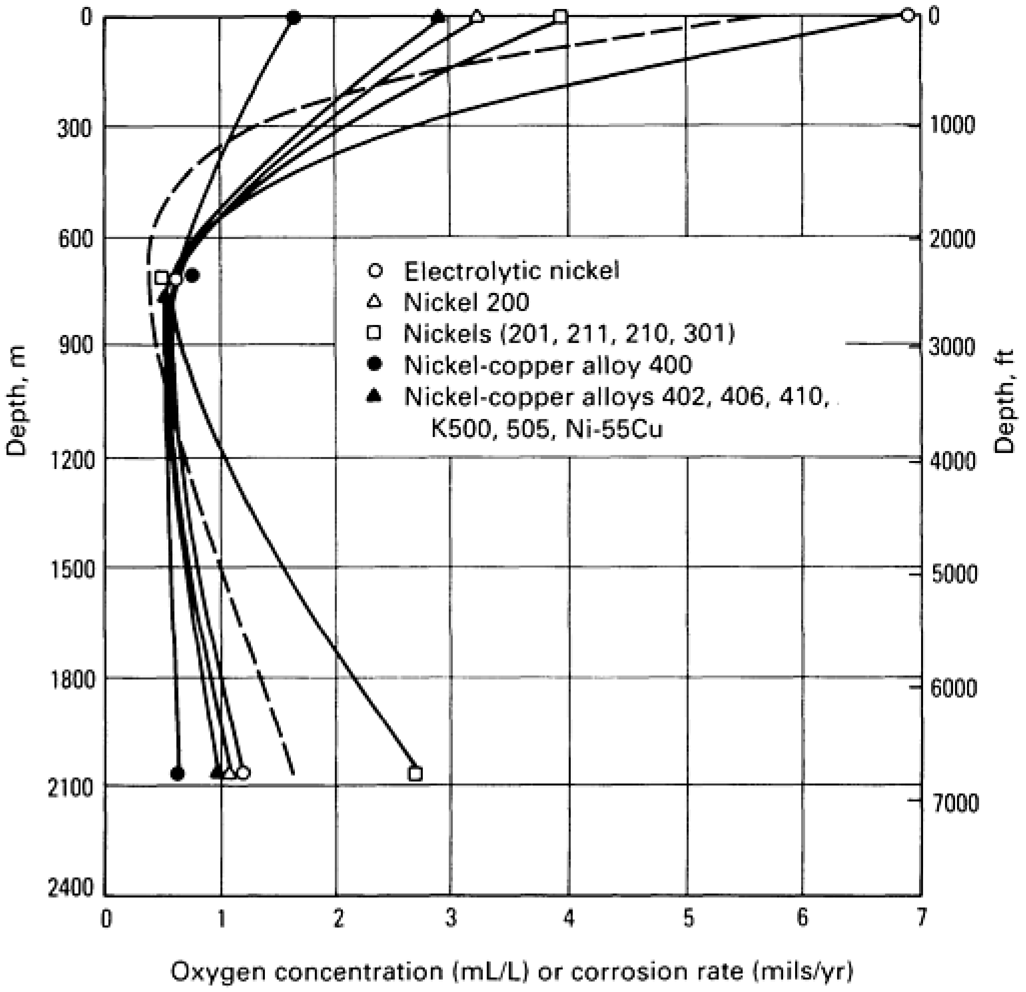

Fig. 20 Corrosion of nickels and nickel-copper alloys versus depth after 1 year of exposure compared to the shape of the dissolved oxygen profile (dashed line). Source: Ref 2

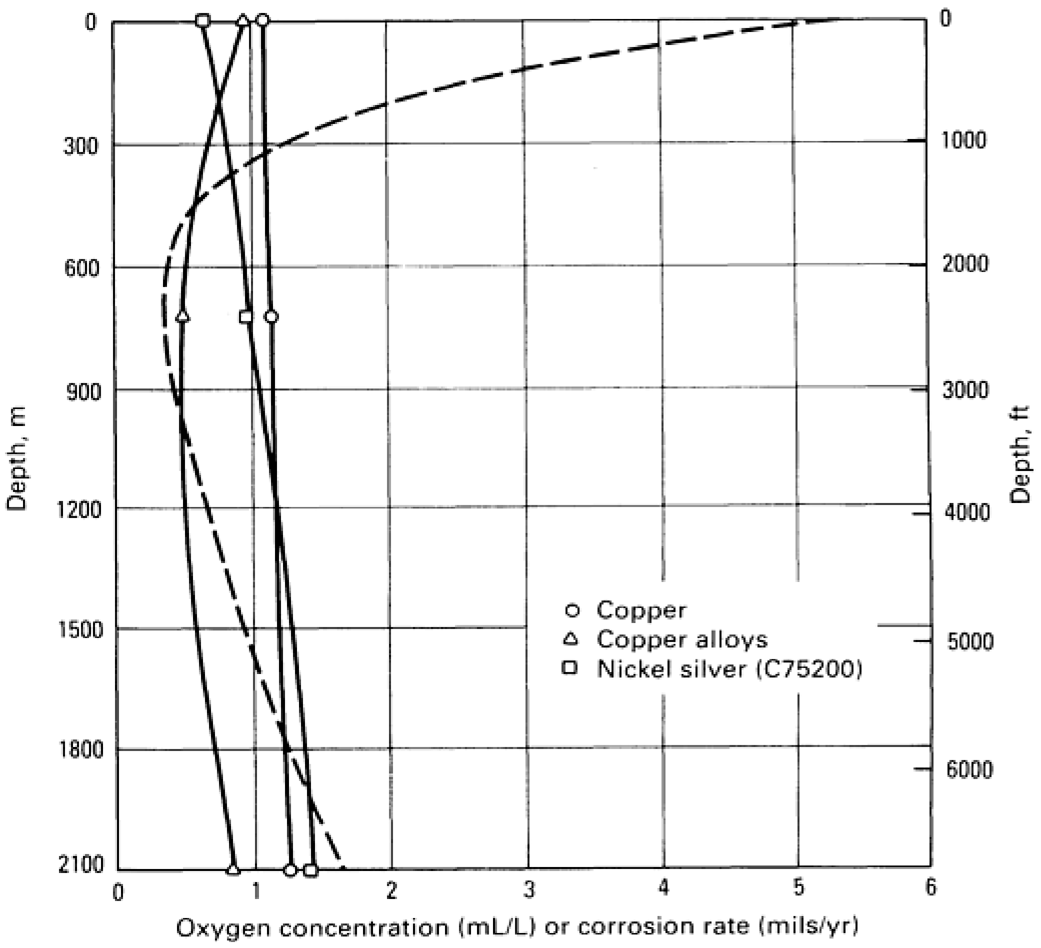

Fig. 21 Corrosion of copper alloys versus depth after 1 year of exposure compared to the shape of the dissolved oxygen profile (dashed line). Source: Ref 2

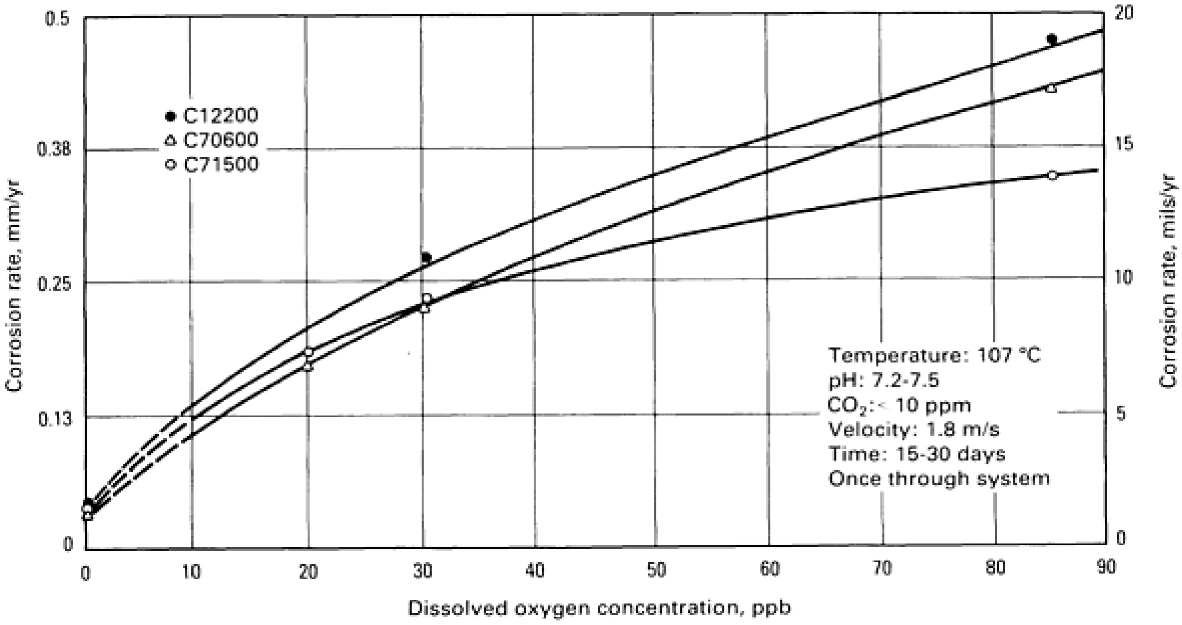

Fig. 22 Effect of dissolved oxygen in seawater on the corrosion rate of three CDA copper alloys. Source: Ref 7

In contrast, the effect of oxygen on the corrosion rates of active-passive metals, such as the aluminum and stainless alloys, can be quite variable (Fig. 23). In such alloy systems, high oxygen concentrations tend to promote healing of the passive film and thus retard initiation of pitting corrosion. On the other hand, high oxygen favors a vigorous cathodic reaction and tends to increase the rate of pit and crevice propagation after initiation.

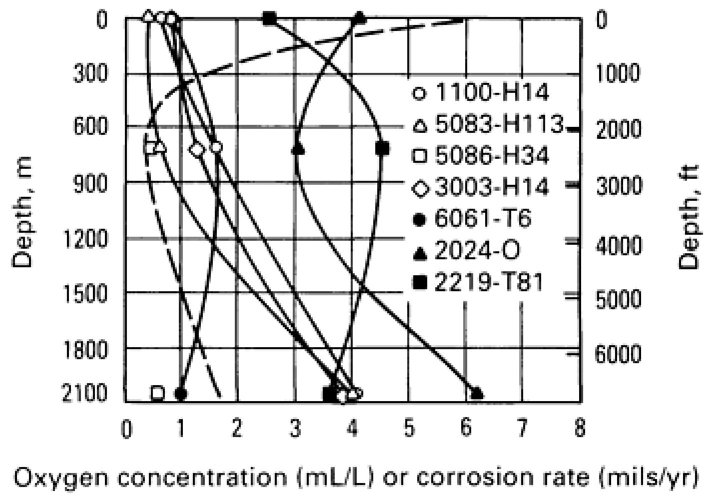

Fig. 23 Corrosion rates of aluminum alloys versus depth after 1 year of exposure compared to the shape of the dissolved oxygen profile (dashed line). Source: Ref 2

For all alloy systems, the conditions most conducive to corrosion are those in which differences in dissolved oxygen are allowed to develop between two regions of the wetted metal surface. This can lead to an oxygen concentration cell, with potential differences as large as 0.5 V. The portion of metal surface on which the oxygen concentration is lowest becomes the anode and is subject to localized corrosion. Differences in dissolved oxygen concentration of this type are unlikely to be caused by variation in the water; instead, they are caused by localized deposits or structural design factors that create oxygen-shielded regions on the metal surface.

These effects also can lead to pitting corrosion of active metals such as carbon and low-alloy steels. The average uniform corrosion rates of carbon and low-alloy steels in a wide variety of marine environments are found to range from 50 to 125 m/yr (2 to 5 mils/yr), slowly decreasing with time of exposure. Data from the Panama Canal zone showed that, although the average penetration rate was 68 m/yr (2.7 mils/yr), the penetration by pitting was some five to eight times higher (Fig. 24).

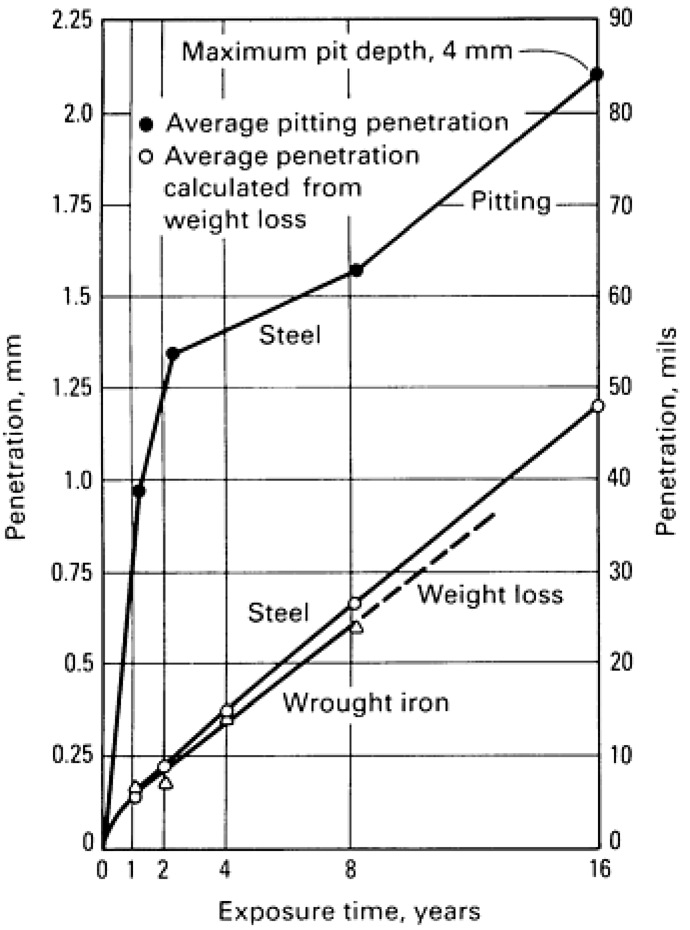

Fig. 24 Corrosion of carbon steel and wrought iron continuously immersed in seawater. Average penetration rate was 68 m/yr (2.7 mils/yr) for steel; that of wrought iron was 61 m (2.4 mils/yr). Source: Ref 7

Differences in dissolved oxygen from point to point along the metal surface caused by spotty biofouling films can contribute to the pitting rate. Dissolved oxygen differences are not the only factor in controlling pitting, however. Metallurgical factors can also be major contributors (see the article "Metallurgically Influenced Corrosion" in this Volume). In contrast to the effects of a spotty film, complete coverage of the surface by hardshelled, sedentary fouling organisms can lead to a marked decrease in the overall corrosion rate by acting as a diffusion barrier against dissolved oxygen reaching the metal surface. In the case of aluminum and stainless alloys, point to point differences in oxygen concentration can lead to both pitting and crevice corrosion.

Dissolved Carbon Dioxide and pH. The concentration of carbon dioxide is less affected by air-sea interchange than the concentration of dissolved oxygen, because the carbon dioxide system in seawater is buffered by the presence of bicarbonate and carbonate ions. Carbon dioxide is a weak acid and undergoes two ionizations in aqueous solutions:

$$CO_2 + H_2O = H^+ + HCO_3^- \quad \text{(Eq 4)}$$

First ionization

$$HCO_3^- = H^+ + CO_3^{2-} \quad \text{(Eq 5)}$$

Second ionization

Surface seawater usually has a pH values greater than 8 because of the combined effects of air-sea exchange and photosynthesis. At this pH, 93% of the total inorganic carbon is present as HCO_3^-, 6% as CO_3^{2-}, and 1% as CO_2. Bicarbonate ion accounts for at least 85% of the total inorganic carbon under all naturally occurring conditions. However,

the relative concentrations of CO_2 and CO_3^{2-} vary greatly depending on pH. The CO_3^{2-} concentration is relatively high in surface waters, and surface waters are nearly always supersaturated with respect to the calcium carbonate phases calcite and aragonite. This supersaturation favors deposition of calcareous scales on metal surfaces undergoing cathodic protection, as will be discussed in the section "Effects of pH on Corrosion and Calcareous Deposition" in this article.

Relationship Among CO_2, Oxygen, and pH. The concentrations of carbon dioxide and oxygen are closely coupled and related to the pH of seawater through the processes of photosynthesis and biochemical oxidation, as represented in the following general reaction:

$$CH_2O + O_2 \underset{\text{Biochemical oxidation (respiration)}}{\overset{\text{Photosynthesis}}{\rightleftharpoons}} CO_2 + H_2O \qquad \textbf{(Eq 6)}$$

where CH_2O represents a typical carbohydrate molecule. During decomposition of this organic material in seawater, Eq 6 proceeds from left to right, dissolved oxygen is consumed, and CO_2 is produced. Production of CO_2, in turn, makes the water more acidic (that is, lower pH) and decreases the saturation state with respect to carbonates.

Variability of pH. The pH of the Pacific surface waters ranges from 8.1 to 8.3, and its general distribution for the months of January to March is shown in Fig. 25. Distributions of pH at depths of 500 and 1000 m (1640 and 3280 ft) are shown in Fig. 26 and 27. In comparing these to the dissolved oxygen distributions at the same depths (Fig. 14 and 15), it should be noted that the trends for the two variables are similar. For example, at a depth of 500 m (1640 ft), the region of maximum dissolved oxygen, centered on 180° longitude between 20 and 40° north latitude in Fig. 15(a), is reproduced closely for pH in Fig. 26.

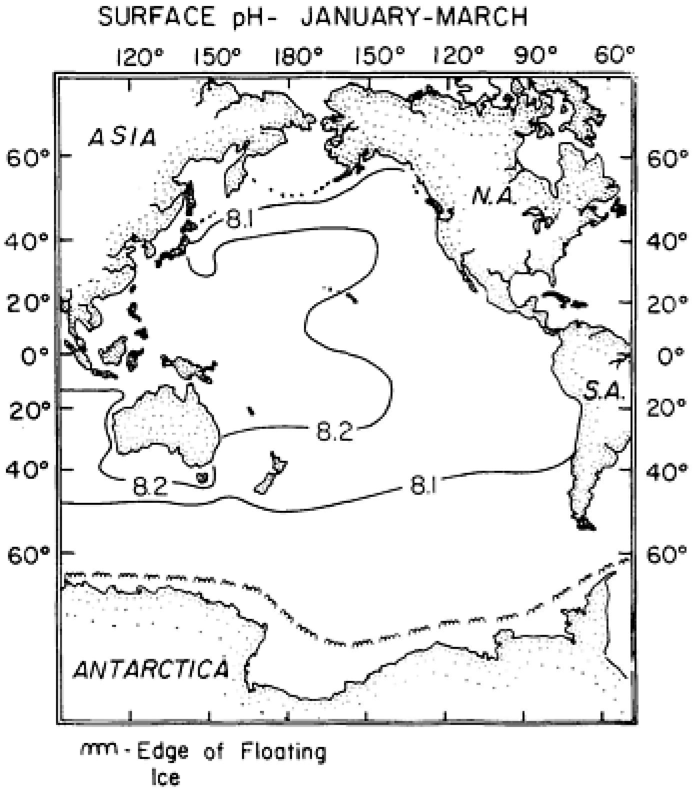

Fig. 25 Pacific Ocean surface pH for the period January to March. Source: Ref 5

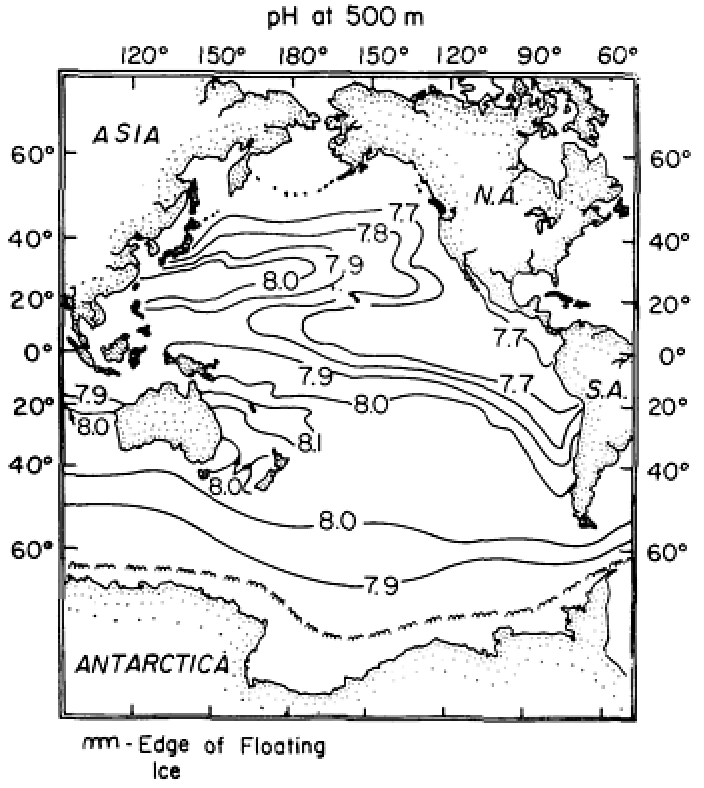

Fig. 26 Pacific Ocean pH at a depth of 500 m (1640 ft). Source: Ref 5

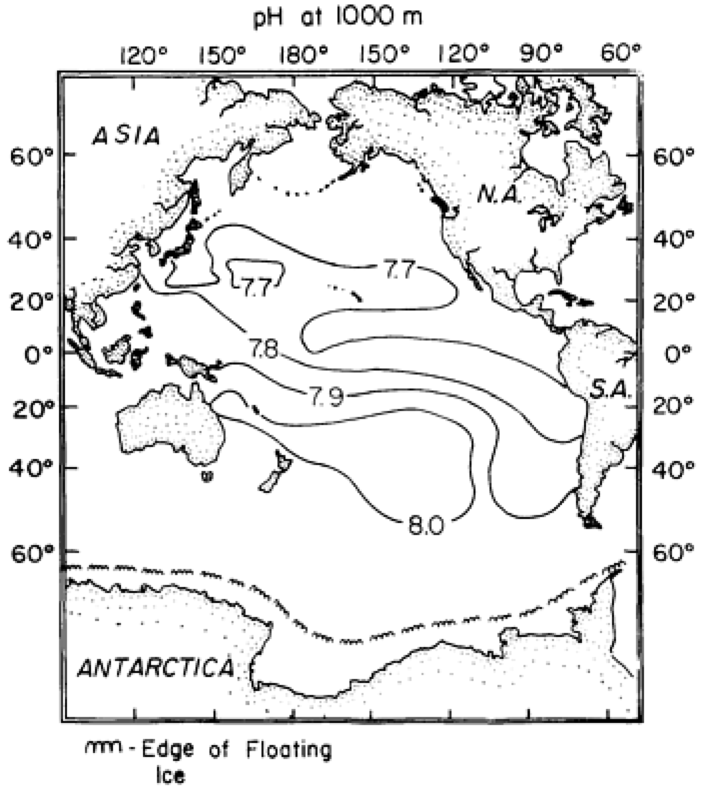

Fig. 27 Pacific Ocean pH at a depth of 1000 m (3280 ft). Source: Ref 5

Profiles of pH with depth for the two open ocean locations are shown in Fig. 28. A comparison of the corresponding pH and oxygen profiles from Fig. 16 and 28 reveals the closely coupled nature of their relationship through the carbon dioxide system, as discussed above. The oxygen and pH minima are reached at the same depth for a given location, as was predicted. The deep north Pacific water is from 0.15 to 0.40 pH units more acidic than that in the North Atlantic, primarily because of the increased oxidation of organic matter in the North Pacific.

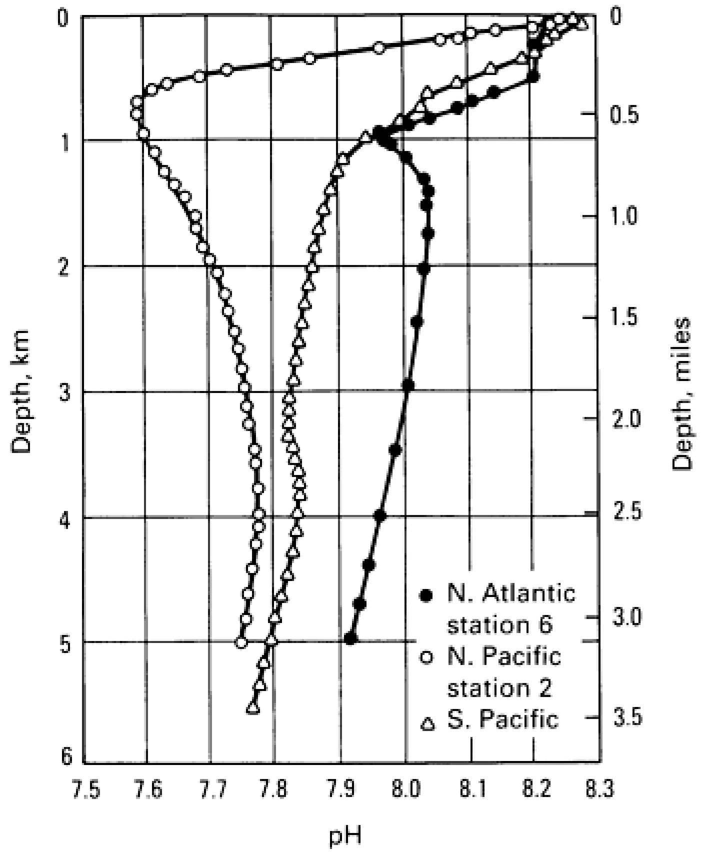

Fig. 28 Comparison of pH-depth profiles for open ocean sites 2 and 6 (see Fig. 5). Note that the data for the south Pacific are highest at the surface, but are intermediate at depths greater than 500 m (1640 ft). Source: Ref 5

Profiles of pH for the coastal waters off Oregon and New Jersey are shown in Fig. 11 and 13, respectively. The close correlation between the shapes of the oxygen and pH profiles in both winter and summer for the Oregon data in Fig. 11 is particularly striking. Upon close examination, the oxygen and pH profiles in Fig. 13 do not appear to be closely related in the manner seen earlier. In March, the water column is well mixed down to the bottom, and the changes with depth of all four variables are small. In August, however, the dissolved oxygen profile is nearly independent of depth, while the pH and temperature profiles show substantial changes. Based on salinity and temperature, the oxygen saturation levels during August are about 5.2 mL/L in the surface waters and 6.5 mL/L in the deep water. The oxygen profile for August shows that the surface waters are nearly saturated, while in the deep waters, biological activity has used up enough oxygen and produced enough CO_2 to decrease the pH--but not enough to produce a strong oxygen minimum. This indicates the danger inherent in assuming that a pH minimum will always correspond to a similar minimum in oxygen. The two profiles may not correspond closely in shape when the biological demand for oxygen is not sufficiently intense to produce a strong oxygen minimum or when there is a strong temperature gradient.

Effects of pH on Corrosion and Calcareous Deposition. The pH of open ocean seawater ranges from about 7.5 to 8.3. Changes within this range have no direct effect on the corrosion of most structural metals and alloys. The one exception to this general statement is the effect of pH on aluminum alloys. A decrease in pH from the surface water value of 8.2 to a deep water value of 7.5 to 7.7 causes a marked acceleration in the initiation of both pitting and crevice corrosion. This effect accounts for the reported increase in corrosion of aluminum alloys in the deep ocean (see the article "Corrosion of Aluminum and Aluminum Alloys" in this Volume).

Although variations in seawater pH have little direct effect on corrosion, they do have an indirect effect through their influence on calcareous deposition. The surface waters of most of the oceans of the world are 200 to 500% supersaturated with respect to the calcium carbonate species calcite and aragonite. This means that precipitation of carbonate-type scales is likely to be an important part of any corrosion reaction in surface water at most locations. The predominant species precipitated in warm surface waters are aragonite and, at interface pH values above 9.3 as experienced in cathodic protection, brucite ($Mg(OH)_2$).

Scale precipitation is most likely to occur in the elevated-pH regime adjacent to cathodically protected surfaces, where OH^- ions are produced during reduction of dissolved oxygen. For many years, the corrosion protection industry has relied on the buildup of calcareous scales to make cathodic protection more economical. The higher the pH at the water/metal interface, the more brucite is favored and the lower the calcium-magnesium ratio of the deposit will be. A lower calcium-magnesium ratio, in turn, makes the scale less dense and less protective. Thus, a high level of cathodic protection applied in the early stages of immersion, as is sometimes done to accelerate scale buildup, can be counterproductive in terms of scale quality.

In deep waters, where the temperature and pH are both lower than at the surface, calcareous deposits do not form spontaneously under ambient conditions, and it has often been difficult to form deposits even under cathodic protection conditions. This is partly because the deep waters--below 300 m (985 ft) in the Atlantic and 200 m (655 ft) in the North Pacific--are undersaturated in carbonates because of low pH and high pressure. At the low temperatures of the deep water, calcite is the predominant calcium carbonate phase. At first, this would seem to be beneficial because calcite forms a dense, protective film. However, calcite formation is strongly inhibited by the free magnesium ions that are abundant in seawater. Therefore, only brucite, which is much less protective, tends to form in deep water, and even brucite forms only under cathodic protection conditions when the interface pH is greater than 9.7.

In the laboratory, fine-grain, dense, and protective deposits can be formed in cold water with elevated calcium and bicarbonate concentrations and decreased magnesium. An economical way to achieve these conditions on a large structure in the real environment does not yet exist.

Influence of Biological Organisms

Seawater is a biologically active medium that contains a large number of microscopic and macroscopic organisms. Many of these organisms are commonly observed in association with solid surfaces in seawater, where they form biofouling films. Because this subject has been dealt with in detail in the sections on biological corrosion in the articles "General Corrosion" and "Localized Corrosion" in this Volume, only a brief description will be given here.

Immersion of any solid surface in seawater initiates a continuous and dynamic process, beginning with adsorption of nonliving, dissolved organic material and continuing through the formation of bacterial and algal slime films and the settlement and growth of various macroscopic plants and animals. This process, by which the surfaces of all structural materials immersed in seawater become colonized, adds to the variability of the ocean environment in which corrosion occurs.

Bacterial Films. The process of colonization begins immediately upon immersion with the adsorption of a nonliving orgnanic conditioning film. This conditioning film is nearly complete within the first 2 h of immersion, at which time the initially colonizing bacteria begin to attach in substantial numbers. The bacterial, or primary, slime film develops over a period of 24 to 48 h in most natural seawaters, although further changes in the film can often be observed over more than a 2-week period. Additional information is available in the Selected References at the end of this article.

The bacterial film changes the chemistry at the metal/liquid interface in a number of ways that have an important bearing on corrosion. As the biofilm grows, the bacteria in the film produce a number of by-products. Among these are organic acids, hydrogen sulfide, and protein-rich polymeric materials commonly called slime. The first effect of the composite film of bacteria and associated polymer, an example of which is shown in Fig. 30, is to create a diffusion barrier between the metal/liquid interface and the bulk seawater. The barrier itself is over 90% water, so it does not truly isolate the interface; instead, it supports strong concentration gradients for various chemical species. Thus, the water chemistry at the interface may be different from that in the bulk water, although the two are closely coupled through diffusive processes.

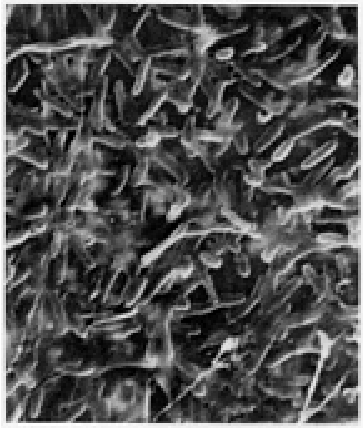

Fig. 30 Rod-shaped marine bacteria embedded in slime film growing on the surface of a copper-base antifouling paint after immersion in natural seawater at Woods Hole, MA, for 7 days. Depth of immersion was 5 m. 3000×

Two chemical species, oxygen and hydrogen, that are often implicated (or even rate-controlling) in corrosion are also important in the metabolism of the bacteria. A given bacterial slime film can be either a source or a sink for either oxygen or hydrogen. Moreover, these films are rarely continuous. Usually, they provide only spotty coverage of the metal surface. Thus, they are capable of inducing oxygen (or other chemical) concentration cells. Bacterial action on decaying organic matter in the slime film can also result in the production of ammonia and sulfides. Ammonia causes stress-corrosion cracking of copper alloys, and sulfides have been implicated in accelerated localized and/or uniform corrosion of both copper alloys and steels.

Under anaerobic (no oxygen) conditions, such as those found in marshy coastal areas, in which all the dissolved oxygen in the mud is used in the decay of organic matter, the corrosion rate of steel is expected to be very low. Under these conditions, however, the sulfate-reducing bacteria of the genus *desulfovibrio* utilize the hydrogen produced at the metal surface in reducing sulfates from the decaying organic material to sulfides, including H_2S. The sulfides combine with iron from the steel to produce an iron sulfide (FeS) film, which is itself corrosive. The bacteria thus transform a benign environment into an aggressive one in which steel corrodes quite rapidly.

Even under open ocean conditions at air saturation, the presence of a bacterial slime film can result in anaerobic conditions at the metal surface. Oxygen-utilizing bacteria in the initial film may eventually increase sufficiently in numbers that they use all the oxygen diffusing through the film before it can reach the metal surface. This creates an anaerobic layer right next to the metal surface and provides a place where the sulfate-reducing organisms can flourish. In all of these examples, the biofilm is able to change the chemistry of the electrolyte substantially at the water/metal interface. Thus, the corrosion rate may depend as much on the details of the electrolyte chemistry at the interface as it does on the ambient bulk seawater chemistry. Additional details about many aspects of biological corrosion can be found in the Selected References at the end of this article and in the articles "General Corrosion," "Localized Corrosion," and "Evaluation of Microbiological Corrosion" in this Volume.

Macrofouling Films. Within the first 2 or 3 days of immersion, the solid surface, already having acquired both conditioning and bacterial films, begins to be colonized by the macrofouling organisms. A heavy encrustation of these organisms can have a number of undesirable effects on marine structures. Both weight and hydrodynamic drag on the structure will be increased by the fouling layer. Interference with the functioning of moving parts may also occur.

In terms of corrosion, the effects of the macrofouling layer are similar to those of the microfouling layer. If the macrofoulers form a continuous layer, they decrease the availability of dissolved oxygen at the metal/water interface and can reduce the corrosion rate. If the layer is discontinuous, they may induce oxygen or chemical concentration cells; this leads to various types of localized corrosion. Fouling films may also break down protective paint coatings by a combination of chemical and mechanical action. Additional information is available in the Selected References at the end of this article.

Marine Atmospheres

Richard B. Griffin, Department of Mechanical Engineering, Texas A&M University

The annual cost of corrosion in the United States has been estimated at $167 billion. A reasonable fraction of this amount is the result of atmospheric corrosion. The buildings, automobiles, bridges, storage tanks, ships, and other items that must be coated, repaired, or replaced represent only some of the problem areas of corrosion to the U.S. economy.

Typically, atmospheric corrosion is broken down into the types listed in Table 9. A variety of factors affect the atmospheric corrosion behavior of materials. These include the time of wetness, temperature, material, air contaminants, solar radiation, biological species, and the composition of the corrosion products. The particular location of a composed is also important with respect to its corrosion behavior.

Table 9 Types of atmospheres and corrosion rates of low-carbon steel

Test duration: 2 years

Atmosphere	Location	Corrosion rate	
		mm/yr	**mils/yr**
Marine	Point Reyes, CA	0.5	19.71
Severe	25-m (80-ft) lot, Kure Beach, NC	0.53	21.00
Industrial	Brazos River, TX	0.093	3.67
Mild	250-m (800-ft) lot, Kure Beach, NC	0.146	5.73
Rural	Esquimalt, BC, Canada	0.013	0.53
Industrial	East Chicago	0.084	3.32
Marine	Bayonne, NJ	0.077	3.05
Urban	Pittsburgh, PA	0.03	1.20
Suburban (semi-industrial)	Middletown, OH	0.029	1.13
Rural	State College, PA	0.023	0.90
Marine	Esquimalt, BC, Canada	0.013	0.53
Desert	Phoenix, AZ	0.0046	0.18

The marine or marine-industrial type is generally considered to be the most aggressive environment. This discussion of marine atmospheric corrosion will include atmospheric corrosion (zone 1, Fig. 2) and the splash zone above high tide (zone 2, Fig. 2). For carbon steels in marine exposure, the maximum corrosion rate occurs in the splash zone, in which the alloy is wet almost continually with well-aerated seawater. The atmospheric corrosion of low-carbon steel is in the range of 0.025 to 0.75 mm/yr (1 to 30 mils/yr). This section will discuss the specific details associated with the rates of corrosion in marine atmospheres.

Important Variables

A number of factors, such as moisture, temperature, winds, airborne contaminants, alloy content, location, and biological organisms, contribute to atmospheric corrosion. Each of these factors will be discussed with regard to its contribution to corrosion in the marine atmosphere.

Moisture. For corrosion to occur by an electrochemical process, there must be an electrolyte present. An electrolyte is a solution that will allow a current to pass through it by the diffusion of anions (negatively charged ions) and cations (positively charged ions). Water that contains ions is a very good electrolyte. Therefore, the amount and availability of moisture present is an important factor in atmospheric corrosion. For steel beyond a certain critical humidity, there will be an acceleration in the rate of corrosion in the atmosphere. An example of this is shown in Fig. 31, in which the critical humidity is 60% for iron in an atmosphere free of sulfur dioxide (Fig. 31a). For magnesium under similar conditions, the critical relative humidity is 90% (Fig. 31b). The critical relative humidity is not a constant value; it depends on the hygroscopicity (tendency to absorb moisture) of the corrosion products and the contaminants.

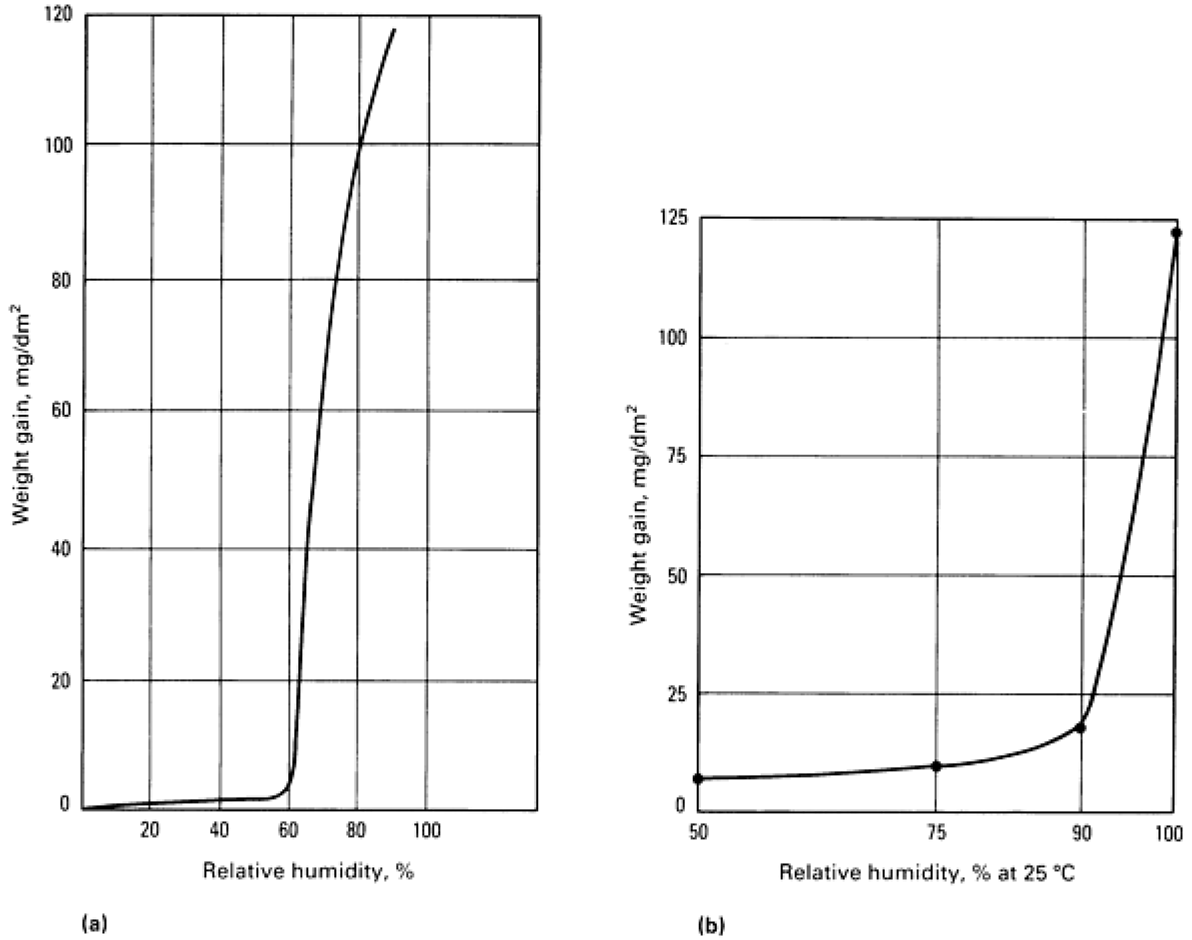

Fig. 31 Corrosion rates of iron and magnesium as a function of relative humidity. (a) For iron, the critical relative humidity is 60%. (b) For magnesium, corrosion rate increases significantly at a critical relative humidity of about 90%. Source: Ref 10

One of the measures of the effects of moisture is the time of wetness. As Fig. 32 shows, corrosion rate increases as time of wetness increases. In addition. Fig. 32 shows the importance of a contaminant. When the sulfur dioxide level increases, there is a corresponding increase in the overall corrosion rate. However, the severity of the marine environment is related to the salt content of the sea spray or dew that contacts the material surface, which is usually more corrosive than rainfall.

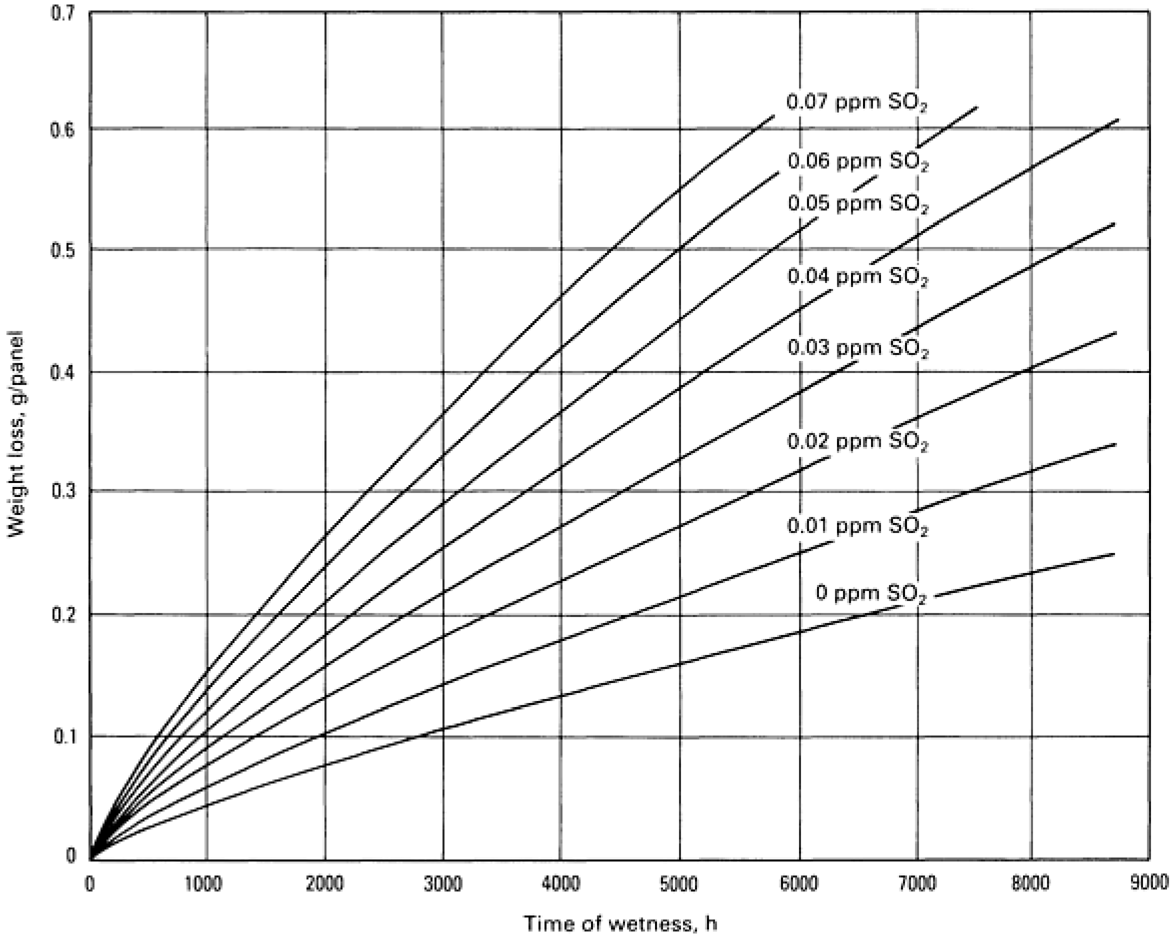

Fig. 32 The increase in corrosion rate of zinc as a function of time of wetness and SO_2 concentration. Source: Ref 10

For acid rain conditions, there appears to be no significant increase in corrosion rate. A study conducted in Sweden from October 1974 to November 1976 for carbon steel showed an increase in corrosion rates with increasing sulfur dioxide; however, the incidences were relatively infrequent. The study also showed that the corrosion rates measured for a longer time do not seem to be influenced by the incidences of acid rain. Similar results were obtained in a British study on the atmospheric-corrosion rate of zinc.

Airborne Contaminants. The second most important factor in atmospheric corrosion is the contaminants found in the air. These can be manmade or natural, such as airborne moisture carrying salt from the sea or sulfur dioxide put into the atmosphere by a coal-burning utility plant. Figure 32 illustrates the importance of the atmospheric sulfur dioxide level on the corrosion rate of zinc. The important contaminants are chlorides, sulfur dioxide, carbon dioxide, nitrogen oxides, and hard dust particles (for example, sand or minerals).

Chlorides. There is a direct relationship between atmospheric salt content and measured corrosion rates. The amount of sea salts measured off the coast of Nigeria illustrate this relationship between the salinity and the corrosion rate. This is shown in Fig. 33, in which salinity of 10 mg/m^2/d results in a corrosion rate of less than 0.1 g/dm^2/mo, while a salinity of 1000 mg/m^2/d results in a corrosion rate of almost 10 g/dm^2/mo. At the LaQue Center for Corrosion Technology test site at Kure Beach, NC, a similar effect has been observed for carbon steel. The corrosion rate at the site 25 m (80 ft) from the mean tide line was 1.19 mm/yr (47 mils/yr), while at the 250-m (800-ft) site, the corrosion rate for the same material was 0.04 mm/yr (1.6 mils/yr).

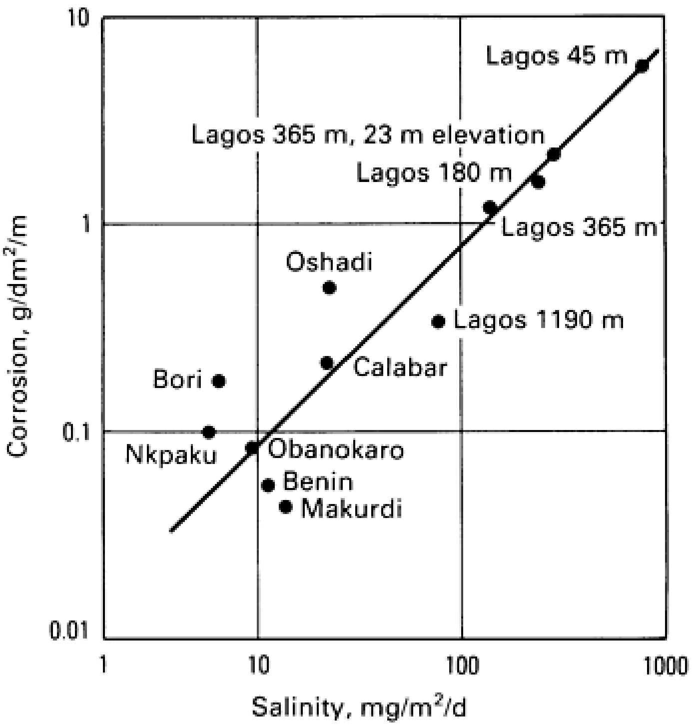

Fig. 33 Atmospheric corrosion as a function of salinity at various sites in Nigeria. Source: Ref 11

The average atmospheric chloride levels, as collected in rainwater for the United States, are shown in Fig. 34. The highest levels occur along the coast of the Atlantic Ocean, Pacific Ocean, the Gulf of Mexico. The maximum corrosion rate is related to the maximum chloride in the atmosphere. This will of course be related to the distance inland, the height above sea level, and the prevailing winds. The chlorides of calcium and magnesium are hygroscopic and have a tendency to form liquid films on metal surfaces.

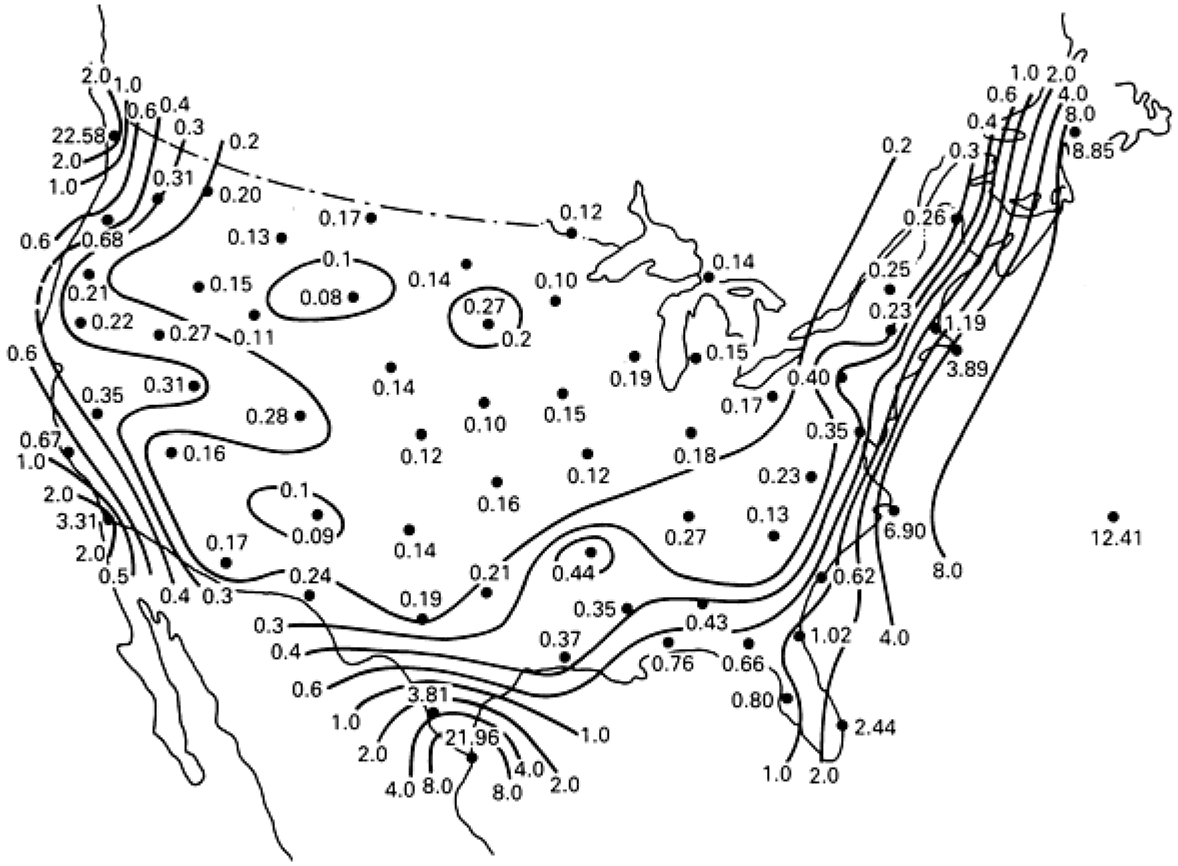

Fig. 34 Average chloride concentration (mg/L) in rainwater in the U.S. Source: Ref 10

Sulfur Dioxide. The presence of SO_2 in the atmosphere lowers the critical relative humidity while increasing the thickness of the electrolyte film and increasing the aggressiveness of the environment. For carbon steel, the effect of SO_2 levels is shown in Fig. 35, in which data are plotted from three Norwegian test sites. The data show that as SO_2 concentrations are increased the corrosion rate, measured as weight loss, increases. For example, at an SO_2 concentration of 25 μg/m^3, the corrosion rate is approximately 55 g/m^2/mo, while for an SO_2 concentration of 100 μg/m^3 the corresponding corrosion rate is approximately 170 g/m^2/mo. A summary of Scandinavian data for carbon steel and zinc showed the following relationships between corrosion rate and SO_2 concentration:

$$\dot{K}_{steel} = 5.28\,[SO_2] + 176.6 \qquad \textbf{(Eq 7)}$$

and

$$\dot{K}_{zinc} = 0.22\,[SO_2] + 6 \qquad \textbf{(Eq 8)}$$

where $\dot{K}$ is the atmospheric corrosion rate in g/m^2/yr, and $[SO_2]$ represents the concentration of SO_2 in μg/m^3. Similar types of relationships have been shown for other alloy systems and locations.

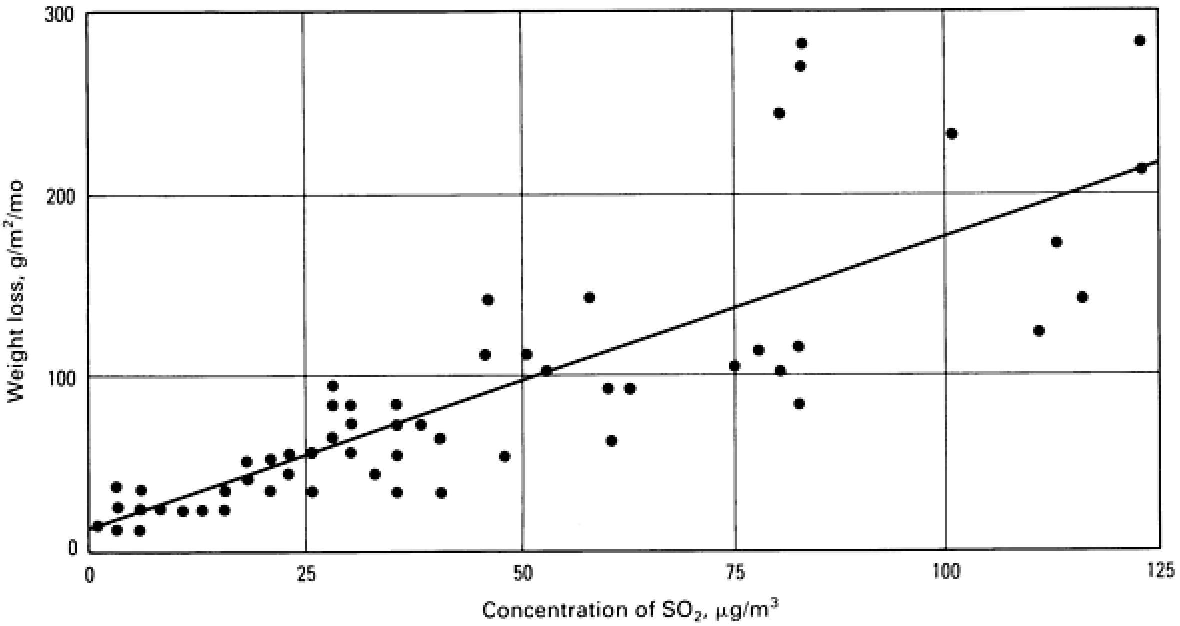

Fig. 35 Effect of SO_2 concentration on the corrosion rate of carbon steel at three Norwegian sites. Source: Ref 10

Carbon Dioxide. The opinion of the majority of investigators is that carbon dioxide (CO_2) has an effect on the corrosion of metals. Carbon dioxide in the presence of water forms carbonic acid (Eq 4); a pH of 5.6 could be obtained with atmospheric CO_2 in equilibrium with pure water. Carbonates are found in the corrosion products on a number of metals. It is possible that for steel and copper the presence of CO_2 might lessen the corrosion effects of SO_2, because of the nature of the corrosion products formed. Carbon dioxide does not have nearly the same level of importance in atmospheric corrosion as SO_2 and chlorides do.

Location is a very important variable. The distance from the sea and the height above the ground are both significant.

Distance. Figure 33 shows the effect of moving inland along the coast of Nigeria from the 45-, 365-, and 1190-m (50-, 400-, and 1300-yd) sites at Lagos. From studies done on Barbados, the effect of distance is confirmed by the map of the island shown in Fig. 36. As can be seen, this represents one of the worst conditions: tropical beach, on-shore winds, and facing a large, uninterrupted stretch of ocean. Similarly, at a site in Aracaju, Brazil, low-carbon steel samples were tested at five sites from about 0.1 km (0.06 miles) to almost 4 km (2.5 miles) from the sea. There was, as Fig. 37 shows, a rapid falloff in the corrosion rate as the testing site was moved inland. By about 1.5 km (0.9 miles) inland, the corrosion rate had reached a value that shows it is basically independent of the marine atmosphere.

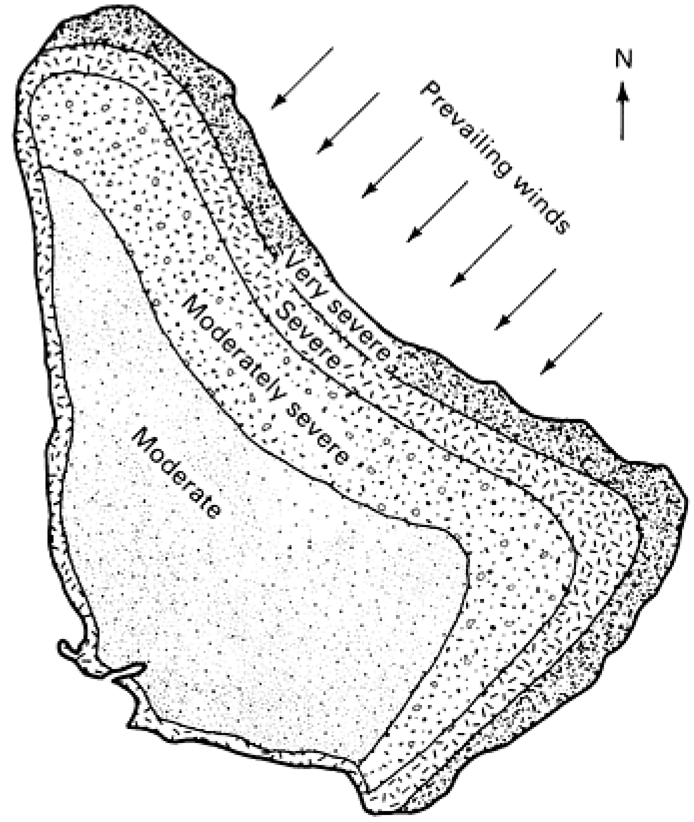

Fig. 36 Estimates of marine atmosphere corrosivity at various locations on the island of Barbados in the West Indies. Based on CLIMAT data. Source: Ref 10

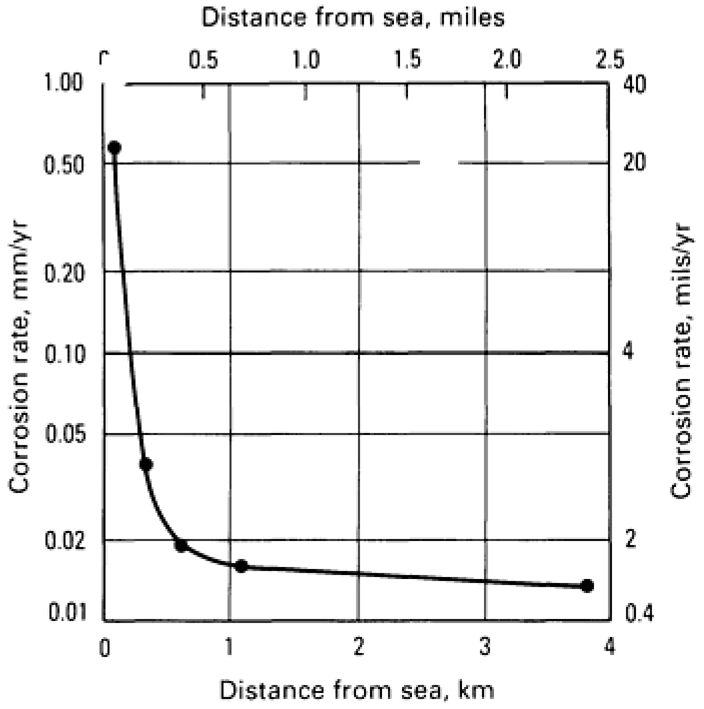

Fig. 37 Corrosion rate of carbon steel as a function of distance from the sea at Aracaju, Brazil. Source: Ref 10

The height of the specimens above seawater is also important. This is illustrated in Fig. 38(a) in which the corrosion rate of the carbon steel specimens in the 25-m (80-ft) lot at Kure Beach, NC, varies from less than 400 m/yr (16 mils/yr) at a height of 5 m (16.5 ft) to 600 m/yr (24 mils/yr) at a height of about 8 m (26 ft). The corrosion rate is in direct proportion to the amount of chloride in the atmosphere. There is considerably less corrosion for the carbon steel at the Kure Beach, NC, 250-m (800-ft) test site (Fig. 38b). The 25-m (80-ft) lot has an average chloride content of approximately 400 $mg/m^2/d$, while the 250-m (800-ft) lot has an average chloride value of approximately 100 $mg/m^2/d$.

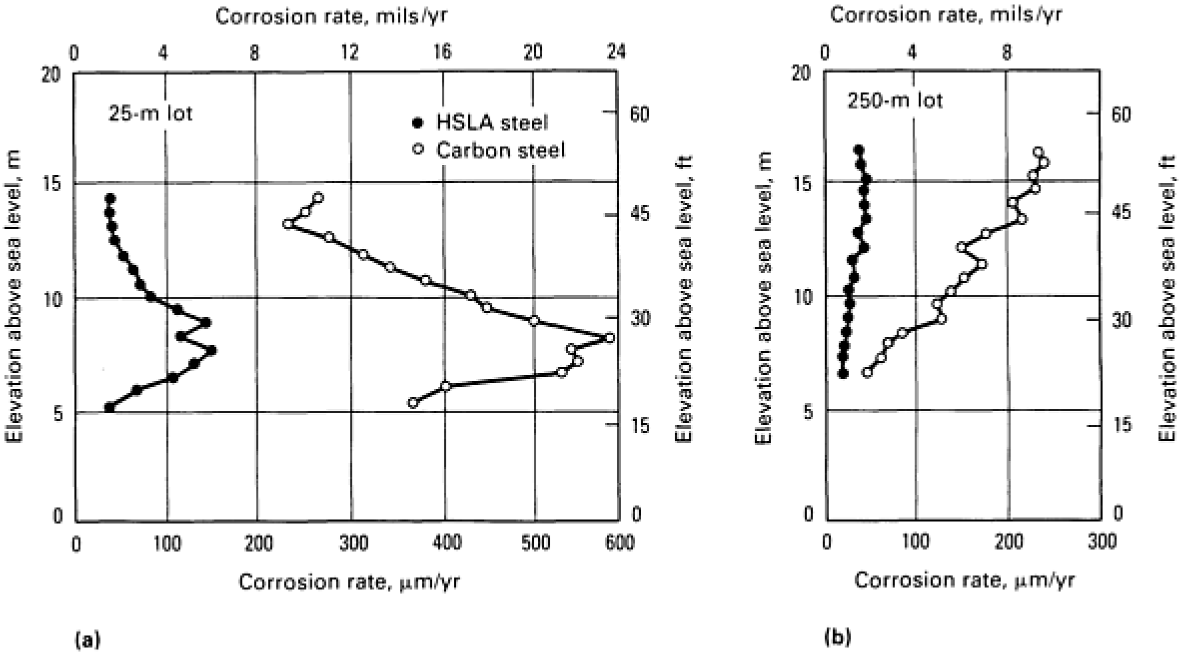

Fig. 38 Effect of elevation above sea level for carbon and HSLA steels at Kure Beach, NC. (a) 25-m (80-ft) lot; (b) 250-m (800-ft) lot. Source: Ref 12

In the splash zone, the effect of height above the sea is illustrated in Fig. 2, which shows that the corrosion rate is highest slightly above mean high tide. This zone would not only have a high chloride content, but would also be alternately wet and dry. As the height above the sea increases, the corrosion rate decreases because the specimen is not wet as often.

Orientation. Another important factor with regard to the atmospheric corrosion of a material is its orientation with respect to the earth's surface. Results for a 1-year exposure of iron specimens placed vertically and inclined at an angle of 30° with respect to the ground are shown in Fig. 39. The spread in the data is much greater for the Kure Beach 25-m (80-ft) test lot than for the 250-m (800-ft) test lot. In both cases, the vertical specimens showed a higher corrosion rate. This was attributed to the formation of a nonuniform, less protective oxide in the vertical position than in the 30° position. It is also possible that the 30° samples have the chloride deposits cleaned from their surfaces more easily than the vertical specimens. Ratios of the corrosion rate in the vertical position to that in the 30° position are given in Table 10 for five sites. In the vertical position, the corrosion rate is greater on the side facing the sea than on the side facing land. At the 25-m (80-ft) lot at Kure Beach, steel pipe specimens corroded at the rate of 850 m/yr (33.5 mils/yr) facing the ocean, as compared to 50 m/yr (2 mils/yr) facing away from the ocean, over a 4.5 year period.

Table 10 Comparison of atmospheric-corrosion rates for specimens held vertically and inclined at 30° to the horizontal

Location	Corrosion rate ratio, vertical/30°
Kearny, NJ	1.25
Vandergrift, PA	1.26
South Bend, PA	1.20
25-m (80-ft) lot, Kure Beach, NC	1.41

Source: Ref 12

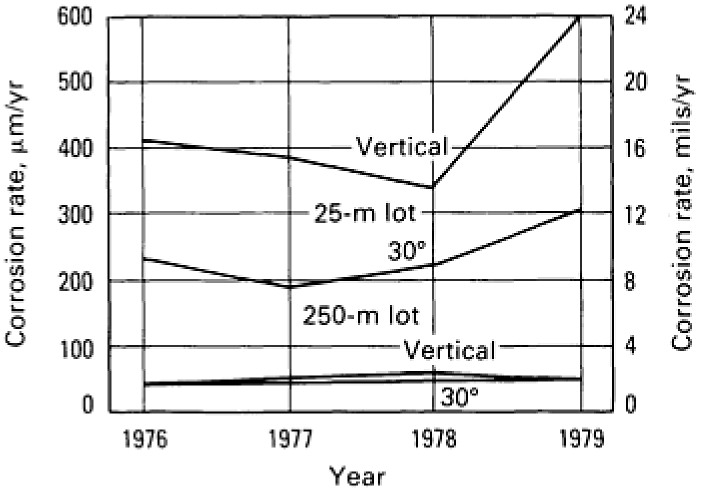

Fig. 39 Effect of specimen orientation on corrosion rates of iron specimens exposed vertically and at an angle of 30° to the horizontal. Results of 1-year test at Kure Beach, NC. Source: Ref 12

The corrosion rate can also be measured on the skyward or groundward side of specimens that are parallel to the earth's surface. Tests conducted at Kure Beach showed that the skyward side corroded at a greater rate after 3 months. However, after 6 months of testing, the rates were identical. Similarly, for an AZ31 B magnesium alloy in a 30-day test, the skyward-facing specimens lost more material than the groundward-facing ones.

The temperature affects the relative humidity, the dew point, the time of wetness, and the kinetics of the corrosion process. For atmospheric corrosion, the presence of moisture, as determined by the time of wetness, is probably the most important role of temperature. Figure 40 illustrates the effect of temperature on iron, zinc, and copper. There are three distinct patterns with increasing temperature over the range of 20 to 40 °C (70 to 100 °F):

- Corrosion rate increases for iron
- Corrosion rate decreases for zinc
- Corrosion remains constant for copper

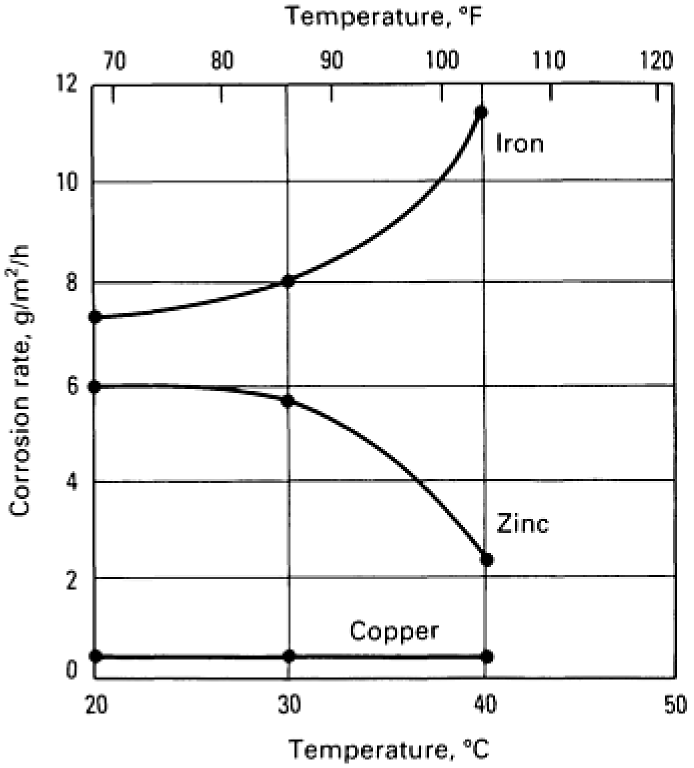

Fig. 40 The effect of temperature on the corrosion rates of iron, zinc, and copper. Source: Ref 10

The temperature of interest may not be the average daily temperature. It may be more important to know the dew-point temperature or the test panel surface temperature. From an atmospheric corrosion standpoint, dry, hot conditions are preferable to cooler, moist conditions.

Sunlight influences the degree of wetness and affects the performance of coatings and plastics. Sunlight may also stimulate photosensitive corrosion reactions on such metals as copper and iron. In addition, it may stimulate biological reactions, such as the development of fungi. Ultraviolet (UV) light and photo-oxidation can cause embrittlement and surface cracks in polymers. This can be avoided by the addition of UV stabilizers (for example, carbon black).

Wind. The direction and velocity of the wind affect the rate of accumulation of particles on metal surfaces. Also, wind disperses the airborne contaminants and pollutants. Figure 36 illustrates the very severe corrosion that can occur on an ocean beach facing the prevailing wind. The effect caused by the chloride ions being carried inland is illustrated in Fig. 37, which shows an increased corrosion rate at 1 km (0.6 mile) inland. Stronger prevailing winds can carry the airborne contaminants even further inland. A marine site may be made even more aggressive by the prevailing winds bringing industrial pollutants, particularly SO_2, to the marine site.

Time. For many materials, there is a decrease in the corrosion rate as time increases. This decrease is associated with the formation of protective corrosion layers. Figure 41 provides an example of this for a low-carbon steel at eight sites in South Africa. There is an initial sharp increase in the atmospheric-corrosion rate, followed by a slowing down of the corrosion rate as corrosion products form on the alloy surface. This is particularly true for the sites C through G. For site B, the corrosion rate is sufficiently high to prevent the formation of a protective layer; therefore, a very high corrosion rate can be maintained. The effect of corrosion on tensile strength is shown in Fig. 42 for a low-carbon steel and aluminum. The rate of loss in ultimate tensile strength is initially large, but as time continues, the rate of loss decreases.

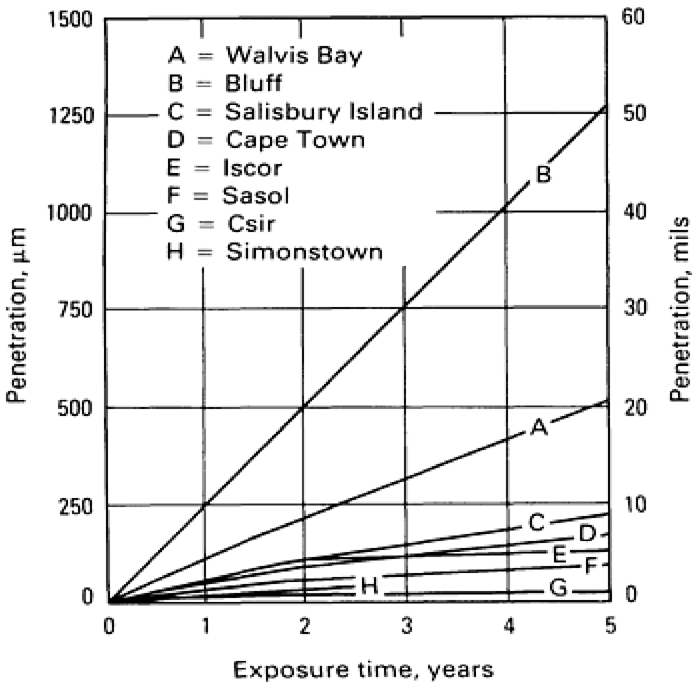

Fig. 41 Change in corrosion rate as a function of time for eight South African sites. Source: Ref 10

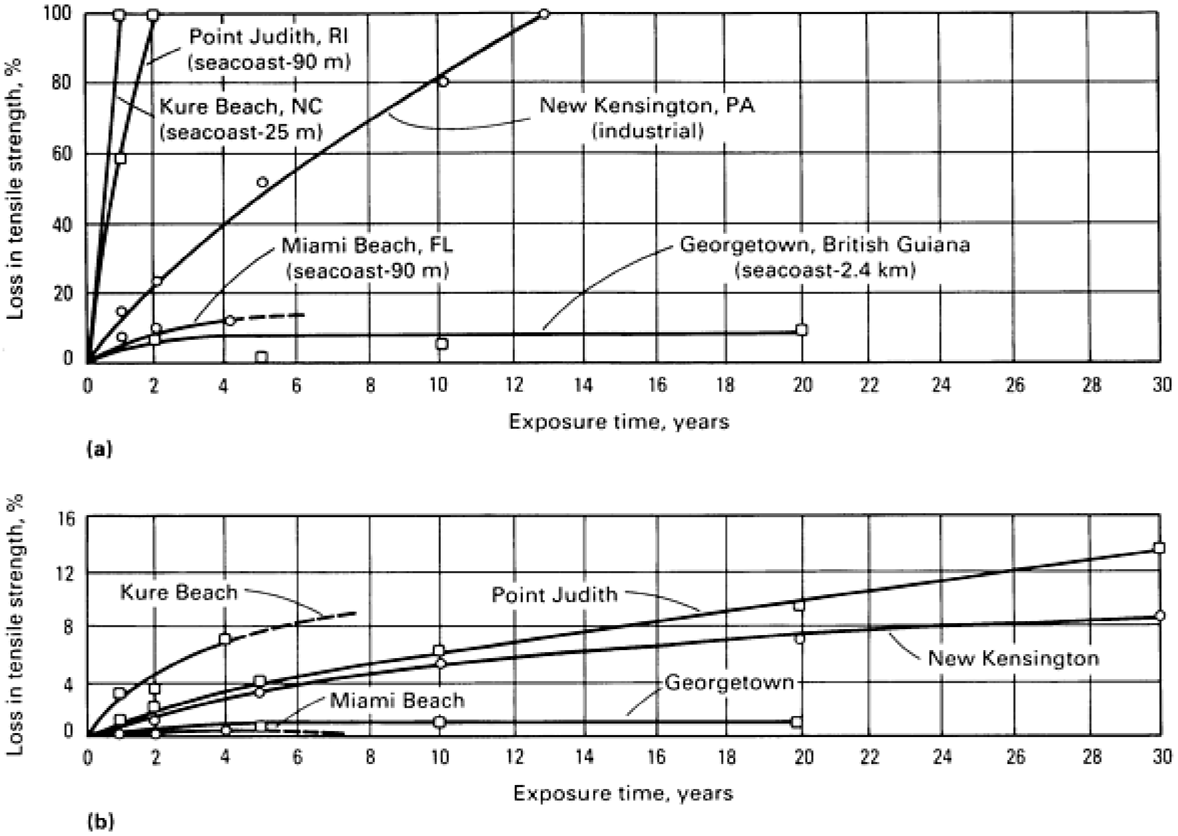

Fig. 42 Loss in tensile strength as a function of time for (a) 1.6 mm ($\frac{1}{16}$-in.) low-carbon steel and (b) aluminum alloys of the same thickness at five test sites. Data in (b) are averages for aluminum alloys 1100, 3003, and 3004. Source: Ref 10

Starting Date. There can be a variation in the corrosion rate that depends on when the tests were started. Figure 43 compares the measured weight losses for iron and zinc in tests started at two different dates. Over a 60-day test, the variation in corrosion rate for zinc is much larger than that for iron. Similarly, for iron specimens at the Kure Beach, 25-m (80-ft) lot, there are variations of hundreds of microns per year in corrosion rates, as measured on samples exposed vertically for 1 and 2 years each. This is shown in Fig. 44 for iron calibration specimens tested from 1949 to 1979.

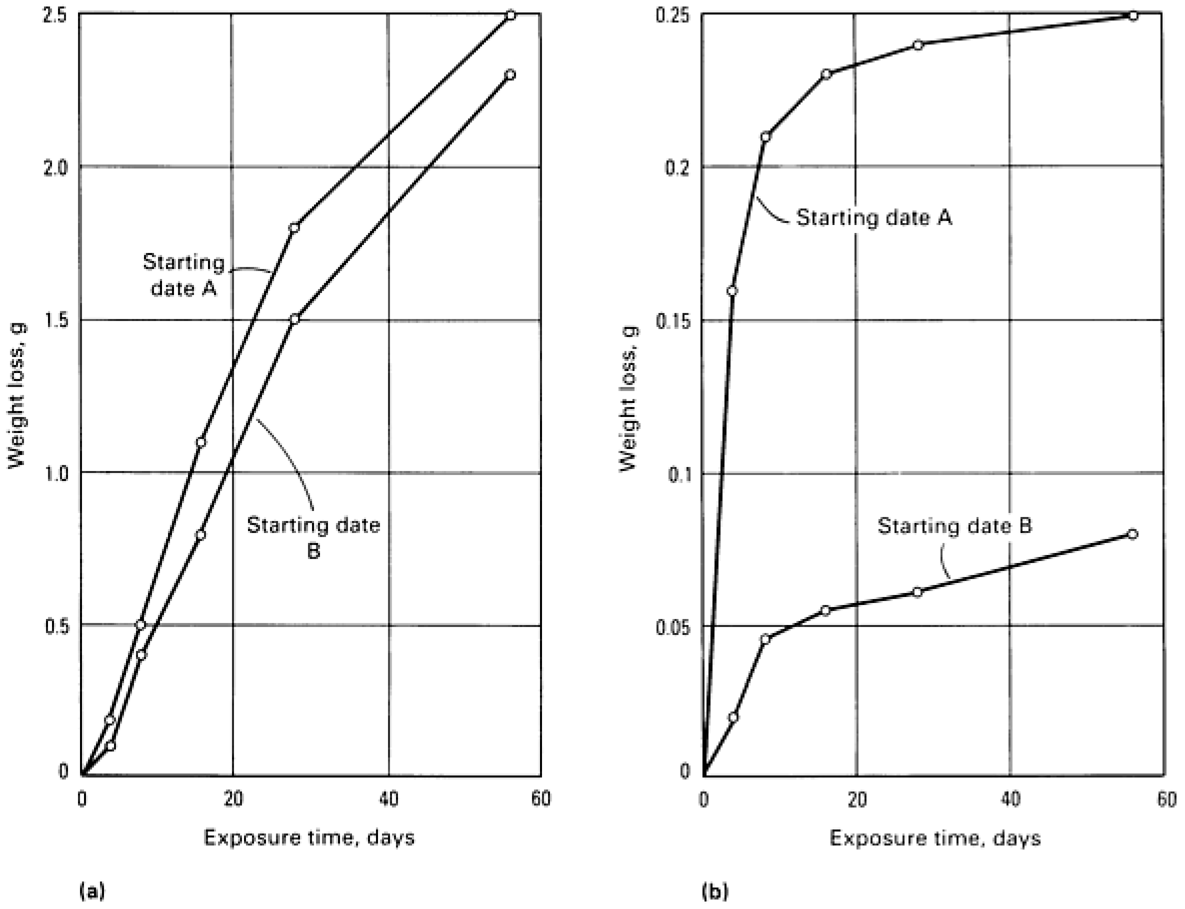

Fig. 43 Effect of different starting dates on the corrosion rate of iron (a) and zinc (b). Source: Ref 10

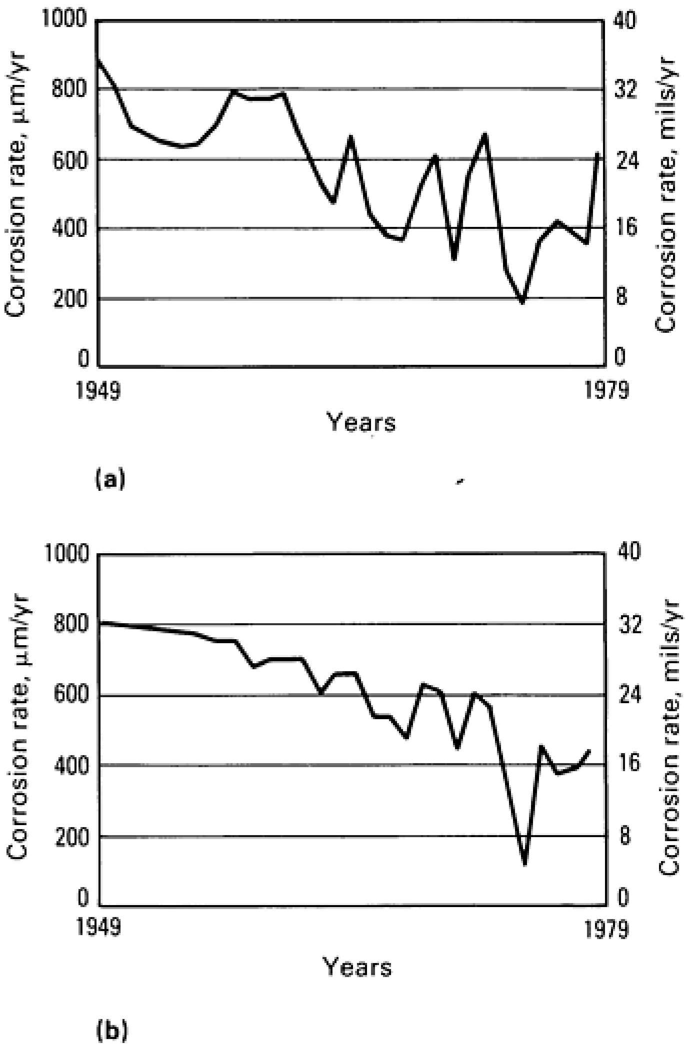

Fig. 44 Corrosion of iron calibration specimens tested for 1 year (a) and 2 years (b) at the 24.4-m (80-ft) lot at Kure Beach, NC. Source: Ref 12

Site Variability. Large variations in atmospheric corrosion rate occur within a particular type of region. An example would be the various corrosion behaviors of steel and zinc in different tropical environments, especially in a tropical seacoast for 1 year. Figure 45 shows the average penetration for steel in a 1-year test at various tropical sites. For zinc under similar conditions, the average penetration varied from 3 to 15 m (0.11 to 0.6 mil). Similarly, Fig. 42 illustrates the loss of tensile strength with increasing time in different temperate marine environments. As Fig. 42 shows, there is a wide variation in the loss of tensile strength between the four seacoast locations.

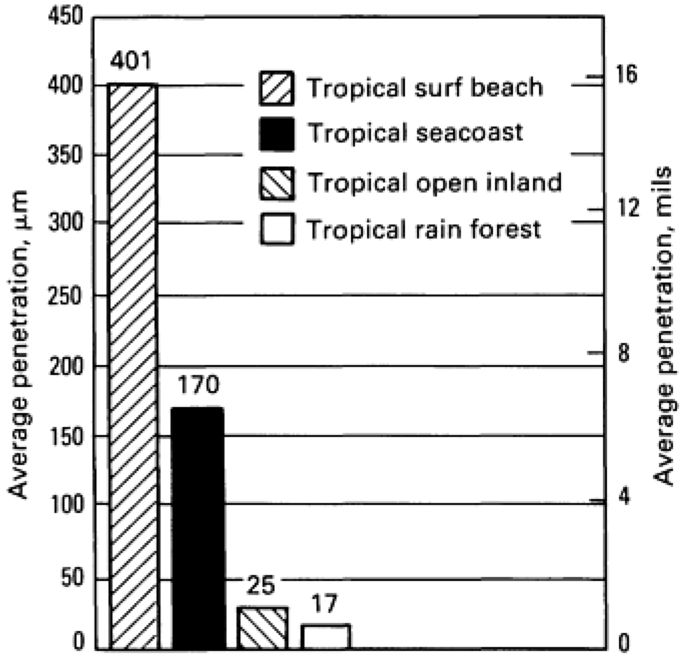

Fig. 45 Variation in corrosion rate after 1-year exposure of steel at four different tropical sites. Data are averaged from various investigations; see Ref 10 for details. Source: Ref 10

Temperate and tropical marine sites, along with inland sites, are compared in Fig. 46 for copper and zinc. Overall, the long-term rates are similar at both marine and inland sites.

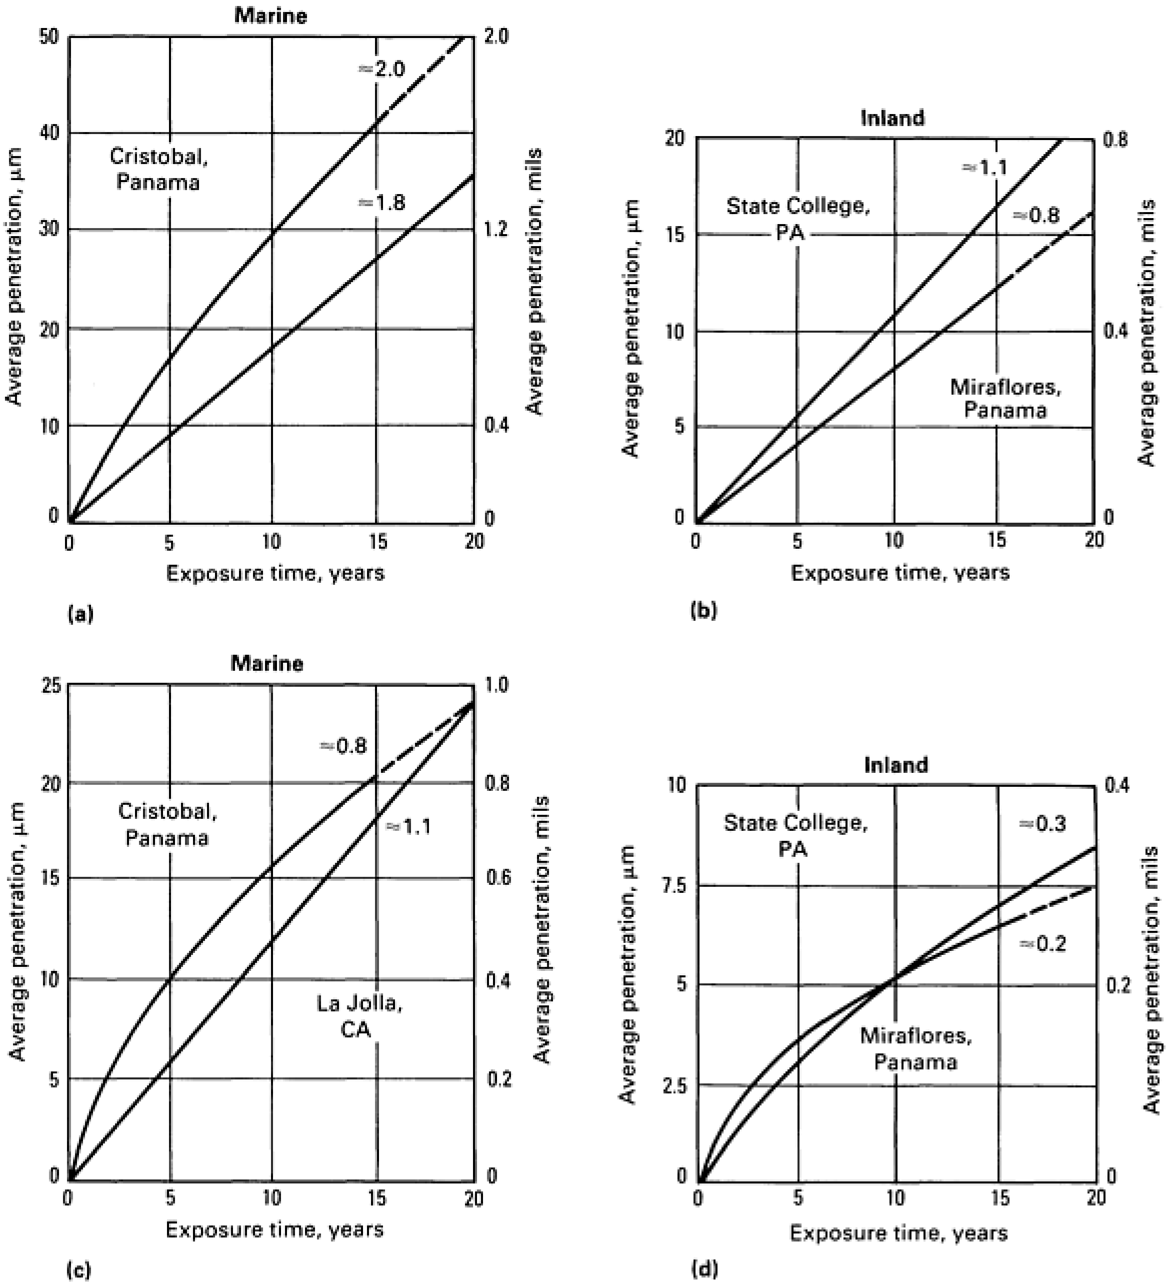

Fig. 46 Comparison of corrosion rates for zinc (a and b) and copper (c and d) at tropical and temperature exposure sites. Numbers on curves are stabilized corrosion rates in microns per year. Source: Ref 10

However, a similar comparison for carbon steels and low-alloy steels (Fig. 47) illustrates that for these materials the tropical environment has a higher overall corrosion rate. Figure 47(a) compares the stabilized corrosion rate of carbon steel at Cristobal, Panama (20 m/yr, or 0.8 mil/yr), to that at Kure Beach 250 m (800 ft) from the ocean (16 m/yr, or 0.63 mil/yr). Low-alloy steels exhibit a similar increased rate of corrosion, as shown in Fig. 47(b) and a similar pattern is exhibited for carbon steels compared at inland sites (Fig. 47c).

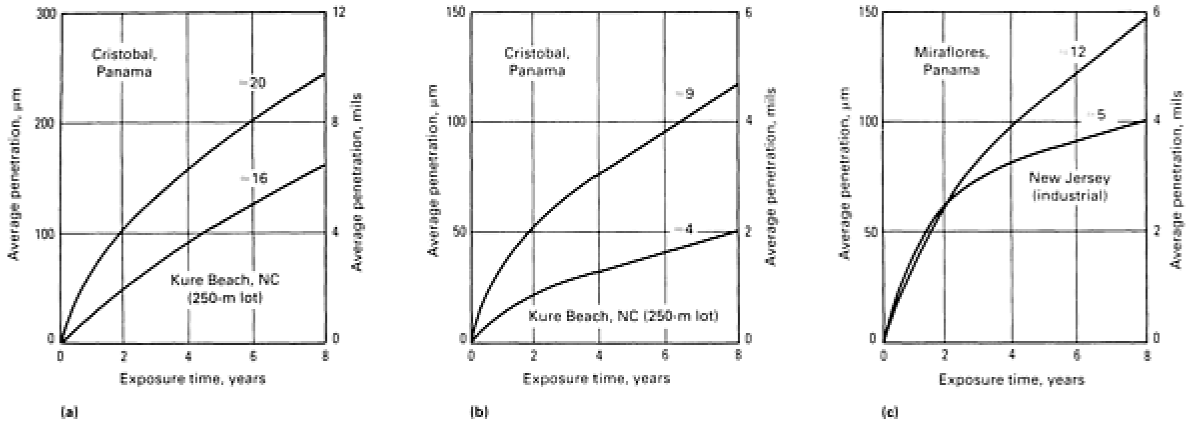

Fig. 47 Comparison of corrosion rates of steels at temperate and tropical exposure sites. Numbers on curve are stabilized corrosion rates in microns per year. (a) Carbon steel, marine exposure. (b) Low-alloy steel, marine exposure. (c) Carbon steel, inland exposure. Source: Ref 10

Alloy Content. The selection of a particular alloy composition can make a significant difference in the corrosion rate of a material. For steels, a comparison can be made for carbon steels, low-alloy steels, and steels with 5% alloying elements (Fig. 48). Figure 48 also compares marine versus inland exposure, and in each case, the long-term corrosion rate is greater for the marine environment. Figure 48 also shows the more rapid corrosion that takes place in the first 1 to 3 years and the leveling off associated with long-term atmospheric corrosion. Very similar results have been reported for a study done in South Africa at eight sites that were classified as rural to severe marine.

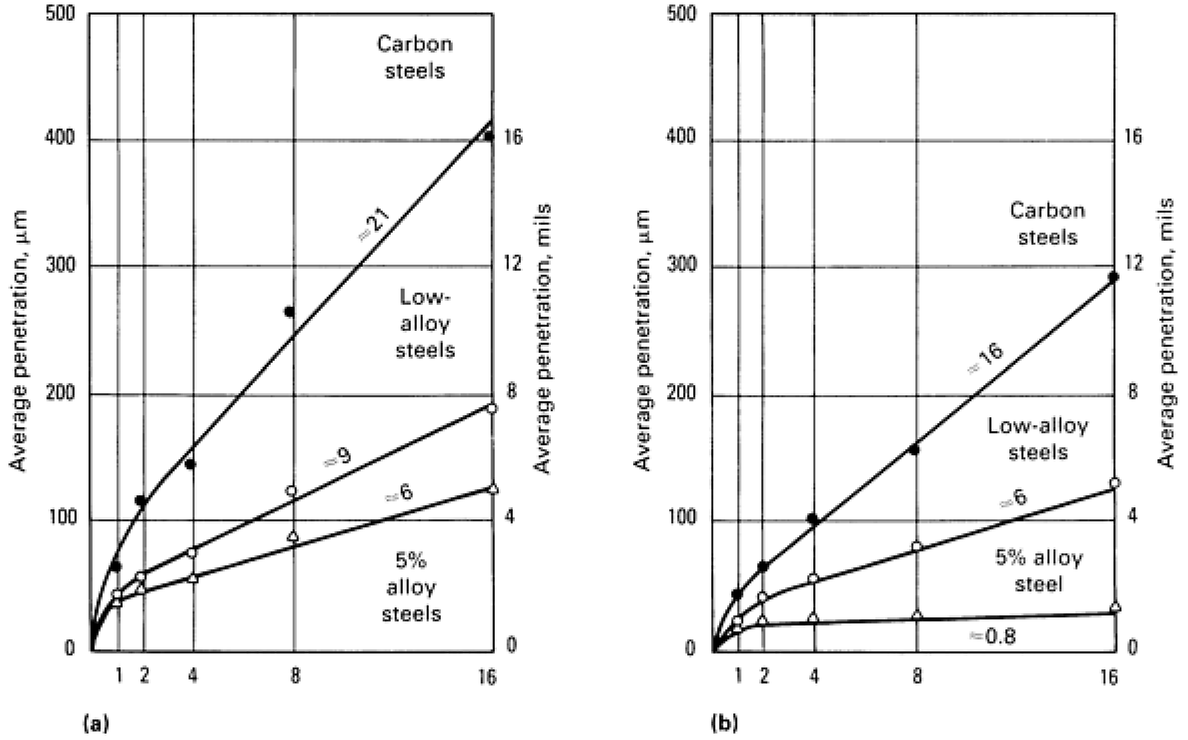

Fig. 48 Comparison of marine (a) and inland (b) corrosion rates for carbon steel, low-alloy steels, and 5% alloy steels at the Naval Research Laboratory test sites in Panama. Numbers on curves are stabilized corrosion rates in microns per year. Source: Ref 10

The results of 15.5-year studies of low-alloy steels in 13 groups conducted at the Kure Beach, NC, 250-m (800-ft) lot are shown in Fig. 49, in which the mass loss per unit area is plotted as a function of the total alloy content. Alloy additions of about 2 wt% result in the mass loss per area being reduced from 40 mg/dm^2 to less than 12 mg/dm^2.

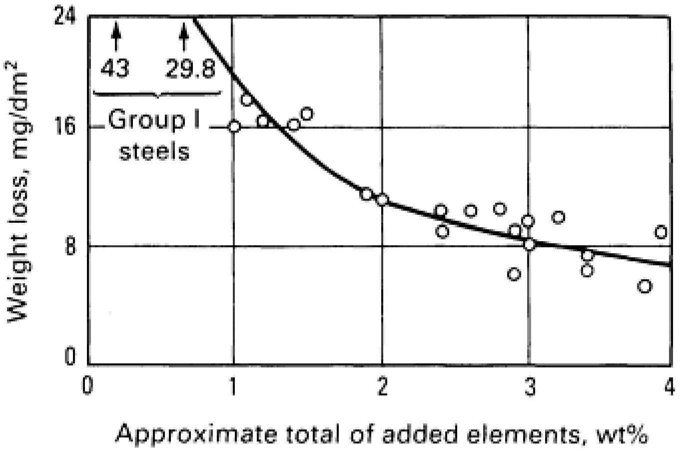

Fig. 49 Corrosion data for 25 low-alloy steels tested over a 15.5-year period at the Kure Beach, NC, 250-m (800-ft) lot. Source: Ref 11

The significance of chromium as an alloying element is shown in Fig. 50 for atmospheric-corrosion conditions classified as moderate and severe marine. Above 12 or 12.5 wt% Cr, the atmospheric corrosion becomes negligible; lower chromium levels result in a rapid increase in the corrosion rate. This effect is also illustrated in Table 11. For AISI 300-series stainless steels tested at the Kure Beach, NC, 250-m (800-ft) lot over a 15-year period, the atmospheric-corrosion rates were equal to or less than 0.03 m/yr (0.001 mil/yr) (see Table 11).

An excellent summary of marine atmospheric-corrosion data is given in Table 12. A wide variety of metals and alloys are listed. In addition, information on general corrosion, pitting, and loss of tensile strength is given for materials exposed at a seacoast site at Cristobal, Panama.

Table 12 Corrosion data for noncoupled metal panels exposed at the US Naval Research Laboratory tropical seacoast site at Cristobal, Panama

(a) All specimens were degreased before exposure; any treatment prior to degreasing is listed.

(b) Average penetration over a 4.23-dm^2 (65.6-$in.^2$) exposed area; calculations based on weight loss and density.

(c) Rate after time-corrosion relation had stabilized; slope of the linear portion of the curve, usually after two to eight years.

(d) Averages obtained by measuring the five deepest measurable (>125 m, or 5 mils) penetrations on each surface of duplicate panels.

(e) Percent loss in ultimate tensile strength for 1.59-mm (-in.) thick metal.

Exposure Time. One of the difficulties with marine atmospheric corrosion testing is the length of time required for the tests. For steels, a reasonable estimate of long-term corrosion performance can be made from short-term data. This is not always the case; any short-term result must be used very cautiously, and it is always best to have long-term test data available.

Atmospheric Corrosion Test Sites

There are a large number of atmospheric corrosion sites throughout the world; Table 13 lists some of them. Where available, the 2-year corrosion rates for low-carbon steel and zinc are given. Some of the sites have a marine corrosion index and/or an atmospheric corrosion index number after them. The higher the index number, the more aggressive the environment.

Table 13 Some marine atmospheric-corrosion test sites around the world

Corrosion rates of steel and zinc are also listed for some sites.

(a) MCI, Marine Corrosivity Index; determined by the weight loss of an aluminum wire-mild steel bolt couple. ACI, Atmospheric Corrosivity Index; determined by the weight loss of an aluminum open helical coil specimen or an aluminum wire-plastic bolt specimen.

Metallic Coatings

Jean A. Montemarano and Barbara A. Shaw, David Taylor Naval Ship R & D Center

Effective protection from the marine environment can be provided by metallic coatings, which include thermal spray, galvanizing, and, for certain applications, electroplating. In general, metallic coatings are two to three times more expensive than their traditional organic counterparts; therefore, their use is usually justified by longer service life and reduced maintenance. Metallic coatings function by providing a barrier, similar to organic coatings, for the bare metal from the marine environment and by corroding preferentially with respect to the substrate (normally, steel) when the coating is scratched or nicked. Aluminum and zinc are more active in seawater than steel and are the metals most widely used as protective coatings. Aluminum and zinc can be thermal sprayed. Zinc, aluminum, and zinc-aluminum alloy hot dip coatings are also used for the corrosion protection of steel in marine environments. Only the hot-dip zinc process, better known as galvanizing, is commercially available for the coating of fabricated articles. Lastly, the electroplating process is commonly used for the zinc or cadmium plating of fasteners for marine applications.

Metal Spray

Thermal spray has been used by industry and in European countries for corrosion protection since the 1940s. Bridges, structural steel work, boat holds and tanks, sluice gates and canal lock gates, and offshore drilling rigs are some of the items that have been metallized (Ref 13). Thermal spray for corrosion protection is normally applied by either the wire flame (combustion) or wire arc process. In either case, the metal wire is fed into a gun and melted either by a flame (normally oxyacetylene) or an electric arc. The atomized particles are propelled by means of compressed air onto the surface, where they cool, forming layers of splat-quenched particles (Ref 14). Both methods are portable and can be easily automated. Figures 2 and 4 in the article "Thermal Spray Coatings" in this Volume illustrate the wire flame and wire arc processes.

Surface preparation, as with all coatings, is an essential part of the coating process. Care must be taken to ensure that the surface is properly prepared and cleaned. Grit-blasting to white metal is used to achieve the necessary surface roughness. Typical grit media include aluminum oxide and chilled iron. The coating is largely mechanically bonded to the substrate in the flame or arc spray process used for corrosion control (Ref 15). If a component cannot be cleaned such that all rust and oil are removed, the thermal spray coating will not remain attached for long.

For example, field tests were conducted in Norway on steel piles coated with aluminum thermal spray followed by a wash primer, a coal tar vinyl paint, and then a topcoat. After 1 year or less, in spite of the organic coatings, blisters appeared in the coatings on all the piles in the splash zone. The failure analysis indicated that the major contributing factor was inadequate adhesion between the steel and aluminum thermal spray coating due to poor surface preparation (Ref 16). On the other hand, carefully prepared thermal sprayed steel specimens gave 19 years of complete base metal corrosion protection in seawater and marine atmosphere tests performed by the American Welding Society (AWS) (Ref 17).

The metal coating is normally applied to a thickness of 75 to 180 μm (3 to 7 mils) to provide adequate corrosion protection. The thickness of the coating is selected to limit interconnected porosity (too thin a coating) and to minimize

thermal expansion mismatch (too thick a coating) with the substrate, which could result in bond-line separation (Ref 18). For marine applications, thermal sprayed aluminum coatings 180 to 250 μm (7 to 10 mils) thick are used in order to limit through porosity (Ref 19).

Zinc is widely used by industry and in European countries for thermal spray for corrosion control protection. In addition, a duplex coating of aluminum followed by zinc has also been used in Europe, although aluminum thermal spray coatings are being stressed for marine applications in the United States (Ref 20). The zinc thermal spray coating has a high electrochemical activity and therefore high corrosion rates; this results in depletion of the coating, although it affords excellent cathodic protection to steel. On the other hand, the aluminum coating forms a passive film of aluminum oxide, resulting in very low corrosion rates (Ref 21). In an attempt to combine the best features of both materials, zinc-aluminum coatings (85Zn-15Al) were examined for their marine corrosion protection. This combination of metals can be obtained either in a prealloyed wire or by spraying the two wires simultaneously in the dual wire arc process. Both coatings provided adequate cathodic protection to the substrate, but suffered severe coating degradation after just 6 months of exposure (Ref 14).

Sealing. Standard practice is to seal the thermal spray coating with low-viscosity sealers because the metal coating is inherently porous (Fig. 51). The sealer is normally sprayed or brushed on, and it penetrates and fills the pores. Sealers should also be used in acidic or alkali environments (Ref 18). Vinyls and thinned epoxies are typical sealers. For high-temperature applications, a silicone alkyd sealer is used (Ref 22). Topcoats are normally used for cosmetic reasons. The roughness of the thermal spray coatings offers an excellent surface for paint adhesion. Rusting of the substrate underneath the paint film, which is the common mode of paint failure, is not the same mode of failure for thermal spray coatings (Ref 18). The topcoated thermal spray system provides excellent long-term maintenance-free corrosion protection (10 to 15 years).

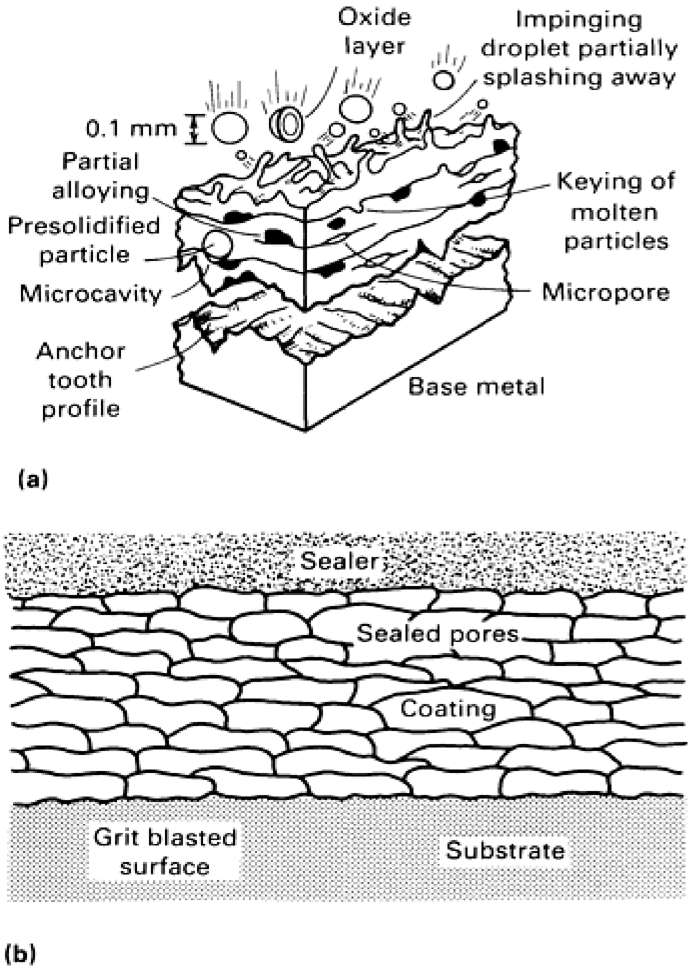

Fig. 51 Schematics of metal sprayed coating on steel. (a) As-sprayed coating. (b) Sealed coating

For ship applications, thermal spray coatings offer corrosion protection for topside weather equipment, machinery spaces, and interior wet spaces (Ref 18). Specifically, these categories include auxiliary exhaust stacks; diesel headers; steam valves, piping, and traps; boiler skirts; stanchions, pipe hangers; rigging fittings; lighting fixtures; ladders; hatches and scuttles; boat davit machinery components; bilges; and machinery foundations. Figure 52 shows two topside applications. For marine atmospheric service, the use of thermal spray aluminum coatings is an outstanding method of corrosion control. However, use of thermal spray coatings for immersion service lacks extensive field experience. Underwater hulls of small boats have been thermal sprayed, followed by primer and antifouling topcoats. More recently, thermal spray coatings, sealed with a silicone sealer, were applied to the flare boom of a North Sea oil rig platform (Ref 23). In addition, tension-leg elements, the risers, and the flare tower of a North Sea tension-leg rig platform were coated using the same materials (Ref 23).

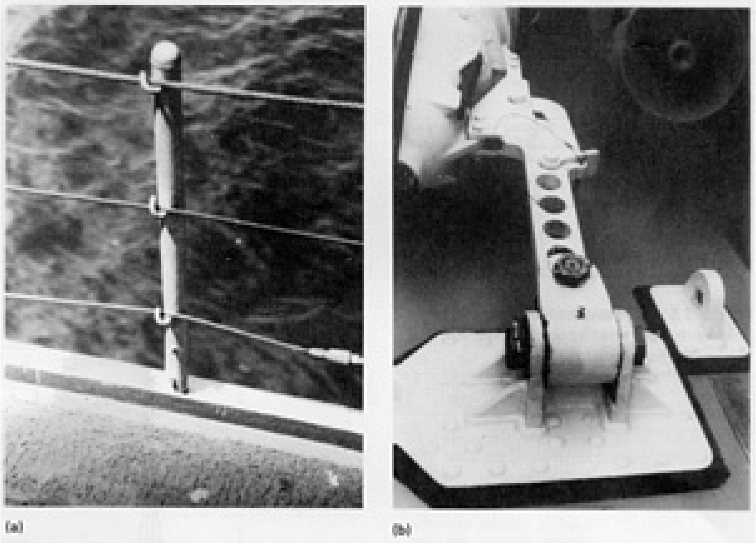

Fig. 52 Examples of aluminum flame sprayed topside weather equipment. (a) Stanchion. (b) Swivel arm assembly

Comparative corrosion tests support the long-term performance of thermal spray in marine environments. The longest test (19 years), which was conducted by AWS, indicates that 75 to 150 μm (3 to 6 mils) of aluminum thermal spray coating, whether sealed or unsealed, provided long-term protection in total seawater immersion, splash and spray zone, and marine atmosphere tests. Although no significant base metal attack occurred, some blistering and rust staining of the aluminum coating on unsealed panels were noted (Ref 17). In this study, zinc thermal spray coatings gave equivalent performance in marine atmosphere; but for total seawater immersion and splash and spray zone tests, a minimum thickness of 300 μm (12 mils) was required to prevent base metal attack for unsealed panels, and a minimum of 230 μm (9 mils) was required for sealed panels. However, for the latter two marine environments, the unsealed zinc had completely converted to corrosion products (Ref 17).

Sealed aluminum thermal spray coatings again performed well in a 7-year study conducted by the National Bureau of Standards to ascertain what coating provided the best corrosion protection for steel piles. Sand abrasion, seawater immersion, splash and spray, and marine atmosphere test zones of the coated piles were evaluated for coating performance. Hot-dip zinc, sealed zinc thermal spray coatings, and unsealed aluminum thermal spray coatings performed equivalently and had at least two to three times the corrosion rate of sealed aluminum thermal spray coating (Ref 24).

A study of coated 3-m (10-ft) long panels designed to simulate coated piles also demonstrated the effectiveness of thermal spray coatings. After 20 years of field exposure, unpainted aluminum thermal spray coatings and painted zinc thermal spray coatings showed excellent corrosion protection (Ref 25). After 5 years, pipe columns, pumps, and oil flow lines were internally and externally protected against the marine atmosphere in offshore oil facilities by 200 μm (8 mils) of aluminum thermal spray, followed by a wash primer and two coats of aluminum sealer (Ref 26). Tensile steel links of a suspension bridge, which were coated with zinc flame spray, primed with red lead, and topcoated, showed no rusting after 44 years of marine exposure (Ref 27). After $1\frac{1}{2}$ years of marine atmosphere and splash and spray exposure in Norway,

flamed-sprayed zinc and arc-sprayed and flamed-sprayed aluminum steel panels showed good corrosion performance (Ref 28).

Laboratory tests, such as salt spray (fog), as well as electrochemical techniques, demonstrate the excellent corrosion performance of thermal spray coatings. For example, after 1600 h of exposure in tests, aluminum flame-sprayed panels showed no rust, although zinc flame-sprayed panels showed rust after 500 h of exposure (Ref 21). Other investigations indicated that zinc thermal spray panels rusted after 100 h of exposure (Ref 29). The results from the salt spray test are difficult to correlate with actual service performance; therefore, it is not a good accelerated test method for prediction (Ref 30, 31). Electrochemical methods have also been used to evaluate the corrosion behavior of thermal spray coatings (Ref 14, 31, 32, 33, 34). For example, in one study, corrosion potential monitoring tests and potentiodynamic polarization measurements were conducted. The results from the latter test indicated that the aluminum flame spray coatings provide corrosion protection by passivation of the coating but that zinc and 85Zn-15Al alloy flame spray coatings operate solely through a galvanic mechanism (Ref 14). Another study, based on potential versus time curves, indicated that aluminum became electrochemically active after spraying (Ref 33). Duplicate studies by other researchers did not find this activation phenomenon (Ref 35). Other applications and materials for thermal spray coatings are discussed in the article "Thermal Spray Coatings" in this Volume.

Hot Dip Coatings

Galvanizing has been extensively used for protection against the marine environment. The advantages associated with applying zinc by flame spray versus galvanizing makes the former method attractive for certain applications (Ref 36). Hot dip galvanizing produces a fully dense coating that is metallurgically bonded to the substrate. In galvanizing, the size of part, heat distortion, ease of application, and the thickness and uniformity of coating are factors that must be considered. The thickness of galvanized coatings can vary from 75 to 200 μm (3 to 8 mils) and should be selected depending on the environment to be experienced and the desired lifetime. A 43-μm (1.7-mil) coating thickness is projected to give approximately 10 to 15 years of protection to steel in temperate to tropical marine atmospheric environments, but in service, this life may not be realized. Thick galvanizing and thermal spray were the only protection methods recommended by the British Standards Institution for providing long-term corrosion protection in a polluted marine atmosphere (Ref 37).

The American Society for Testing and Materials (ASTM) exposed galvanized sheet specimens in two marine environments--Sandy Hook, NJ, and Key West, FL--in 1926 and reported that panels with a coating weight of 760 g/m^2 (2.5 oz/ft^2) of zinc first showed rust after 13.1 and 19.8 years of exposure, respectively (Ref 38). An extensive study on the atmospheric corrosion of galvanized steel at the 244-m (800-ft) lot at Kure Beach, NC, resulted in predicted weight losses after 10 years of 103 g/m^2 and 55 g/m^2 for skyward and groundward marine exposures, respectively (Ref 39). Most investigators agree that the life of a zinc coating is roughly proportional to its thickness in any particular environment and is independent of the method of application. Galvanizing is used for corrosion protection on cables of suspension bridges in Norway (Ref 16). One study indicated that galvanized steel panels were in good condition ater $1\frac{1}{2}$ years (Ref 28). Hot-dip aluminized coated steel panels, which also were exposed, showed rusting after this time period.

Hot dip aluminum coatings, or aluminized coatings, are also used for the corrosion protection of steel in marine environments. Hot dip aluminizing of fabricated articles is no longer carried out in the United States or in Europe on a commercial basis (Ref 40). The coatings in use today are produced by a continuous strip process. An extensive comparative study was conducted on the atmospheric corrosion behavior of aluminized and galvanized steels (Ref 41, 42). Table 14 shows predicted 10-year weight losses of both of these coatings based on exposures conducted in the 250-m (800-ft) lot at Kure Beach, NC. A further comparison of the atmospheric-corrosion behavior of aluminized and galvanized panels was conducted by ASTM. After 20 years of marine atmospheric exposure (250-m, or 800-ft, lot, Kure Beach, NC), many of the galvanized steel panels were showing rust, but consistently good results were reported for the aluminized coating, which showed only minor pinholes of rust (Ref 43). Since 1972,a commercially produced aluminum-zinc (55Al-1.5Si-43.5Zn) hot dip coating has also been available for the corrosion protection of steel. One study reported that after 11 years of severe marine exposure (25-m, or 80-ft, lot, Kure Beach, NC) the 55Al-Zn coated panels were in good condition, with some corrosion products starting to creep inward on the faces of the panels from the cut edges (Ref 44). The advantages of hot dip aluminum coatings are discussed in Ref 45. The corrosion behavior of aluminum coatings obtained from aluminizing baths of various compositions was studied in laboratory tests. Aluminized coatings containing manganese were suggested as possible candidates for corrosion protection for coastal structures and deep sea oil rigs. More information on hot dip galvanized and aluminized coatings is available in the article "Hot Dip Coatings" in this Volume.

Table 14 Predicted 10-year corrosion rates for galvanized and aluminized steel panels

Tested 250 m (800 ft) from the ocean at Kure Beach, NC

Coating	Predicted weight loss, g/m^2	
	Skyward exposure	**Groundward exposure**
Galvanized	103.3	55.2
Type 1 aluminized (Al-Si)	17.8	20.1
Type 2 aluminized (pure aluminum)	11.6	17.9

Source: Ref 43

Electroplating

Electroplated zinc or cadmium is the standard coating used to provide corrosion protection to steel fasteners in the marine environment. The cadmium coating is used because of its hardness, close dimensional tolerance, and barrier to hydrogen permeation into or out of steels (Ref 46). The disadvantages of cadmium plating are its short life (for example, 4 months) in the marine atmospheric environment and concerns about occupational health due to the toxicity in the plating process. Zinc plating also has a short service life. Alternatives for this application include ion vapor deposited aluminum and paints containing zinc or aluminum pigment in a ceramic binder. These coatings, including zinc with a potassium silicate binder and aluminum with a phosphate-chromate binder, exhibit excellent corrosion protection for fasteners (minimum 1 year marine protection) (Ref 47). They are normally applied by conventional hand spraying.

Methods for electroplating aluminum are still in development, although plating using an organic aprotic solvent is a promising process (Ref 48). In laboratory polarization and galvanic tests, ion-deposited aluminum coatings performed well, indicating their potential for use on aircraft fasteners (Ref 49). Zinc and aluminum coatings for aircraft fastener applications showed variable results in corrosion tests (Ref 50). Aluminum and zinc pigmented performed better than electroplated zinc, ion vapor deposited aluminum, and electroplated cadmium on steel fasteners in laboratory seawater immersion tests (Ref 46). However, hydrogen permeability through the coating, as well as the corrosion performance of the coating, must be considered for a given fastener application (Ref 49).

Organic Coatings

J.S. Smart III, Amoco Production Company; R. Heidersbach, California Polytechnic State University

Organic coatings are the principal means of corrosion control for the hulls and topsides of ships and for the splash zones on permanent offshore structures. Most stationary offshore oil industry platforms are not painted below the waterline, and most marine pipelines are factory coated with special proprietary coatings (see the articles "Corrosion in Petroleum Production Operations" and "Corrosion of Pipelines" in this Volume).

Figure 53 shows the marine environments that are destructive to shipboard coatings. Similar environments are found on offshore oil production platforms (Fig. 54), lighthouses, docks, and other marine structures.

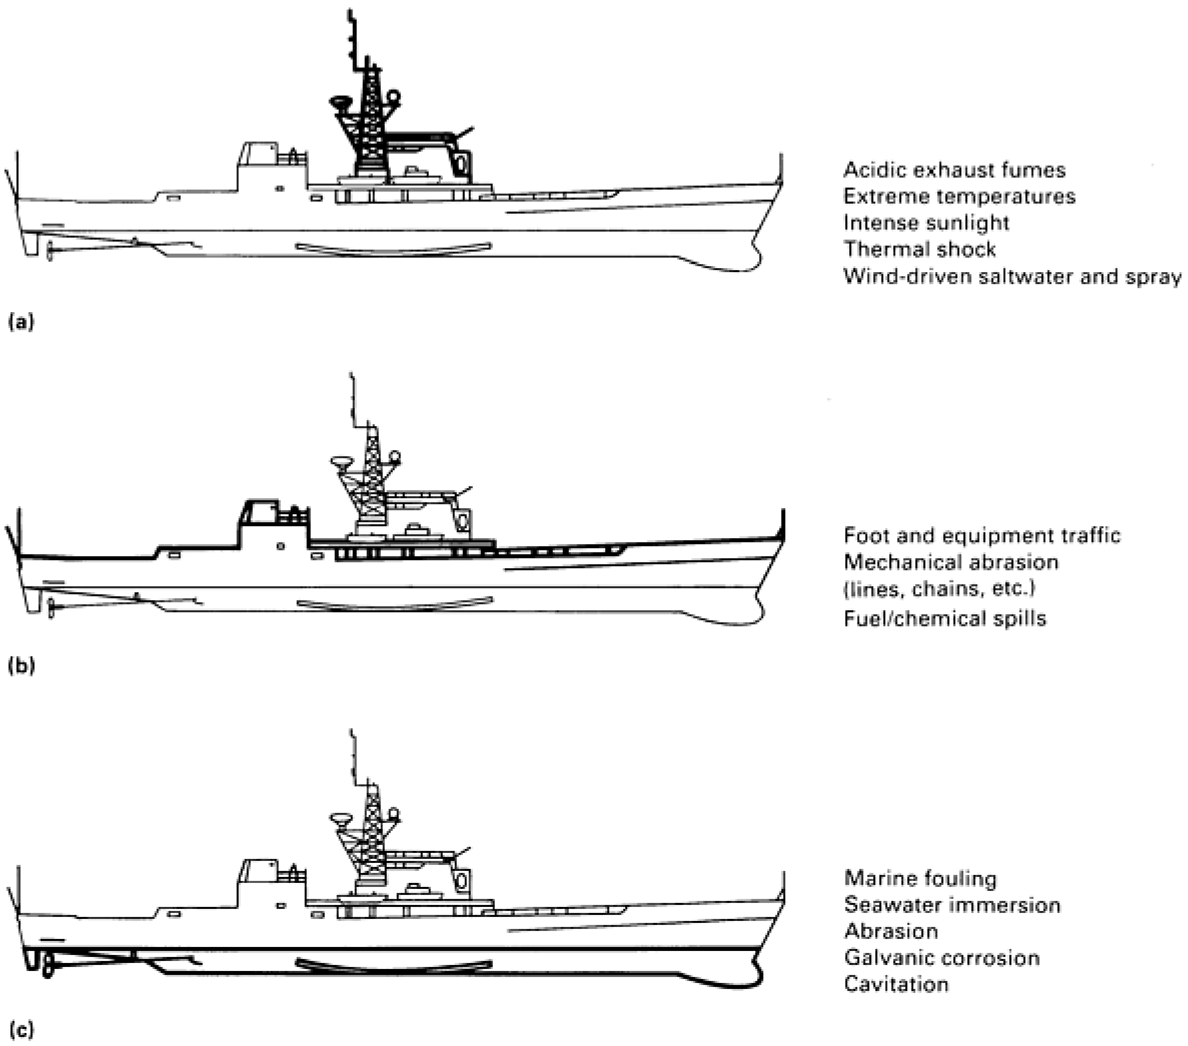

Fig. 53 Environments that are destructive to shipboard coatings. (a) Antennas and superstructures. (b) Deck areas. (c) Underwater hull

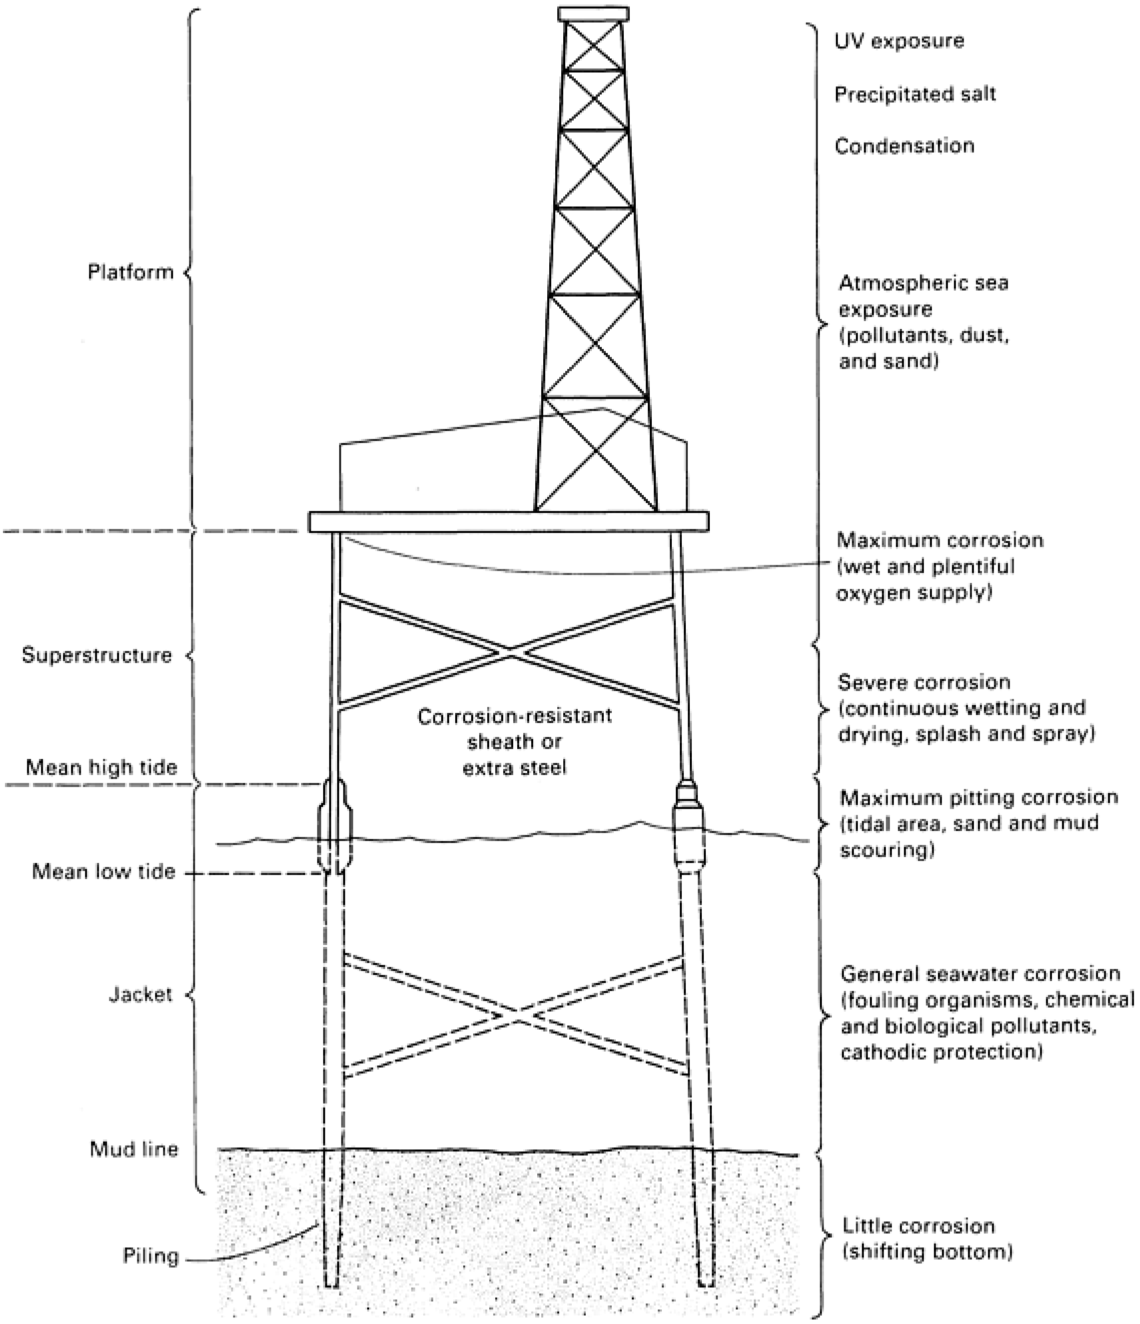

Fig. 54 Zones of severity of environment for a typical offshore drilling structure

Before the 1960s, most marine coatings were fairly simple and could be applied by laborers such as seamen or maintenance personnel. Although the advent of high-performance marine coatings in the 1960s changed this, the performance of marine coatings has improved to such an extent that topside coating lives of 20 years have been experienced on some offshore oil production platforms.

Surface Preparation

Proper surface preparation is the most important consideration in determining the performance of organic coating systems. Surface cleanliness and proper surface profile are both important. Surface preparation frequently accounts for two-thirds of total painting costs for offshore structures.

The Steel Structures Painting Council (SSPC), the National Association of Corrosion Engineers (NACE), and standards groups in Sweden, Germany, the U.K., and Japan have all issued standards for surface preparation. These are listed in Table 15. Wet abrasive blast cleaning and waterblasting are not yet included in the standards, but are now being extensively used. Wet blasting is useful for dust control and for avoiding electrical sparking in Class I (explosive) areas. Generally, a small amount of nitrite inhibitor is added to the water to prevent re-rusting before priming.

Table 15 Recommended surface preparation methods for various metallic substrates

Substrate	Recommended surface preparation method
Steel	Abrasive blast cleaning to near-white finish (SSPC SP10) for touchup and full-scale repainting
	Hand or power tool (preferably power) cleaning with wire brushes, chipping hammers, grinders, sanders, and so on, for maintenance
Galvanized steel	Solvent cleaning (degreasing) of new surfaces, followed by application of one coat of a wash primer
Aluminum	Anodizing or chromate conversion coating whenever possible. Otherwise, clean as for steel using only stainless steel wire brush.

Waterblasting can be used around rotating equipment, such as pumps, turbines, and generators; underwater; and in Class I areas. No grit is used; therefore, few solids result that could harm equipment. Waterblasting with 34.5 to 138 MPa (5000 to 20,000 psi) of pressure will remove all but all most adherent paint and oxide scale and, once the surface is blown dry, provides an excellent surface for painting. Waterblasting with detergent in the water at lower pressure is a good alternative to solvent washing for preparing oily and greasy surfaces for painting.

Gritblasting is usually used for surface preparation for marine coatings. The severe corrosion exposure conditions in offshore and coastal locations require the best possible surface preparation.

Inorganic zinc primers, which are frequently used in marine applications, require white metal gritblasting to remove all surface contamination because inorganic zinc has both a chemical bond and a mechanical bond to the surface. Epoxy primers can be applied over commercial grade surfaces for land-based exposures, but require near-white metal surfaces to maintain performance offshore.

Table 16 lists the characteristics of several types of grit. Grit that is used offshore is not recoverable; this limits the economical choices to either boiler slag or copper slag. Other types are too expensive unless they can be recycled. Silica sand is generally not used because of the possibility of silicosis, its friable nature, and its rounded shape, which is not conducive to high productivity.

Table 16 Properties of abrasives

Abrasive	Moh's hardness	Shape	Bulk density		Color	Free silica, wt%	Degree of dusting	Reuse
			kg/m^3	**lb/ft^3**				
Naturally occurring abrasives								
Sand								
Silica	5	Rounded	1600	100	White	90+	High	Poor
Mineral	5-7	Rounded	2000	125	Variable	5	Medium	Good
Flint	6.7-7	Angular	1280	80	Light gray	90+	Medium	Good
Garnet	7-8	Angular	2320	145	Pink	nil	Medium	Good
Zircon	7.5	Cubic	2965	185	White	nil	Low	Good
Novaculite	4	Angular	1600	100	White	90+	Low	Good
By-product abrasives								
Slag								
Boiler	7	Angular	1360	85	Black	nil	High	Poor
Copper	8	Angular	1760	110	Black	nil	Low	Good
Nickel	8	Angular	1360	85	Green	nil	High	Poor
Walnut shells	3	Cubic	720	45	Brown	nil	Low	Poor
Peach pits	3	Cubic	720	45	Brown	nil	Low	Poor
Corn cobs	4.5	Angular	480	30	Tan	nil	Low	Good
Manufactured abrasives								

Silicon carbide	9	Angular	1680	105	Black	nil	Low	Good
Aluminum oxide	8	Blocky	1920	120	Brown	nil	Low	Good
Glass beads	5.5	Spherical	1600	100	Clear	67	Low	Good
Metallic abrasives								
Steel shot[(a)]	40-50[(b)]	Round	. . .	. . .	. . .	. . .	. . .	Excellent
Steel grit (made by crushing steel shot)[(a)]	40-60[(b)]	Angular	. . .	. . .	. . .	. . .	. . .	Excellent

Source: Ref 51

(a) Steel shot produces a peened surface, while steel grit produces an angular, etched type of surface texture.

(b) Rockwell C hardness.

Topside Coating Systems

Organic coatings are usually composed of three components: binders (resins), pigments, and solvents. Not all paints, however, have all three components. For example, solventless paints have been developed in response to environmental restrictions on the use of volatile solvents. Solventless paints can be applied at thicknesses to 13 mm ($\frac{1}{2}$ in.); such thick films would not be possible in a paint containing volatile solvents, because the thickness of the film would prevent solvent evaporation.

Paints can be classified by the type of binder or resin into the following categories.

- Air-drying oils (for example, linseed oil, alkyds)
- Lacquers (vinyls, chlorinated rubbers)
- Chemically cured coatings (epoxies, phenolics, and urethanes)
- Inorganic coatings (silicates)

The article "Organic Coatings and Linings" in this Volume contains detailed information on the formulation of all of these types of organic coatings.

Primers

The primer is by far the most important coat in the protection of steel substrates. The primary function of subsequent coats is to protect the primer and to give color and a pleasing appearance.

Inhibitive primers contain substances that resist the effects of contaminants on the steel, such as rust and salt, and that resist disbondment under corrosive conditions and cathodic protection. Formerly, lead pigments and chromates were used as inhibitors, but this is no longer the case, because of tightened environmental regulations that prohibit or severely restrict their use. The inhibitors currently in use include a number of proprietary compounds.

Zinc-Rich Primers. The introduction of coatings containing a high percentage of metallic zinc is probably the outstanding development in protective coatings in the last 30 years. Zinc dust is loaded into both organic and inorganic binders to form primers that are extremely effective in the prevention of corrosion, underfilm creepage, and coating system failure.

Inorganic zinc-rich primers are based on various silicate binders. There are several types of self-curing and postcuring primers. The binder serves as a strong, adherent matrix for the zinc metal. The zinc dust must be present in sufficient amounts to provide metal-to-metal contact between both the zinc particles and the steel surface. The zinc dust provides protection to the steel substrate in the same manner as in galvanizing. If a break develops in the coating, the zinc acts as a sacrificial anode and corrodes preferentially; this provides protection of the iron for long periods. Laboratory tests and field experience indicate that inorganic zinc-rich primers can at least double the life of a coating system and can often increase it tenfold. To be effective, however, inorganic zinc-rich primers must be applied to a clean surface.

Organic zinc-rich primers are alternatives to the inorganic zinc-rich coatings when conditions are not appropriate for inorganic zinc-rich coatings. Organic zinc-rich primers can be formulated with epoxy, urethane, vinyl, and chlorinated rubber binders. The most common binder used for marine applications is polyamide epoxy. Zinc-rich epoxies provide a lower degree of conductivity and cathodic protection than inorganic zinc but impart several other desirable characteristics:

- Organic zinc-rich primers frequently may be applied over old paint, which makes them a good choice for maintenance painting
- The good adhesion of the epoxy binder makes surface preparation requirements less stringent than those for inorganic zinc-rich coatings. Near-white metal surfaces are adequate for offshore applications, and commercial grade gritblasting can be used in less severe environments
- The epoxy binder provides some protection to the zinc, and this allows moderate exposure of the primer to the marine environment without corrosion of the zinc and formation of zinc corrosion products. Zinc corrosion products can cause intercoat adhesion problems and paint blistering

Topcoats

Topcoats for steel serve mainly to protect the primer and to add color and appearance. To serve this function, they must be:

- Barrier coatings impervious to moisture, salt, chemicals, solvents, and ion passage
- Strong and resistant to mechanical damage
- Of adequate color and gloss retention

Some of the most common topcoats in use are discussed below, and detailed information on each of these types is available in the article "Organic Coatings and Linings" in this Volume.

Alkyds are the most common and versatile coatings in existence, but they are seldom used in severe marine applications, because of their poor performance over steel. This poor performance is due to the oil base of the alkyd. As corrosion proceeds on steel, hydroxyl ions (OH^-) are generated at cathode sites. Hydroxyl ions saponify the oils in the coating, and this results in coating failure.

Alkyds are the product of the reaction of a polybasic acid, a polyhydric alcohol, and a monobasic acid or oil. The number of possible combinations is large; therefore, a wide range of performance is available. Alkyds are used in marine service in relatively mild applications, such as interior coatings for cabins, quarters, engine rooms, kitchens, heads, and some superstructure applications.

Vinyls also have a broad range of desirable properties. Most vinyl resins are the product of the polymerization of polyvinyl chloride (PVC) and polyvinyl acetate (PVA). Vinyls are solvent-base coatings that form a tight homogenous film over the substrate. They are easy to apply by brush, roller, and spray. Intercoat adhesion is excellent because of the solvent-base nature of the coating. Vinyls do not oxidize or age, and they are inert to acids, alkalies, water, cement, and alcohols. They do soften slightly when covered with some crude oils. Vinyl coatings dry quickly and can be recoated in a short time (often in minutes), depending on the solvent used. Vinyl coatings are also flexible and can accommodate the motion of the steel beneath them, such as when a ship or platform is launched.

Vinyls were extensively used on ships and offshore platforms for many years, and they are still in use in many areas. However, they have given way to epoxies in most marine applications because vinyl coatings are relatively thin and are not very strong. Film thickness is typically only 50 μm (2 mils) per coat, and the coatings cannot withstand mechanical abuse. In addition, vinyls are not very effective for covering rough, previously corroded surfaces.

Chlorinated rubber coatings are based on natural rubber that has been reacted with chlorine to give a hard high-quality resin that is soluble in various solvents. Chlorinated rubbers have been used for many years as industrial-type paints because of their low moisture permeability, strength, resistance to UV degradation, and ease of application. Chlorinated rubbers have found application on ships and containers, railroads, and as traffic paint for road stripes. For many years, chlorinated rubber coatings were used to paint ships because of their ease of application and repairability, tolerance of poor surface preparation, fast drying characteristics, and relatively good wear and abrasion resistance. They

are still used to a great extent on ships and are the standard paint system for containers. Modern fleet owners, however, have phased out chlorinated rubbers in favor of higher-quality coating systems, such as epoxy, for reasons to be discussed below.

Epoxies. The combination of excellent adhesion (some can be applied underwater), good impact and abrasion resistance, high film builds (up to 6.4 mm, or $\frac{1}{4}$ in., on a wet, vertical surface), relatively low cost, and excellent chemical and solvent resistance has made epoxy coatings the workhorses of modern marine coatings. These properties result in service lives of 7 to 12 years on ships, offshore platforms, and coastal applications when epoxy topcoats are applied over inhibited epoxy or inorganic zinc-rich primers. Because epoxies are chemically cured, a wide range of properties can be achieved by varying the molecular weight of the resin, the type of curing agent, and the type of pigments or fillers used.

Immersion Coatings

Immersion coatings for marine service have far greater requirements than other organic coatings. They must resist moisture absorption, moisture transfer, and electroendosmosis (electrochemically induced diffusion of moisture through the coating). They also must be strong and have good adhesion.

Most ship hulls and many marine structures use cathodic protection to supplement the protection afforded by organic coatings (see the section "Cathodic Protection" in this article). This is desirable because it is virtually impossible to apply and maintain a defect-free organic coating system on a large structure.

Barrier Properties. To be effective in seawater immersion service, an organic coating must have a low moisture vapor transfer rate as well as low moisture absorption. Moisture absorption is the molecular moisture absorbed into and held within the molecular structure of the coating. This property is not important to the effectiveness of the coating unless the moisture absorption lowers the dielectric characteristics of the coating and increases the passage of electrical current. Moisture vapor transfer, on the other hand, is important, particularly when the coating is exposed to an external current (as in cathodic protection). Generally, the lower the moisture vapor transfer rate of a coating, the more effective the coating.

Where electroendosmosis may be encountered, adhesion is also very important. Most organic coatings are negatively charged, and under cathodic protection, the cathode has an excess of electrons, which makes it negatively charged. This being the case, coatings with a high moisture vapor transfer rate or questionable adhesion would be more subject to damage and blistering by cathodic potentials.

Mechanical Properties. Coatings used on marine structures must be strong. Most damage to marine coating systems is mechanical, not a breakdown of the coating from exposure to seawater. Immersion coatings must have good impact and abrasion resistance and must be able to flex well enough to maintain contact with the steel substrate when it is bent. Rubbing by mooring ropes, chains, and crane wire ropes, as well as impact from cargo handling, work parties, and berthing operations, are major causes of damage.

Types of Immersion Coatings. Many of the common paint formulations can be used for immersion service, but the most common coatings in use are coal tar epoxies and straight epoxies.

Coal tar epoxies were introduced in 1955 and are the most common coatings in use on fixed marine structures (Ref 52). These thermosetting materials are available with a variety of setting temperatures and chemical curing systems. Coal tar epoxies require near-white surface preparation and are very adherent and abrasion resistant. They tend to be brittle and should not be used on flexible structures. Straight epoxies have been commercially available longer than coal tar epoxies (Ref 53). Epoxies are usually applied in thinner coats and are more expensive than coal tar epoxies. Epoxies have become the material of choice for immersion service because of their superior performance (Ref 51, 53). They have replaced chlorinated rubbers for most ship hull applications, and they are available in a variety of polyamide- or amine-based formulations (Ref 52). Detailed information on these and other coating materials is available in the article "Organic Coatings and Linings" in this Volume.

Antifouling Topcoats. Most shipboard applications require antifouling topcoats. The formulations for these coatings are changing because of environmental legislation. In some parts of the world, copper-containing antifouling coatings are still popular, but in North America, these coatings have been replaced by organo-tin compounds.

Cathodic Protection

Robert H. Heidersbach, California Polytechnic State University; Richard Baxter, Deepwater Corrosion Services; John S. Smart III, Amoco Production Company; Michael Haroun, Oklahoma State University

Cathodic protection is an electrochemical means of corrosion control that is widely used in the marine environment. A detailed explanation of the principles of cathodic protection appears in the article "Cathodic Protection" in this Volume.

Cathodic protection can be defined as a technique of reducing or eliminating the corrosion rate of a metal by making it the cathode of an electrochemical cell and passing sufficient current through it to reduce its corrosion rate. All cathodic protection systems require the following components:

- Voltage
- Anode
- Cathode
- Return circuit
- Electrolyte

Two types of cathodic protection systems are commonly used: impressed-current (active) systems and sacrificial anode (passive) systems. Both are common in marine applications. In recent years, hybrid systems--combinations of impressed-current and sacrificial anodes--have been used for very large marine structures. More information on land-based applications of cathodic protection is available in the article "Cathodic Protection" and "Corrosion of Pipelines" in this Volume.

Cathodic Protection Criteria

A number of criteria are used to determine whether or not a structure is cathodically protected. These criteria, which are covered in NACE RP-01-76 (Ref 54), include potential measurements, visual inspection, and test coupons.

Potential Measurements. Reference 46 specifies a negative (cathodic) voltage of at least 0.80 V between the platform and a silver-silver chloride reference electrode contacting the water. Normally, voltage is measured with the protective current applied. The 0.80 V standard includes the voltage drop across the steel/water interface, but does not include the voltage drop in the water.

Application of the protective current should produce a minimum negative (cathodic) voltage shift of 300 mV. The voltage shift is measured between the platform surface and a reference electrode contacting the water; it includes the voltage drop across the steel/water interface but not the voltage drop in the water.

Visual inspection should indicate no progression of corrosion beyond limits acceptable for platform life (Ref 54).

Corrosion test coupons must indicate a corrosion type and rate that is within acceptable limits for the intended platform life (Ref 54).

A number of other criteria are also possible, but in practice, -0.80 V versus Ag/AgCl is the most commonly used. Other reference electrodes can be used for marine applications. They are listed in Table 17.

Table 17 Reference electrodes used for cathodic protection systems on offshore structures

Type of electrode	Protection potential of steel, V
Ag/AgCl	-0.80 (or more negative)
Cu/CuSo$_4$	-0.85 (or more negative)
Zinc	+0.25 (or less positive)

Anode Materials

The choice of anode material depends on whether active (impressed-current) or passive (sacrificial anode) cathodic protection systems are under consideration. Sacrificial anodes must be naturally anodic to steel and must corrode reliably (avoid passivation) in the environment of interest. However, above all, sacrificial anodes should be inexpensive and durable. Impressed-current anodes rely on external voltage sources; therefore, they do not need to be naturally anodic to steel. They usually would be cathodic to steel if not forced to assume anodic potentials by the impressed current. Additional information on materials for sacrificial and impressed-current anodes is available in the article "Cathodic Protection" in this Volume.

Sacrificial Anodes. Commercial sacrificial anodes are either magnesium, aluminum, or zinc alloys. Table 18 lists the energy capabilities of sacrificial anode alloys.

Table 18 Energy characteristics of materials used for sacrificial anodes

Material	Energy capability		Consumption rate	
	A·h/kg	**A·h/lb**	**kg/A·yr**	**lb/A·yr**
Aluminum-zinc-mercury	2750-2840	1250-1290	3.1-3.2	6.8-7
Aluminum-zinc-indium	1670-2400	760-1090	3.6-5.2	8-11.5
Aluminum-zinc-tin	925-2600	420-1180	3.4-9.4	7.4-20.8
Zinc	815	370	10.8	23.7

Magnesium anodes have not been popular for offshore applications in recent years, because of developments in improved aluminum and zinc anodes. However, several operators have begun experimenting with composite sacrificial anode systems for offshore platforms. These designs use aluminum or zinc anodes for long-term performance and have magnesium anodes that are intended to provide an initially high current density and polarize the platform quickly to the desired protection potential. Results from the limited applications of this composite design are mixed, and this concept remains controversial.

Aluminum anodes and, more recently, aluminum-zinc alloys, have become the preferred sacrificial anodes for offshore platform cathodic protection. This is because aluminum anodes have reliable long-term performance when compared to magnesium, which may be consumed before the platform has served its useful life. Aluminum also has better current/weight characteristics than zinc. Weight can be a major consideration for large offshore platforms.

The major disadvantage of aluminum for some applications--for example, the protection of painted ship hulls--is that aluminum is too corrosion-resistant in many environments. Aluminum alloys will not corrode reliably onshore or in freshwaters. In marine environments, the chloride content of seawater depassivates some aluminum alloys and allows them to perform reliably as anode materials. Unfortunately, it is necessary to add mercury, antimony, indium, tin, or similar metals to the aluminum alloy to ensure that this depassivation occurs. Heavy-metal pollution concerns have led to bans on the use of mercury alloys in some locations. Problems with alloy production result in aluminum alloys with supposedly adequate alloying additions that still corrode in an unreliable manner. This problem is the subject of ongoing research, but current indications are that alloy segregation may be the source of the problem.

Zinc anodes are similar to aluminum in many respects. They are used on ship hulls because aluminum passivates when ships enter the brackish water or freshwater of many harbors but zinc will continue to perform. Tankers with combination ballast/product tanks use zinc anodes because of their lower tendency to cause sparks if they fall from their supports and strike steel.

Zinc bracelet anodes are also used on offshore pipelines. Part of the reason for this is to ensure that the anode will corrode and provide protective current in bottom mud environments where aluminum may passivate. Because marine pipelines must be buoyancy compensated, the increased weight of zinc is an advantage, and zinc is also usually less expensive on a cost per delivered coulomb basis.

Impressed-Current Anodes. Impressed-current anodes need not be anodic to steel, and normally they are not. Most materials used as impressed-current anodes are insoluble and corrosion resistant, with very low rates of consumption

(Table 19). Exchange current density--the ability of a material to sustain high current densities with lower power consumption--is an important consideration for some applications.

Table 19 Typical current densities and consumption rates of materials used for impressed-current anodes

Material	Typical anode current density		Consumption rate	
	A/m^2	**A/ft^2**	**kg/A·yr**	**lb/A·yr**
Pb-6Sb-1Ag	160-215	15-20	0.045-0.09	0.1-0.2
Platinum (plated on substrate)	540-1080	50-100	6×10^{-6}	1.3×10^{-5}
Platinum (wire or clad)	1080-5400	100-500	10^{-5}	2.2×10^{-5}
Graphite	10.8-43	1-4	0.23-0.45	0.5-1.0

High-silicon cast iron is the most corrosion-resistant nonprecious alloy in commercial use. It is widely used as an impressed-current anode material, and the anodes are very strong, durable, and abrasion resistant. The major disadvantage in offshore applications is the high weight/current characteristics of high-silicon cast iron. Marine applications for high-silicon cast iron anodes include docks and similar coastal structures.

Precious metals have the advantage of high exchange current densities (Ref 54). The practical result is that a small precious metal surface is equivalent to thousands of times the surface area of other anode materials. Therefore, a small surface of platinum or palladium may be more economical than a much less expensive material. Early precious metal anodes were alloys that, after a short period of use, became enriched on the surface with the precious metal component. Anodes of this type are still used in harsh environments, such as Cook Inlet or the North Sea, where anode sleds weighing several tons are necessary to withstand high currents and storm conditions. For most other applications, smaller anodes consisting of precious metals clad to stronger substrates (for example, platinum bonded to a niobium substrate) are gaining acceptance. The extreme weight advantages of these anodes over other systems make them especially desirable for deep water structures.

Ceramic anodes consisting of metal oxides on conductive metal substrates are gaining acceptance for cathodic protection applications. Although these anodes have been used for years in the electrochemical-processing industry, their application to cathodic protection is recent. Ceramic anodes have many of the same advantages as precious metal anodes (light weight, high current capacity).

Polymer Anodes. Several suppliers are marketing polymer anodes. These contain embedded graphite conductors and are used in applications requiring low current densities. Most offshore applications require the opposite--anodes with high current capacities. Coastal concrete structures that use cathodic protection to reduce the corrosion of reinforcing steel are possible marine applications for polymer anodes.

Comparison of Impressed-Current and Sacrificial Anode Systems

Sacrificial anode cathodic protection systems are simpler than impressed-current systems and require little or no maintenance except for periodic anode replacement. The capital cost of small systems is minimal, and they are often used for such applications as small pipelines and fishing boats.

The capital costs of impressed-current cathodic protection systems may be lower than those of sacrificial anode systems in certain applications (for example, long pipelines and large offshore platforms). Impressed-current systems are normally used for the protection of large structures or where the low conductivity of the electrolyte (freshwater, concrete, and so on) makes sacrificial anodes impractical.

Cathodic Protection of Marine Pipelines

Corrosion control of marine pipelines is usually achieved through the use of protective coatings and supplemental cathodic protection. A variety of organic protective coatings can be used. They are usually applied in a factory so that the only field-applied coatings are at joints in pipeline sections. Most marine pipelines have an outer "weight coating" of concrete. The cathodic protection system supplements these coatings and is intended to provide corrosion control at holidays (defects) in the protective coating.

Design Considerations. The average cathodic protection current density required to protect a marine pipeline will depend on the type of coating applied, the method used to coat field joints, the amount of damage inflicted on the coating during shipment and installation, whether or not burial is specified, and the location of the pipeline. Large-diameter pipelines can be protected by installing an impressed-cathodic protection system at one or both ends of the pipeline. Such a system would include a suitably sized transformer/rectifier unit and inert anodes, such as graphite or high-silicon cast iron.

Most marine pipelines are protected by the installation of bracelet-type zinc or aluminum alloy sacrificial anodes (Fig. 55). Electrical contact between the anode and the pipeline is made through an insulated copper cable bonded to the pipeline. Zinc anodes may either be high purity or alloyed. Aluminum anodes are usually fabricated from a proprietary aluminum-zinc-indium alloy.

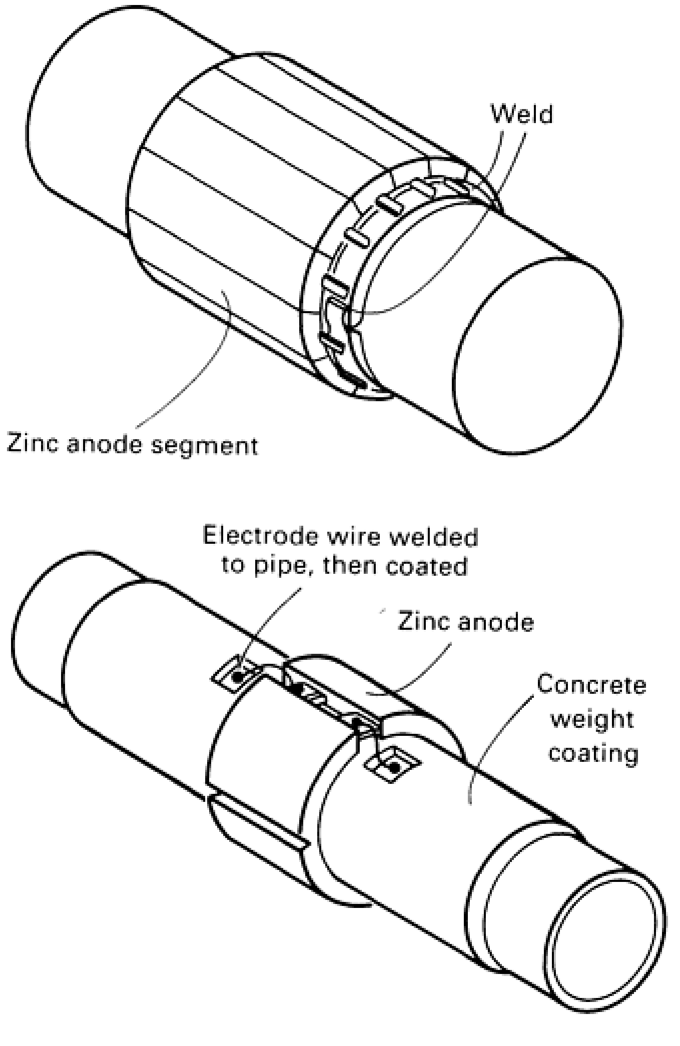

Fig. 55 Typical pipeline bracelet anodes

Design Procedures. Typically, bracelet anodes are spaced at a maximum of 150 m (500 ft) on small-diameter pipelines (<355 mm, or 14 in.) and 300 m (1000 ft) on larger pipelines. The current required for a segment of pipeline is calculated by using the current density required for the given environment, the surface area of the pipe segment, and the fraction of steel assumed to be bare. Anodes are then sized to fit the conditions; that is, the anode must have adequate weight to satisfy the relationship:

$$\frac{W}{C} > IL \quad \textbf{(Eq 9)}$$

where W is the anode weight in kilograms, C is the alloy consumption rate in kilograms per amp year (kg/A · yr), I is the anode current output in amps, L is the desired design life in years, and the anode nominal current output must exceed the required current. Anode current output I is determined from Ohm's law:

$$I = \frac{E}{R} \quad \textbf{(Eq 10)}$$

where I is the current output in amps, E is the net driving voltage in volts, and R is the anode-to-electrolyte resistance in ohms.

Anode-to-electrolyte resistance R can be calculated using an empirical relationship, such as McCoy's equation:

$$R = \frac{0.315\,p}{\sqrt{A}} \quad \textbf{(Eq 11)}$$

where p is the electrolyte resistivity in ohm centimeters (Ω · cm), and A is the anode area in square centimeters.

Data sheets from the manufacturer can also be consulted for information on the electrochemical properties of specific proprietary alloys. Anode geometry can be optimized by using a successive iteration technique, but most anode manufacturers offer a range of standard sizes, which can be optimized for specific applications. If the pipeline is to have a concrete weight coating for stabilization, the thickness of the anode should match the concrete thickness to facilitate installation. Anodes to be installed on nonweight-coated pipelines should have tapered ends so that the anodes do not hang up on the rollers of the lay barge.

Isolation. If the pipeline and the offshore production facilities are operated by separate parties, the pipeline is usually electrically isolated from the production facilities through the use of insulated flanges or monolithic isolation joints. This practice prevents loss of current from the pipeline cathodic protection system to the platform and facilitates recordkeeping. Pipelines are always electrically isolated from shore-based facilities, usually at the valve pit on the beach.

Cathodic Protection of Offshore Structures

Offshore oil production platforms are unusual because most platforms are not painted below the waterline. The cathodic protection system causes a pH shift in the water, which becomes more alkaline (higher pH). Most minerals are less soluble in alkalis than in near-neutral environments (neutral water has a pH of 7; the pH of seawater averages approximately 7.8). The higher pH near the cathode causes minerals to precipitate onto the steel surface and form a protective scale or calcareous deposit. Depending on such factors as water depth, temperature, and velocity, this protective scale may be calcium carbonate, magnesium hydroxide, or a mixture of these and other minerals (Ref 55; see also the section "Seawater" in this article).

The technology of offshore cathodic protection is rapidly changing. Many of these changes are required because water depths are increasing. Therefore, offshore structures are now being built in deeper, colder water in which mineral deposits are less likely to form. The formation of a mineral deposit in such conditions may require current densities as high as approximately 1000 to 2000 mA/m^2 (100 to 200 mA/ft^2).

Another problem associated with deep water platforms is that current density requirements change with depth. In recent years, several deep water platforms have been found to be underprotected. These North American platforms (Gulf of Mexico and Santa Barbara Channel) were located in deep water, but the inadequate protection was at intermediate depths. Gases are more soluble at depth, and carbonate scales (calcareous deposits) are harder to deposit in deep, cold waters. This difficulty is offset by the fact that many deep waters have little dissolved oxygen and should therefore be less corrosive than shallow waters. It should be noted however, that Cook Inlet, the North Sea, and other stormy waters may be oxygen saturated (and presumably carbon dioxide saturated) all the way to the bottom.

Many operators prefer to use sacrificial anodes on offshore platforms because the sacrificial anode systems are simple and rugged. In addition, they become effective as soon as the platform is launched and do not depend on external electric power supplies. Surveys of the reliability of impressed-current systems have led to the conclusion that they do not

perform as well as sacrificial anode systems (Ref 56). One reason for this lack of performance may be the poor or fragile design of some early impressed-current systems.

Unfortunately, the weight of sacrificial anodes is becoming a serious consideration for deep water platforms. Impressed-current systems are gaining acceptance. Some operators have introduced hybrid designs. In these designs, the primary cathodic protection system uses impressed current, and a sacrificial anode system is used to protect the platform after launching and before the electrical system on the platform becomes operational. The Murchison Platform has the most widely publicized hybrid cathodic protection system (Ref 57).

In the past, the inefficiencies associated with cathodic protection design were not serious. Water depths were shallow, and cathodic protection systems were overdesigned to ensure satisfactory performance. This was justified based on economics. A typical cathodic protection system is only 1 to 2% of the total capital cost of a new platform, but a retrofit may cost as much as the platform itself. Early platforms in Cook Inlet and the North Sea were underdesigned, and the costs of retrofits led to the efforts that produced NACE RP-01-76 (Ref 54). References 58 and 59 detail some problems experienced with deep water platforms.

Design Procedures. A typical cathodic protection design procedure for an offshore platform might consist of the following sequence of steps:

- Selection of a proper maintenance current density; this will depend on the geographic location
- Calculation of surface areas of steel in mud and in seawater, and the addition of a safety factor
- Calculation of the total amount of anode material required to guarantee a desired life
- Selection of an anode geometry. Initial current density (calculated for a single anode from Dwight's equation; see the example below) should exceed 160 mA/m^2 (15 mA/ft^2), assuming a native potential of 0.45 V between bare steel and aluminum anodes
- Judicious distribution of anodes on the steel, assuming a throwing power of 7.6 m (25 ft) in line of sight and placing anodes within 3 m (10 ft) of all nodes

The criterion for complete cathodic protection is a steel structure potential more negative than -0.80 V (that is, -0.82, -0.85, etc.) at any point versus the Ag/AgCl reference electrode.

Example: System Design for an Offshore Platform.

The following is a sample of an offshore cathodic protection design procedure. The platform is in the Gulf of Mexico, and the design parameters, which are similar to other Gulf platforms, include the following:

- Maintenance current density: 5 mA/ft^2
- Design life: 20 years
- Calculated surface area: 33,484 ft^2 (water zone) and 47,984 ft^2 (mud zone)
- Anode capacity: 1280 A · h/lb
- Safety factor: 25%
- Water resistivity: 20 $\Omega \cdot$ cm
- Assumed anode parameters: 725-lb net aluminum weight; 8 ft long; 90.25 in.^{2} cross-sectional area

Given these numbers, the total current in the water zone and the mud zone can then be calculated:

$$\text{Current}_{water} = \frac{(5\ \text{mA/ft}^2)\ (33\ 484\ \text{ft}^2)}{1000} = 167.4\ \text{A}$$

$$\text{Current}_{mud} = \frac{(5\ \text{mA/ft}^2)\ (47\ 984\ \text{ft}^2)}{1000} = 239.9\ \text{A}$$

The next step is to evaluate the total weight, TW, of the anode material required:

$$\text{TW}_{water} = \frac{(167.4\ \text{A})\ (8760\ \text{h/yr})\ (20\ \text{yr})\ (1.25)}{(1280\ \text{A} \cdot \text{h/lb})} = 28\ 641\ \text{lb}$$

$$\text{TW}_{mud} = \frac{(239.9\ \text{A})\ (8760\ \text{h/yr})\ (20\ \text{yr})\ (1.25)}{(1280\ \text{A} \cdot \text{h/lb})} = 41\ 045\ \text{lb}$$

At this stage, the number of anodes needed in each section, N, can be evaluated:

$$\text{N}_{water} = \frac{28\ 641\ \text{lb}}{725\ \text{lb/anode}} = 39.5$$

$$\text{N}_{mud} = \frac{41\ 045\ \text{lb}}{725\ \text{lb/anode}} = 56.6$$

$$\text{N}_{total} = 40 + 57 = 97\ \text{anodes}$$

A total number of 97 anodes are needed to prepolarize the steel or to provide the initial current density. The initial current density must be at least 160 mA/m^2 (15 mA/ft^2) to ensure the buildup of an adequate calcareous deposit on the steel members. The total initial current output per anode is calculated by using a potential of 0.45 V between bare, unpolarized steel (-0.60 V) and aluminum (-1.05 V) and an anode resistance calculated from Dwight's equation (Eq 12) for a single cylindrical anode, because experience shows no significant interference between the various numbers of a multiple anode design:

$$\text{Resistance} = \frac{P}{2\pi L}\left[\ln\left(\frac{4L}{R}\right) - 1\right] \quad \textbf{(Eq 12)}$$

where *L* is the anode length in inches, π is 3.14159, *p* is water resistivity in $\Omega \cdot$ cm, and *R* is equivalent radius in inches.

For anode shapes other than cylindrical:

$$R = \sqrt{\frac{\text{cross-sectional area}}{\pi}} \quad \textbf{(Eq 13)}$$

In this case, the anode has a trapezoidal cross section, and the equivalent radius is calculated by using Eq 13, as follows:

$$R = \sqrt{\frac{90.25}{\pi}} = 5.36 \text{ in.}$$

Equation 12 can now be used to calculate the anode resistance:

$$= \frac{20\ \Omega \cdot \text{cm}}{2\pi\ (96 \text{ in.})} \left[\ln \left(\frac{4\ (96 \text{ in.})}{5.36 \text{ in.}} \right) - 1 \right] \left(\frac{1 \text{ in.}}{2.54 \text{ cm}} \right)$$
$$= 0.0427\ \Omega$$

Next, the initial current output, *I*, of the anode is determined:

$$I = \frac{\Delta E}{\text{Resistance}} \qquad \textbf{(Eq 14)}$$

where, ΔE is the potential difference (0.45 V), and the resistance = 0.0427 Ω.

$$I = \frac{0.45 \text{ V}}{0.0427\ \Omega} = 10.54 \text{ A}$$

The initial structure current density is determined as follows:

$$\text{Current density} = \frac{(10.54 \text{ A/anode})\ (97 \text{ anodes})}{33\ 484 \text{ ft}^2}$$
$$= 0.0305 \text{ A/ft}^2 = 30.5 \text{ mA/ft}^2$$

A current of 328 mA/m^2 (30.5 mA/ft^2) is considered to be an adequate current density for the buildup of a calcareous deposit, which leads to a satisfactory polarization of steel.

Fully polarized steel develops a potential more negative than -0.80 V versus the Ag/AgCl reference electrode and will therefore establish a potential drop of 0.20 to 0.25 V versus aluminum anodes. Use of the 0.20 to 0.25 V potential drop for Ohm's law and calculation of the anode resistance with Dwight's equation (Eq 12) based on anode dimensions at 40 to 50% consumption will then result in a maintenance current density that is roughly one-half the value of the calculated initial current density. Therefore, if the steel is polarized to -0.80 V versus Ag/AgCl, the current output of the anode is (according to Eq 14):

$$I = \frac{\Delta E}{\text{Resistance}}$$

where ΔE = 1.05V - 0.8 V = 0.25 V, and resistance = 0.0441 Ω(the derated anode radius based on a 10% reduction of the initial radius).

$$I = \frac{0.25 \text{ V}}{0.0441\ \Omega} = 5.6 \text{ A}$$

The actual potential drop between structural steel cathode and aluminum anodes at some time after launching of the platform is estimated as the difference between the given aluminum versus Ag/AgCl potential and the average of

polarized steel potentials as measured with Ag/AgCl reference electrodes at various locations of the structure. The true current output per anode is, therefore, available for predicting the life of the cathodic protection system given the capacity of 330-kg (725-lb) aluminum anodes, namely:

$$\text{Life} = \frac{(1280\ \text{A} \cdot \text{h/lb})\ (725\ \text{lb/anode})}{(8760\ \text{h/yr})\ (S\ \text{A/anode})}$$

which leads to the life in years for *S* amps of current output per anode as follows:

$$\text{Life} = \frac{106}{S}$$

Based on a current output per anode of 5.6 A, the design life of the cathodic protection system is:

$$\text{Life} = \frac{106}{5.6} = 18.9\ \text{years}$$

The required design life is 20 years, so another anode geometry should be chosen. Suppose that the new anode has the following anode characteristics: length = 10 ft (120 in.), radius = 6 in., weight = 1135 lb, and anode capacity = 1280 A · h/lb. The total number of anodes needed, based on the surface areas of the water and mud sections, is:

$$N_{water} = \frac{28\ 641\ \text{lb}}{1135\ \text{lb/anode}} = 25.2$$

$$N_{mud} = \frac{41\ 045\ \text{lb}}{1135\ \text{lb/anode}} = 36.2$$

$$N_{total} = 26 + 37 = 63\ \text{anodes}$$

The resistance of one anode using Dwight's equation (Eq 12) is:

$$\text{Resistance} = \frac{20\ \Omega \cdot \text{cm}}{2\pi\ (120)} \left[\ln \left(\frac{(4)\ (120)}{(6)} \right) - 1 \right] \left(\frac{1\ \text{in.}}{2.54\ \text{cm}} \right) = 0.03532\ \Omega$$

The initial total current output *I* based on a potential drop of 0.45 V and using Eq 14 is:

$$I = \frac{0.45\ \text{V}}{0.03532\ \Omega} = 12.74\ \text{A}$$

The structure initial current density is now evaluated and is equal to:

$$\text{Current density} = \frac{(12.74\ \text{A/anode})\ (63\ \text{anodes})}{33\ 484\ \text{ft}^2}$$

$$= 0.0239\ \text{A/ft}^2 = 23.9\ \text{mA/ft}^2$$

An initial structure current density of 257 mA/m^2 (23.9 mA/ft^2) is acceptable. A more conservative design will allow for a higher number. Next, the anode resistance is calculated using Eq 12 and based on a derated radius of 5.4 in. (a 10% reduction):

$$\text{Resistance}$$

$$= \frac{20 \cdot \Omega\ \text{cm}}{2\pi\ (120)} \left[\ln\left(\frac{(4)\ (120)}{5.4}\right) - 1\right] \left(\frac{1\ \text{in.}}{2.54\ \text{cm}}\right)$$

$$= 0.03642\ \Omega$$

Using a potential drop of 0.25 V, the total maintenance current *I* available is:

$$I = \frac{0.25\ \text{V}}{0.03642\ \Omega} = 6.86\ \text{A}$$

Based on a current of 6.86 A, the design life in years of the cathodic protection system is:

$$\text{Life} = \frac{(1280\ \text{A} \cdot \text{h/lb})(1135\ \text{lb/anode})}{(8760\ \text{h/yr})(6.86\ \text{A/anode})}$$

$$= 24.2\ \text{years}$$

Therefore, the design is acceptable.

Anode Distribution. A final consideration concerns the positioning of anodes about the structure. They are placed within 3 m (10 ft) of modes (welded or cast locations with the highest structural loading), but elsewhere are assumed to protect steel in line of sight within a 7.6-m (25-ft) radius. Thus, areas shadowed by other structural elements may not be fully protected by any particular anode.

Computer-aided cathodic protection designs for offshore structures have been tried by several organizations in recent years. These computer-aided designs are of two types. Small computers have been used to make the types of calculations (such as wetted surface area versus anode consumption) that have commonly been used for cathodic protection design. For these systems, the computer is a time saver that allows a greater number of alternatives to be considered but does not change the actual methodology of design.

An alternative approach is to use numerical techniques, such as finite element, finite difference, or boundary integral, to model the potential-current distribution field in the region of an offshore structure. Large computers can be programmed to generate complex analyses of various alternative designs (Ref 60). These computerized designs have found limited acceptance because of the expense associated with the designs and the time delay caused by communications difficulties among the operator, the cathodic protection designer, and the computer expert. Efforts are underway to develop software so that small computers can be used with these numerical programs. If these efforts are successful, design engineers will be able to compare a number of design alternatives quickly and inexpensively. The same basic types of computational techniques--finite element, finite difference, and boundary integral modeling--that are used for structural design can be used for cathodic protection design (Ref 60, 61, 62, 63).

Cathodic Protection of Ship Hulls

Ships and pipelines normally have protective coatings as their primary means of corrosion control. Cathodic protection systems are then sized so that an adequate electric current will be delivered to polarize the structure to the desired level. This is done for new structures by estimating the percentage of bare steel that results from holidays in the protective coatings. Once the estimated amount of bare steel is determined, anodes are sized to provide adequate current densities for the design life of the system.

Ships are returned to drydocks; therefore, the size (and weight) of anodes can be reduced from what would be necessary for permanent anodes on offshore pipelines or platforms. Anodes are concentrated near the bow and stern, where coating damage is most likely to occur. The stern is also the location where galvanic couples (for example, propeller to hull) are possible. Relatively small anodes are placed on ships in these locations. Small anodes are desirable to minimize the drag effects caused by turbulence due to anode protrusions.

Anode Materials. Aluminum anodes are available for ship hulls, but they can passivate and become inactive on ships that enter rivers or brackish estuaries. For this reason, zinc anodes are almost universally used in commercial service.

Impressed-current cathodic protection systems are used on very large ships. The galvanic couple between the propeller, the shaft, and the hull of the ship can cause significant corrosion problems. Modeling of the current requirements for cathodic protection near tanker propellers was one of the first applications of the computer in cathodic protection design (Ref 64, 65).

Impressed-current cathodic protection systems can produce overprotection in some cases. Organic coatings can disbond because of the formation of hydrogen gas bubbles underneath coatings. Coating disbondment can produce increased surface areas that require more cathodic protection, and is controlled by placing dielectric shields between the impressed-current anode and the hull. Larger shields are sometimes fabricated from glass-reinforced epoxy, which is molded directly on the ship's hull. At one time, coating disbondment was a major concern, but most modern coatings are resistant to disbonding.

Hydrogen embrittlement of steel due to cathodic protection is sometimes a concern. This has been a problem on case-hardened shafts, bolts, and other high-strength attachments. Most structural steels have relatively low strength as well as minimum susceptibility to hydrogen embrittlement.

Corrosion in the Nuclear Power Industry

Chairman: Joseph C. Danko, American Welding Institute

Introduction

THIS ARTICLE will review the major corrosion problems in light water reactors, the research on the corrosion mechanism(s), and the development of engineering solutions and their implementation. To understand the occurrence of corrosion problems, a brief historical perspective of the corrosion design basis of commercial light water reactors, boiling water, and pressurized water reactors is necessary. Although corrosion was considered in the plant designs, it was not viewed as a serious problem. This was based on the results of laboratory experiments and in-reactor tests that did not indicate any major corrosion problems with the materials selected for the plant construction. However, the laboratory tests did not necessarily reproduce the reactor operating conditions and the early in-reactor test did not fully represent the commercial reactor conditions in all cases, and, finally, the test times were indeed of short duration relative to the plant design lifetime of 40 years. Thus, the design basis for the materials selection was determined on the favorable but limited test data that were available, and corrosion limitations on component integrity were therefore not anticipated.

The initial operation of the early commercial light water reactors encountered few corrosion problems. These were quickly repaired and did not have a major impact on plant availability. As more plants entered service, and more operating time was accumulated on existing plants, more corrosion-related incidents appeared in the piping and other components. Eventually, the corrosion of the plant materials did impact on plant availability, economics, reliability, and, in some cases, plant safety.

The major corrosion-related problems addressed by the utility industry and the nuclear steam system suppliers include the intergranular stress-corrosion cracking of welded austenitic stainless steel pipes in boiling water reactors and the steam generator corrosion in the pressurized water reactors. These have had the greatest impact on plant availability and economics to the utility industry. Other corrosion problems reported in this article cover the influence of corrosion on radiation fields, stress-corrosion cracking in steam turbine materials, erosion-corrosion in steam lines, corrosion of nuclear fuel elements, and the effect of nuclear lubricants on corrosion. Corrosion problems have also occurred in the condenser systems; this problem is discussed in the article "Corrosion in Fossil Fuel Power Plants" in this Volume.

The final section of this article reviews ongoing developments in the disposal of high-level nuclear waste (processed, or spent, fuels) in deep underground repositories. Material selection for waste containment packages, which must keep radioactive isotopes contained for time periods up to 1000 years, and the primary geologic media considered for repository siting are discussed. As will be shown, the properties of geologic media, such as granite, salt deposits, and sub-seabed sediments, are critical because of their influence on the corrosion behavior (particularly stress-corrosion cracking properties) of container materials.

Corrosion in Boiling Water Reactors

Barry M. Gordon, Principal Engineer, Corrosion Performance, General Electric Company; Gerald M. Gordon, Manager, Plant Materials Technology, General Electric Company

Corrosion/materials problems are a major cause of lost availability for both the pressurized water reactor (PWR) and the boiling water reactor (BWR). Despite the differences in operating temperature, pressure, and coolant environment, the current primary materials problem for both of these nuclear power plant systems is stress-corrosion cracking (SCC). For the PWR, SCC of steam generator tubes occurs in both the primary and secondary circuits. In the case of the domestic BWR, the cracking of the heat-affected zones (HAZ) of welded type 304 and 316 stainless steel piping is responsible for the greatest materials impact on availability.

This Section will review only corrosion/materials problems in the BWR; the primary concern of SCC of BWR piping and the SCC of other structural components will be discussed. This Section will also present a discussion on another form of environmental cracking that can occur in the BWR and PWR--corrosion fatigue. Specifically, the BWR components discussed in this Section include piping, control rod collet retainer tubes, jet pump beams, core internals, and feedwater nozzles. However, before presenting case histories of these concerns and their subsequent resolution, it is important to review the basic mechanisms and the conditions necessary for producing these two forms of environmental cracking.

Basics of SCC

The visible manifestations of SCC are cracks that create the impression of inherent brittleness in the material, because the cracks propagate with little or no attendant macroscopic plastic deformation. A metal that suffers from SCC is usually characterized by its typical mechanical values (yield strength and tensile strength), and with the exception of the cracked region, the metal appears normal. Many alloys are most likely susceptible to SCC in at least one environment. However, SCC does not occur in all environments, nor does an environment that induces SCC in one alloy necessarily induce SCC in another alloy.

Perhaps the most critical factor to remember concerning SCC is that the three factors necessary for producing SCC must be simultaneously present. The elimination of any one of these factors or the reduction of one of these factors below some threshold level eliminates SCC. The three necessary conditions for SCC are:

- Susceptible material
- Tensile stress (applied and residual)
- Corrosive environment (an environment that can provide the chemical driving force for corrosion reaction)

This concept is illustrated in Fig. 1, in which the small region consisting of the overlapping areas of three circles represents SCC. If one circle is missing or reduced sufficiently, SCC susceptibility is reduced. The value of this representation is that it is now evident that there are three obvious methods for combating SCC:

- Reducing the tensile stress below some threshold value by new designs or processing techniques
- Eliminating or reducing the severity of the corrosive environment
- Changing the susceptible material by using an alternate material, alloying additions, cladding, or heat treatment

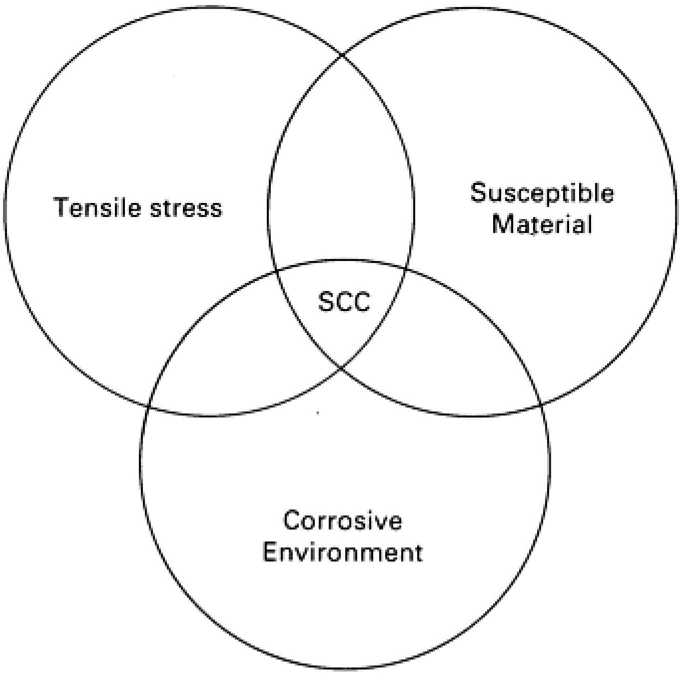

Fig. 1 The three necessary factors for producing SCC

As noted in the article "Environmentally Induced Cracking" in this Volume, SCC can proceed through a material in two modes--intergranular and transgranular. The modes are sometimes mixed, or the mode switches from one morphology to the other. Intergranular SCC and transgranular SCC often occur in the same alloy, depending on the environment or the microstructure.

Cracking usually proceeds perpendicularly to the tensile stress. Another key characteristic of SCC is that the crack is usually tight; that is, the crack has a very large length-to-width ratio, indicating the absence of macroscopic plastic deformation. Cracks also vary in degree of branching or formation of satellite cracks. In numerous cases, the cracks are characterized by virtually no branches, but in some cases, they exhibit multibranched river delta patterns. This dependency is also a function of the environment, crack tip stress intensity, and microstructure, as detailed in the article "Modes of Fracture" in Volume 12 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Increasing the stress level decreases the time for crack initiation, that is, the time to propagate to a specified shallow depth, such as 25 μm (1 mil). In the pure water specified for normal operation of a BWR, the threshold stress is believed to be greater than the at-temperature yield stress. In other alloy-environmental systems, it has been observed to be as low as 10% of the yield stress. It is critical to remember that any threshold value must be used with considerable caution because environmental conditions may change during operation. For example, a reactor component may be stressed below the SCC threshold value until a chloride or resin (sulfate) intrusion incident occurs, at which time SCC may initiate.

The stresses must be tensile and not compressive and must be of sufficient magnitude. Sources of tensile stresses include applied, residual, thermal, welding, and even corrosion product. Numerous cases of SCC have been observed in which no externally applied stress has been identified. As-welded material, for example, contains weld residual stresses approaching the yield point and often exceeding the yield point of the annealed material.

Basics of Corrosion Fatigue

Corrosion fatigue is fatigue aggravated by corrosion reactions. Because fatigue failures usually occur at applied stress levels below or at the operating temperature yield stress after numerous cyclic applications, the presence of an injurious environment reduces the number of cycles necessary to failure and reduces the stress level at which failure occurs. (It is important to note that stress raisers at initiation sites or the crack tip increase the local stress over the yield stress.) This phenomenon is illustrated in Fig. 2. In the case in which an alloy exhibits a fatigue endurance limit below which fatigue

failures would not occur (body-centered cubic materials), the presence of a corrosive environment eliminates or reduces this threshold.

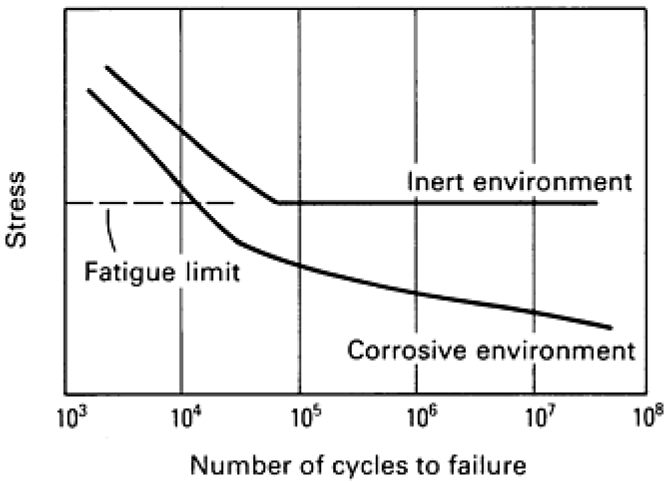

Fig. 2 Elimination of the fatigue limit due to the presence of a corrosion environment

Thus, corrosion fatigue is the reduction of fatigue resistance due to the presence of a corrosive medium. Corrosion fatigue is defined in terms of both environmental and mechanical properties. It may even be considered a special case of SCC. However, the mode of fracture and the preventive measures differ to a degree such that it is considered advisable to examine it separately.

Fatigue in the absence of environmental effects is characterized by fatigue resistance values, such as cyclic crack growth rates, that are nearly independent of the stress cycle frequency. This factor allows fatigue testing to be performed at accelerated rates. However, corrosion fatigue resistance is markedly affected by the stress cycle frequency for the following reasons. At extremely high cyclic frequencies, the material would not have the opportunity to react with the environment during each cycle, but at extremely low frequencies, passivation may take place during each step of the cycle. Thus, in the process of evaluating corrosion fatigue resistance, it is critical to conduct the test under conditions approaching those encountered in the field.

Corrosion fatigue cracks are typically transgranular, although they can be intergranular, especially for sensitized stainless steel in the BWR environment. The cracks are often branched, and several cracks are usually observed in the metal surface adjacent to the major crack. Fatigue cracks are also transgranular (with the exception of lead and tin), but rarely is there evidence of more than one crack. Corrosion pits may serve as nucleation sites for corrosion fatigue, but they are not a necessary precursor to cracking. Aqueous environments producing corrosion fatigue are numerous and not specific; this is contrary to the situation of SCC, for which only certain environment-metal combinations usually result in damage.

Intergranular SCC in BWR Piping

Although the intergranular SCC of BWR piping is not considered a safety problem, these cracking incidents affect plant availability, operating costs, and man-Rem exposure for inspection, repair, and so on. Figure 3 shows the major piping systems and other components affected by intergranular SCC.

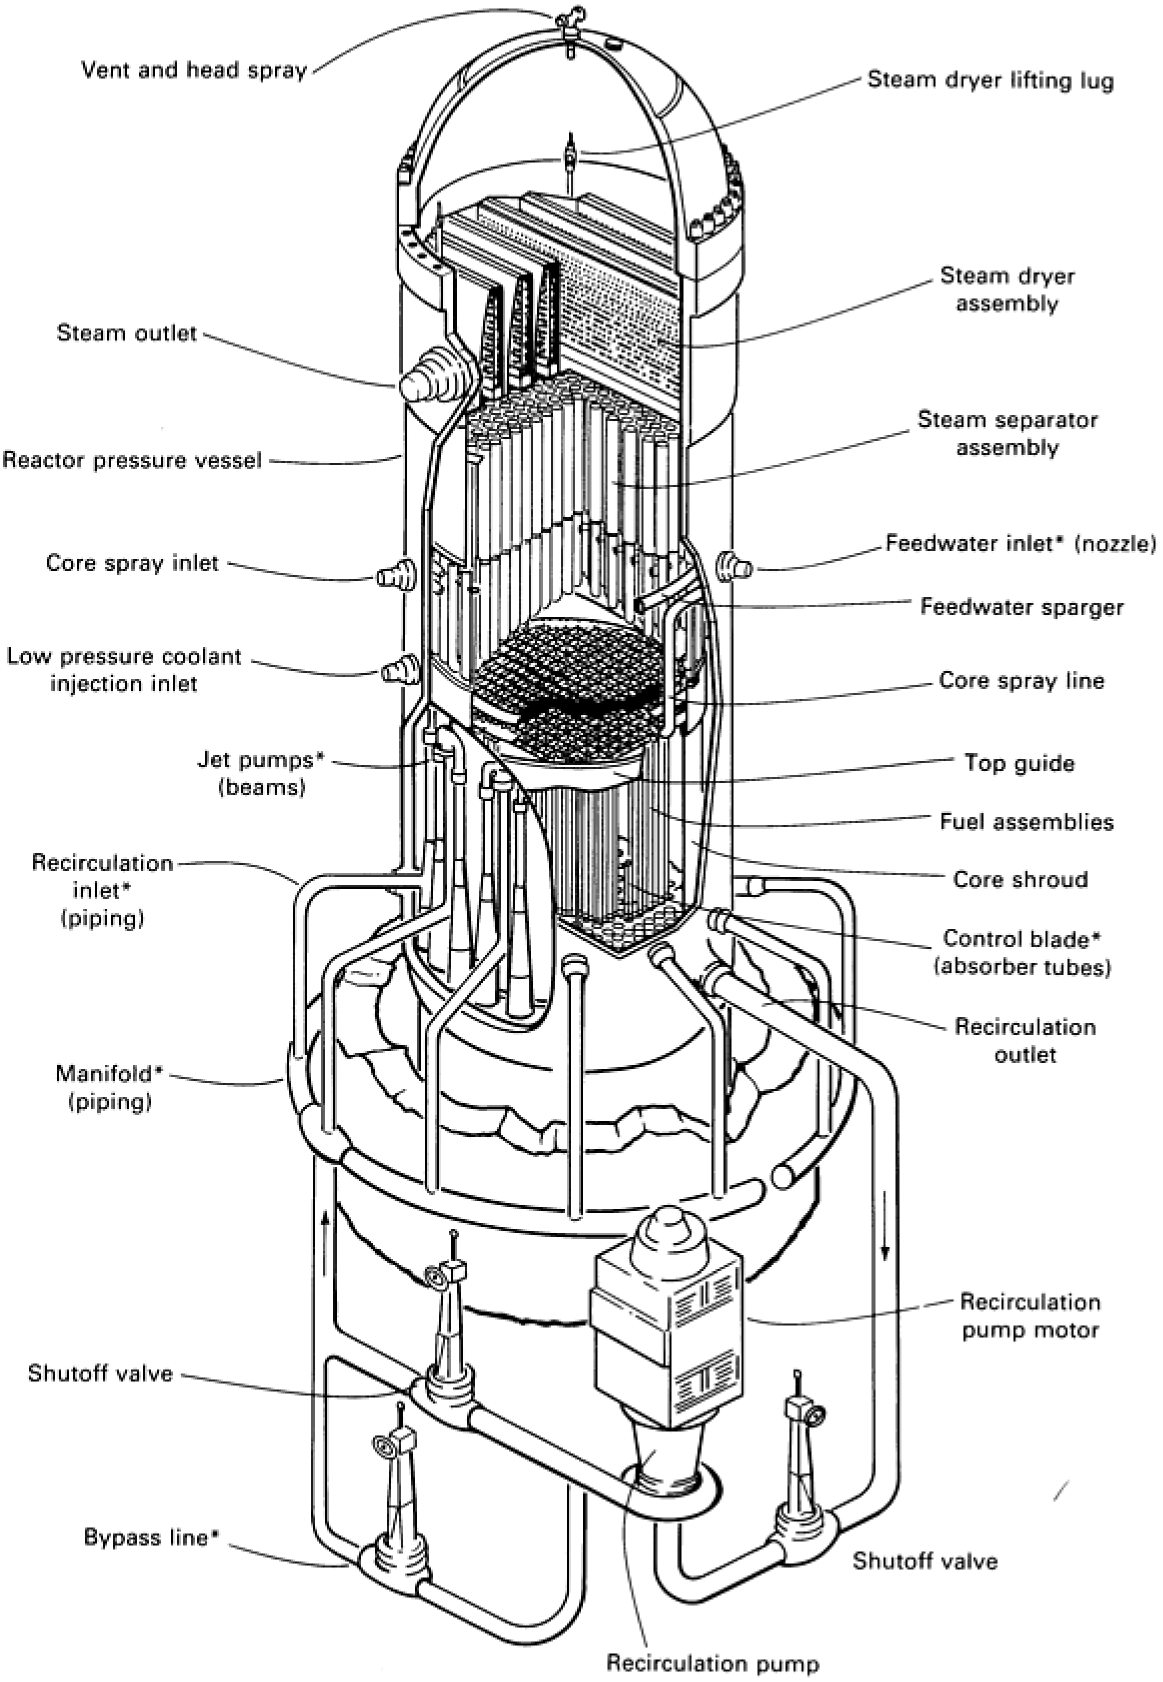

Fig. 3 Some of the key components of the BWR. Asterisks indicate areas of corrosion problems discussed in the Section "Corrosion in Boiling Water Reactors" in this article.

Field Experience

The first observed BWR field intergranular SCC incident occurred in an early plant in the weld HAZ of a 150-mm (6-in.) type 304 stainless steel recirculation bypass line in late 1965 after 68 months of plant operation. This section of piping was replaced by type 304L stainless steel. Subsequently, in 1966 and 1967, there were a number of additional piping indications found by ultrasonic examination or by leakage. The first significant outbreak of intergranular SCC of welded type 304 stainless steel occurred in the fall of 1974 and early 1975. Sixty-four incidents of cracking were identified during this period, and all of them occurred in small-diameter lines (<250 mm, or 10 in.). As will be explained in the discussion "Mechanism of Intergranular SCC in BWR Piping" in this article, research revealed that this cracking was a result of the simultaneous interaction of weld-sensitized type 304 stainless steel, high tensile stress due to the combination of operating stresses and weld residual stresses, and high-temperature oxygenated BWR water (Ref 1).

During 1978, incidents of intergranular SCC were first noticed in a large-diameter (610 mm, or 24 in.) piping in an overseas BWR. This incident established additional concern for the main recirculation piping (Fig. 3) because replacement of these lines would be difficult, costly, and would require additional leak-before-break and degraded pipe behavior analysis. In 1982, extensive intergranular SCC of 710-mm (28-in.) recirculation piping was found in a domestic BWR. Additional inspections revealed cracking in large-diameter piping of other domestic BWRs.

Mechanism of Intergranular SCC in BWR Piping

As noted in the previous discussion on "Field Experience" in this article, the three necessary conditions for intergranular SCC of austenitic stainless steels in the BWR are:

- Sensitized microstructure (chromium depletion at the austenite grain boundaries)
- Tensile stress (applied plus residual) over the yield stress at temperature
- Oxygenated high-temperature water

Metallurgical Factors. When many non-stabilized austenitic stainless steels are heated in the temperature range of approximately 550 to 850 °C (1000 to 1550 °F), they undergo a solid state reaction and become sensitized and susceptible to intergranular corrosion. If a tensile stress is applied (or residually present) to a component characterized by this type of heat treatment, intergranular SCC can occur (if the environment is specifically corrosive to this particular metal system).

It is now accepted that this phenomenon in the BWR is related to local chromium depletion resulting from the precipitation of carbides at the austenite grain boundaries. To understand this phenomenon in terms of microstructure, it is instructive to examine the equilibrium relationships and carbon solubility in an 18Cr-8Ni alloy (Fig. 4). This simplified phase diagram indicates that austenite containing less than approximately 0.03% C should remain in solid solution over the temperature range shown. Austenite containing carbon in excess of 0.03% should precipitate $M_{23}C_6$ upon cooling below the solubility line. However, at relatively rapid rates of cooling, this reaction is partially suppressed, and the room temperature microstructure is characterized by austenite supersaturated with carbon.

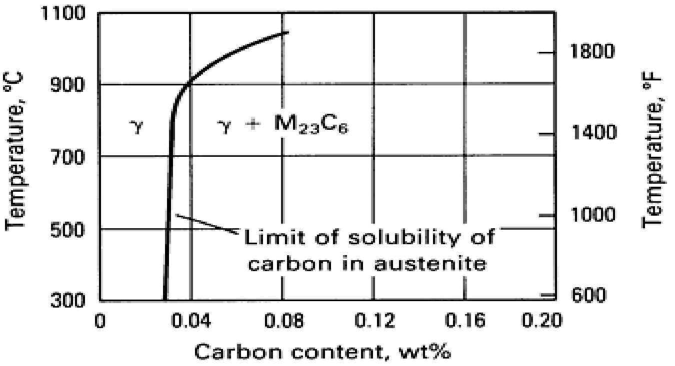

Fig. 4 Solid solubility of carbon in an Fe-18Cr-8Ni alloy. Source: Ref 2

If this supersaturated austenite is reheated to elevated temperatures within the γ+ $M_{23}C_6$ field, further precipitation of the chromium-rich $M_{23}C_6$ (six carbon atoms tie up 23 chromium atoms) will take place preferentially at the austenite grain boundaries. Certain time-temperature combinations will be sufficient to precipitate this chromium-rich carbide, but will be insufficient to rediffuse chromium back into the austenite near the carbide. The net result is the formation of envelopes of chromium-depleted austenite around the carbide, which in certain environments will not resist intergranular attack or intergranular SCC. This chromium depletion results in a sensitized microstructure. This attack, when caused by welding, has been known as weld decay. However, more modern practice is to use the term sensitized to describe chromium depletion, irrespective of whether it has resulted from slow cooling, postweld heat treatment (a process designed to reduce weld residual stress in low-alloy steel pressure vessels), elevated-temperature service, or welding.

It is important, however, to distinguish among the various heat treatments because the stress-corrosion response differs with different heat treatments. For example, furnace-sensitized type 304 stainless steel is somewhat more susceptible to intergranular SCC than weld-sensitized material in an oxygenated pure water environment because of the higher integrated time at temperature. The sensitized regions adjacent to a weld are known as the HAZ (Fig. 5). Figure 6 shows an actual intergranular crack in the HAZ of a 400-mm (16-in.) pipe. The crack does not penetrate the weld metal itself. The use of this intergranular SCC immunity of the weld metal as a means of mitigating cracking will be discussed below in the discussion of "Corrosion-Resistant Cladding" in this article.

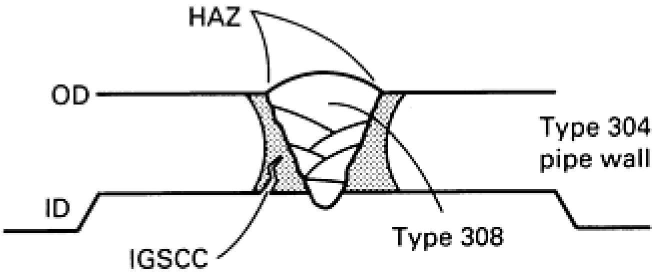

Fig. 5 Location of intergranular SCC in HAZ of type 304 pipe. OD, outside diameter; ID, inside diameter

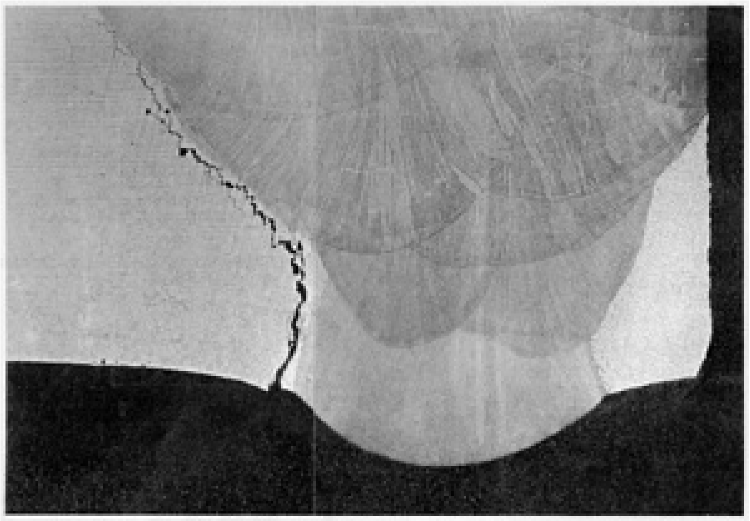

Fig. 6 Pipe test results showing intergranular SCC in a 400-mm (16-in.) type 304 stainless steel pipe HAZ. 13×

The chromium-depleted zone adjacent to the grain boundary (Fig. 7) is basically no longer a stainless steel but rather some type of low-alloy steel, because the chromium content may be considerably below the 10 to 12% required to create a stainless steel. The precipitation of $Cr_{23}C_6$ at the grain boundaries and the creation of a chromium-depleted zone have resulted in the formation of a metallurgical galvanic cell between a small anodic area of low-alloy steel (chromium-depleted zone) and a large cathodic area of stainless steel. This galvanic cell with unfavorable area anode/cathode ratios may result in more rapid attack of the impoverished area even in a low-conductivity oxygenated water environment.

Additional information on sensitization of stainless steels and HAZ corrosion can be found in the articles "Corrosion of Weldments" and "Corrosion of Stainless Steels" in this Volume.

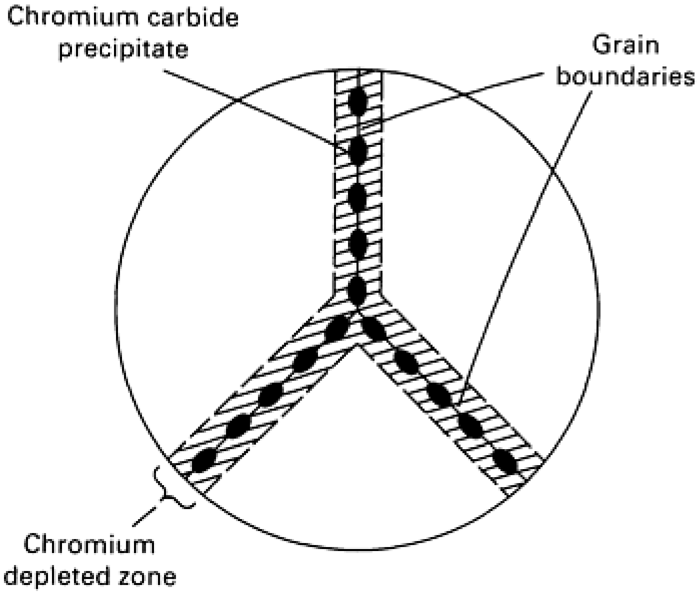

Fig. 7 Diagrammatic representation of a grain boundary in sensitized type 304 stainless steel

Tensile Stress Factors. There are primarily three sources of stress in the BWR (and PWR): fabricational stresses, primary stresses, and secondary stresses. Fabricational stresses consist of stresses introduced during fit-up and assembly in the shop or in the field, those introduced by machining or forming operations (such as surface grinding or cold straightening), and those introduced by other operations (such as welding). For example, abusive grinding can introduce surface tensile stresses of approximately the magnitude of the yield point or higher. Welding residual stresses near the yield point can also be present in pipes. Primary stresses from the operational forces on the equipment may be as high as the yield stress locally at constraints in an assembly. Secondary stresses--for example, from thermal expansion--may also locally reach the yield point. Finally, cyclic stresses from vibrations or from changes in operating mode can also add to the sum. Such varying stresses may be of great importance in initiating cracks or in restarting stopped cracks because they provide continuing plastic strain.

The effect of stress level on the time to failure of sensitized austenitic stainless steels has been studied in detail, and a well-defined dependence of stress on time to cracking has been found. Figure 8 shows this relationship for furnace-sensitized (24 h at 650 °C, or 1200 °F) type 304 stainless steel in 0.2-ppm oxygen (O_2) BWR-type water. As expected, the lower the tensile stress, the longer the time to cracking. Also, it seems apparent that the stress dependency curve is asymptotic to the at-temperature yield strength of the sensitized material.

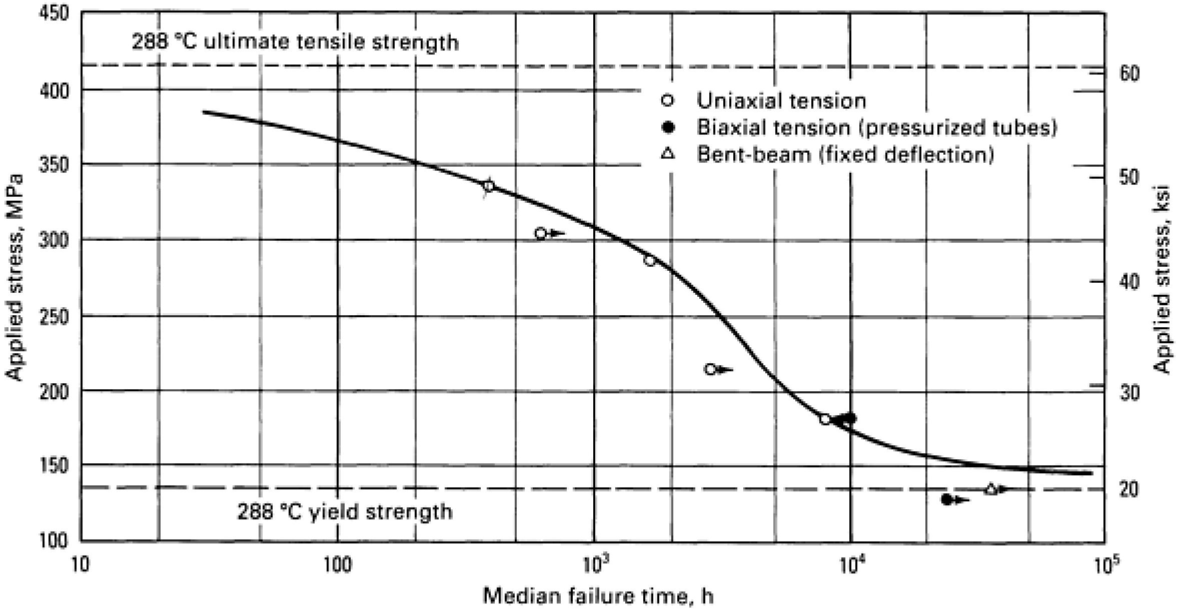

Fig. 8 Stress dependence of intergranular SCC of sensitized type 304 stainless steel in 288-°C (550-°F) water with 0.2 mg/L (ppm) O_2

Environmental Factors. The recirculating coolant in a BWR is high-purity neutral-pH water containing typically 0.2 mg/L (ppm) radiolytically produced dissolved oxygen with less-than-stoichiometric amounts of dissolved hydrogen (~ 0.02 mg/L). This amount of oxygen is sufficient to provide the chemical or electrochemical driving force for intergranular SCC. During the corrosion reaction, the dissolved oxygen is reduced to the hydroxyl ion, and the chromium-depleted zone of the stainless steel is oxidized.

Increasing the dissolved oxygen content to approximately 3 mg/L will increase the rate of cracking. Above 3 mg/L, the rate of oxygen arrival is limited to the limiting diffusion rate. The presence in the oxygenated environment of such anions as chloride, sulfate, and carbonate will significantly increase the propensity for intergranular SCC. Anions such as nitrate and fluoride have only a minor detrimental effect on type 304 stainless steel cracking propensities at operating temperatures when they are present in low concentrations (Ref 3, 4, 5).

Quantitative Model for Intergranular SCC in the BWR. A quantitative model for intergranular SCC (and corrosion fatigue) in the BWR has been developed (Ref 6). The model is based on the slip dissolution/film rupture model and relates crack advance to the oxidation reactions that are occurring at the crack tip where a thermodynamically stable oxide (or protective film) is ruptured by an increase in the strain in the underlying matrix. The amount of subsequent crack propagation is related via Faraday's law to the oxidation charge density associated with both dissolution and oxide growth on the bare surface. Such an environmentally controlled mode of crack advance is sustained by a further increment in matrix strain, which reruptures the oxide after a certain time period.

To validate the slip dissolution/film rupture hypothesis and to use it as a quantitative intergranular SCC prediction tool, several critical factors were evaluated:

- Metallurgical condition at the crack tip
- Crack tip environment, including electrochemical potential, pH, and anion content
- Oxidation rates on bare surfaces of alloy-environment systems symptomatic of those at the strain crack tip
- Crack tip strain rate

The model successfully predicts to within a factor of two the environmentally controlled crack propagation rates for stainless steel and pressure vessel steels in water at 288 °C (550 °F) over a range of system variables (Ref 6). As a point

of comparison, it should be noted that the validation criteria of past models have been limited to orders-of-magnitude predictions for a specific material/environment/stress condition. This model is now being used in the BWR industry as a crack propagation prediction tool.

Mitigation of Intergranular SCC in BWR Piping

The following discussion presents several intergranular SCC mitigation techniques for BWR piping. The mitigation methods are presented under general categories of material solutions, stress solutions, and environmental solutions. A few of the remedies address two of the three necessary intergranular SCC factors.

Materials Solutions

The material solutions to the piping intergranular SCC concern in the United States consist primarily of replacing the susceptible type 304 and 316 stainless steels with more sensitization-resistant materials, such as type 316 and 304 Nuclear Grades, redissolving the chromium carbides by solution heat treatment, and cladding with crack-resistant weld metal. Other materials, such as type-347 Nuclear Grade, have been used successfully overseas.

Nuclear Grade Stainless Steels. The replacement of current piping materials with materials more resistant to sensitization is a straight-forward approach to mitigating intergranular SCC. Because it is well documented that decreasing the carbon content and increasing the molybdenum content of stainless steel would reduce the kinetics of sensitization (Ref 7, 8, 9, 10), these two compositional modifications are synergistically beneficial for increasing the resistance of type 304 stainless steel to sensitization. However, type 316 Nuclear Grade and type 304 (with no added molybdenum) Nuclear Grade stainless steels take this theme a step further. Instead of the nominal 0.03% C maximum of the L-grade stainless steels, the Nuclear Grades are characterized by a maximum carbon content of 0.020%. The second important composition characteristic of type 304NG and type 316NG is the specification of 0.060 to 0.100% N. This modification is designed to recover the decrease in alloy strength due to the reduction of the carbon content. Another successful approach that has been used in the Federal Republic of Germany is the use of low-carbon niobium-stabilized type 347 stainless steel.

For the Nuclear Grade materials, full-size pipe tests have shown that factors of improvement over type 304 stainless steel performance can be expected to be at least 50 to 100 times in normal BWR operation (Ref 11). The necessary factors for improvement for the current 40-year service life is about 20. Therefore, the replacement of type 304 stainless steel piping with type 316, type 304, or type 347 Nuclear Grade will provide substantial resistance to intergranular SCC.

It is important to note that creviced or cold-worked type 316 or type 304 Nuclear Grade can suffer intergranular SCC. When crevices are present, the ionic impurity content in the water can greatly aggravate intergranular SCC. Among the specific impurities, sulfate ions are particularly deleterious (Ref 4). It is therefore extremely important to maintain good-quality water chemistry in the BWR to minimize cracking propensities.

Solution Heat Treatment. Immunity against intergranular SCC of type 304 stainless steel can be provided by eliminating weld-sensitized regions. This can be accomplished by solution heat treatment to redissolve the chromium carbides and eliminate chromium depletion around previously sensitized grain boundaries. Moreover, solution heat treatment will eliminate detrimental cold work and weld residual stress in the pipe.

Following a butt-welding operation, the entire pipe segment is solution annealed at 1040 to 1150 °C (1900 to 2100 °F) for 15 min per 25 mm (1.0 in.) of thickness but not less than 15 min or more than 1 h, regardless of thickness. The pipe segment is then quenched in circulating water to a temperature below 205 °C (400 °F). Solution heat treatment is generally limited to those weld joints made in the shop where heat treatment facilities are available, because of dimensional tolerance consideration, size constraints of the vendor facilities (furnace and quench tank) and cooling rate requirements (dead end legs).

Corrosion-Resistant Cladding. The corrosion-resistant cladding remedy achieves its resistance to intergranular SCC by using the intergranular SCC resistance inherent in duplex austenitic-ferritic weld metals (Ref 11). Although the carbide precipitation observed in the HAZ inside surface is also present in the weld metal, the nature of the duplex structure of the weld metal provides resistance to intergranular SCC in the BWR. In fact, intergranular SCC propagating from the weld HAZ is generally blunted when it reaches the weld metal if sufficient ferrite is present. As shown in Fig. 6, the cracking will actually curve away from the weld metal.

Field experience has indicated that in the as-welded condition very little ferrite is required to prevent intergranular SCC. These results and numerous laboratory data generated on welded and furnace-sensitized type 308 and type 308L weld metal prompted the conclusion that a minimum amount of ferrite (8%) must be present to provide a high degree of resistance to intergranular SCC in BWR environments. As with type 304 stainless steel, reducing the carbon level is also beneficial.

In the corrosion-resistant cladding technique, type 308L weld metal is applied to the inside surface of the pipe at the pipe weld ends before making the final field weld. This duplex weld metal covers the region that will become sensitized during the final weld process, thus providing intergranular SCC resistance by maintaining low carbon and a sufficient ferrite level in the region that would normally be sensitized. Additional information on corrosion-resistant cladding can be found in the article "Corrosion of Clad Metals" in this Volume.

Weld Overlay Repair. Before any discussion of weld overlay, it is important to note that the weld overlay repair technique is not a fully qualified long-term mitigation technique for intergranular SCC. Currently, the Nuclear Regulatory Commission (NRC) has allowed up to three fuel cycles of operation (~54 months) on a cycle-by-cycle basis with weld overlay. However, laboratory environmental qualification programs and effective ultrasonic test procedures have established a basis for its extended lifetime beyond 22 fuel cycles (~396 months) of operation (Ref 12).

The weld overlay is similar to corrosion-resistant cladding in that it uses layers of intergranular SCC resistant duplex weld metal. For cases where Alloy 182 is to be overlayed, Alloy 82 weld metal is used. The most significant difference is that the layer of weld metal is placed on the outside surface of the pipe while the pipe is being cooled internally with water and is used to prevent an existing crack from penetrating through the wall. The weld overlay is also applied as a structural reinforcement to restore the original piping safety margins (Fig. 9). An equally important effect of the weld overlay is that it produces a favorable (compressive) residual stress pattern that can retard or arrest crack growth.

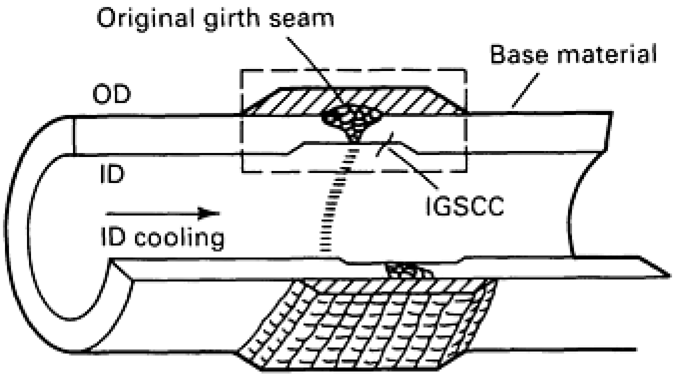

Fig. 9 Weld overlay intergranular SCC mitigation technique

The weld overlay technique has the potential for being the most cost-effective method as compared to other repair techniques (pipe replacement, solution heat treatment, corrosion-resistant cladding), which require draining of the system. For additional information, see the article "Welding of Cast Irons" in *Welding, Brazing, and Soldering,* Volume 6 of the *ASM Handbook.*

Tensile Stress Solutions

The tensile stress solutions primarily affect the weld residual stress profile by placing the inner surface weld residual stress in compression. These solutions, which are discussed below, include heat sink welding, induction heating stress improvement, and last pass heat sink welding.

Heat Sink Welding. If a pipe can be welded without producing a sensitized structure and high residual tensile stresses in the weld HAZ, the resultant component will be resistant to intergranular SCC in the BWR environment. The heat sink welding program has developed procedures that reduce the sensitization produced on the inside surface of welded pipe

and, more important, change the state of surface residual welding stresses from tension to compression. This approach can be used in shop or field applications.

Heat sink welding involves water cooling the inside surface of the pipe during all weld passes subsequent to the root pass or first two layers. Water cooling can be applied by using flowing or turbulent water, by spray cooling through a sparger placed inside the pipe, or, in a vertical run, by still water.

Laboratory type 304 stainless steel butt welds have been produced to evaluate the inside surface heat sink welding techniques (Ref 13). Residual stresses were measured with strain gages. It was found that in a variety of pipe sizes the inside surface tensile residual stress is reduced substantially or changed from tension to compression as a result of this approach. Heat sink welding, as mentioned above, has a secondary benefit in that it reduces the time at temperature for sensitization due to the presence of the cooling water heat sink.

The induction heating stress improvement technique changes the normally high tensile stress present on the pipe inside surface of weld HAZs to a benign compressive stress (Ref 14, 15). This process involves induction heating of the outer pipe surface of completed girth welds to approximately 400 °C (750 °F) while simultaneously cooling the inside surface, preferably with flowing water (Fig. 10). Thermal expansion caused by the induction heating plastically yields the outside surface in compression, while the cool inside surface plastically yields in tension. After cooldown, contraction of the pipe outside surface causes the stress state to reverse, leaving the inner surface in compression and the outside surface in tension (Fig. 11).

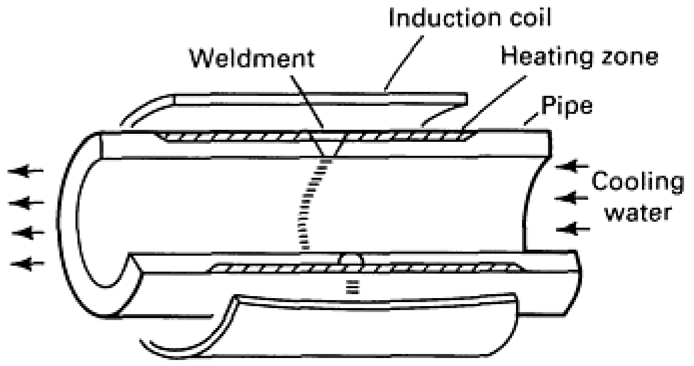

Fig. 10 Illustration of heating and cooling process for induction heating stress improvement

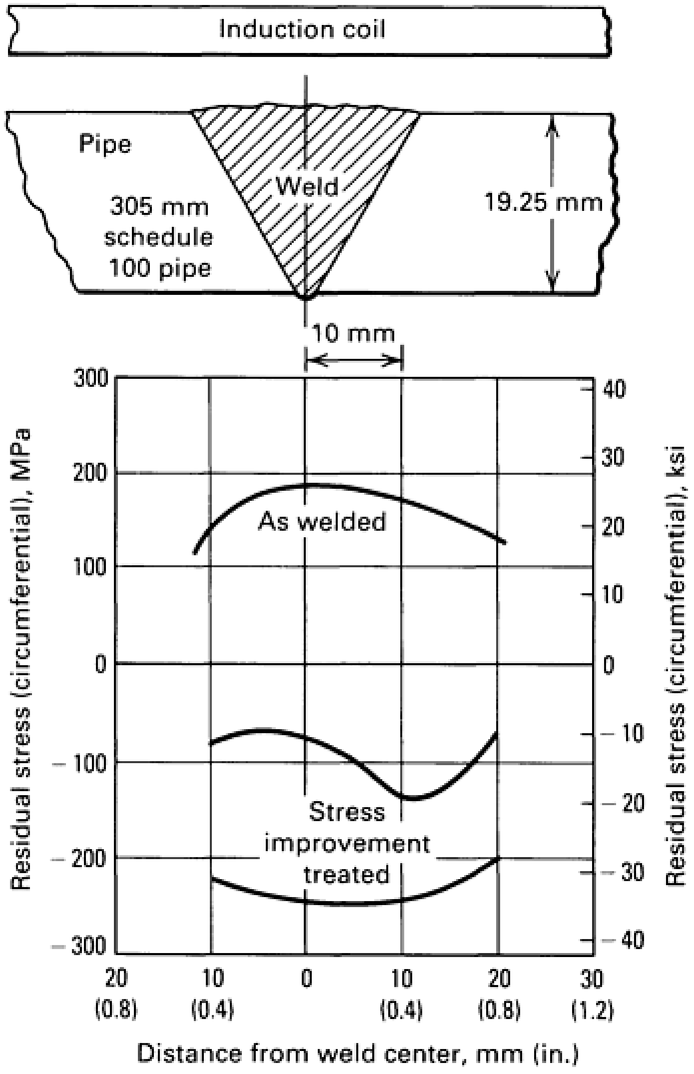

Fig. 11 Residual stress comparison for induction heating stress improvement

Qualification of the effectiveness of induction heating stress improvement has been accomplished by establishing the following (Ref 12, 15):

- Induction heating stress improvement treatment reliably reduces normally high tensile inside surface residual stresses to a zero compressive state
- Full-size environmental pipe testing and residual stress tests have demonstrated that these beneficial residual stresses result in a large improvement in intergranular SCC resistance
- Metallurgical investigations have shown that an induction heating stress improvement treatment produces no adverse effects. No increase in sensitization is found, and no significant variation in mechanical properties occurs
- A minimum life of 12 fuel cycles (~216 months) has been measured on induction heated stress improved precracked pipes in the laboratory if the initial cracking does not exceed about 20% of wall thickness

Last Pass Heat Sink Welding. As discussed in the previous section, induction heating stress improvement is an intergranular SCC mitigation technique that favorably alters the weld residual stress pattern. The welding torch is the heat source that initially produces the undesirable residual stress that induction heating stress improvement counterbalances. Analysis was able to establish that this residual stress state could be made compressive by the introduction of inside

surface water cooling during the welding operation. Cooling during the entire welding process (heat sink welding) or just during the last pass could be effective in reversing the residual stresses analogous to the induction heating stress improvement process.

Qualification of the last pass heat sink welding process consisted of magnesium chloride ($MgCl_2$) residual stress tests, which verified that the last pass heat sink welding process does produce compressive residual stresses uniformly around the pipe circumference (Ref 16). Stress-relief strain gage measurements quantified the compressive axial stress and revealed that the stresses were compressive up to about 50% through-wall.

Finally, intergranular SCC improvement was evaluated by using pipe tests performed at applied stresses above yield in a high-oxygen (8 mg/L) high-temperature (288 °C, or 550 °F) water environment. As shown in Fig. 12, at the end of the program period, the pipes had been on test for over 5500 h, demonstrating a factor of more than 5.5 and more than 6.5 improvement, respectively, at the two test stresses (193.7 and 211 MPa, or 28.1 and 30.6 ksi, respectively). This factor of improvement approaches that determined for induction heating stress improvement.

Environmental Solution (Hydrogen Water Chemistry)

Numerous laboratory studies have indicated that susceptibility to intergranular SCC in stainless steels diminishes with decreasing oxygen content of the water below 0.2 mg/L. At 0.015 mg/L oxygen, intergranular SCC initiation is extremely difficult in the laboratory in sensitized type 304 stainless steel if good water purity (<0.3 μS/cm) is maintained (Ref 17).

The candidate oxygen-reducing additives to the BWR environment consisted of ammonia, hydrazine, ammonia-hydrazine, hydrazine morpholine, and hydrogen. Hydrogen was selected as the most suitable candidate, based on laboratory studies as well as an overall systems and economic analysis. Hydrogen also produces no changes in pH, results in minimum system impact, and is not corrosive or toxic.

Initial, very short term ($\sim$10 hours and 4 days) in-reactor hydrogen injection tests were performed as early as 1979 and 1981, respectively (Ref 18). After a somewhat longer (6 weeks) hydrogen demonstration test at the Commonwealth Edison Dresden-2 plant in 1982 (Ref 19), this plant became the first facility to initiate full-time operation on hydrogen injection. The test clearly demonstrated that the addition of hydrogen gas does indeed reduce the dissolved oxygen content below the intergranular SCC threshold level as measured by electrochemical potential techniques plus oxygen analysis and verified by in-reactor constant extension rate tests (Ref 20).

Potentials obtained during the normal Dresden-2 environment were characterized by an electrochemical potential for type 304 stainless steel of $\sim$0 mV_{SHE} (standard hydrogen electrode), while the hydrogenated Dresden-2 environment reduced the type 304 stainless steel potential to $\leq$-280 mV_{SHE}. This drop in potential at Dresden-2 and the data obtained at other BWRs and in the laboratory are illustrated in Fig. 13.

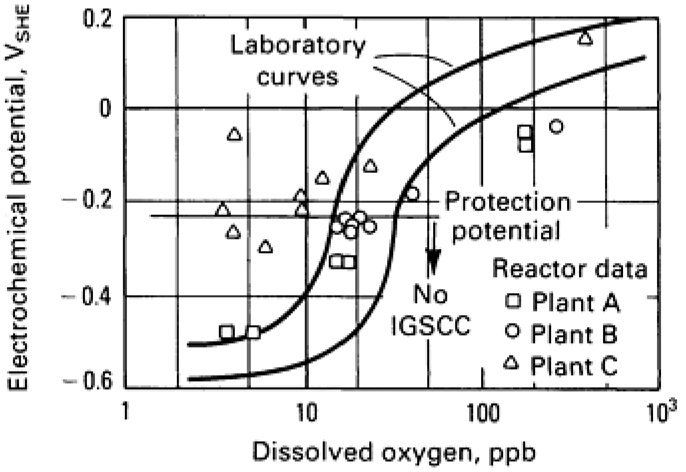

Fig. 13 Relationship between dissolved oxygen and electrochemical potential for type 304 stainless steel

Crack growth data versus time and environment on precracked furnace-sensitized type 304 stainless steel were also obtained at Dresden-2 by using the reversing direct current (dc) electrical potential monitoring technique (Ref 21). The specimen was precracked in the laboratory in the nominal 0.2-mg/L O_2 and then transported to Dresden-2 for testing. The stress intensity factor (K_I) level for the specimen resembles that of cracks previously identified in a sensitized Dresden-2 piping-to-nozzle transition (safe end) at 27.5 MPa $\sqrt{m}$(25 ksi $\sqrt{in.}$). The results of this test revealed that no significant crack extension occurred (Fig. 14). This result verifies the result of the mid-cycle and end-cycle in-service inspection of known pipe cracks at Dresden-2 that also did not grow during this 18-month hydrogen water chemistry exposure.

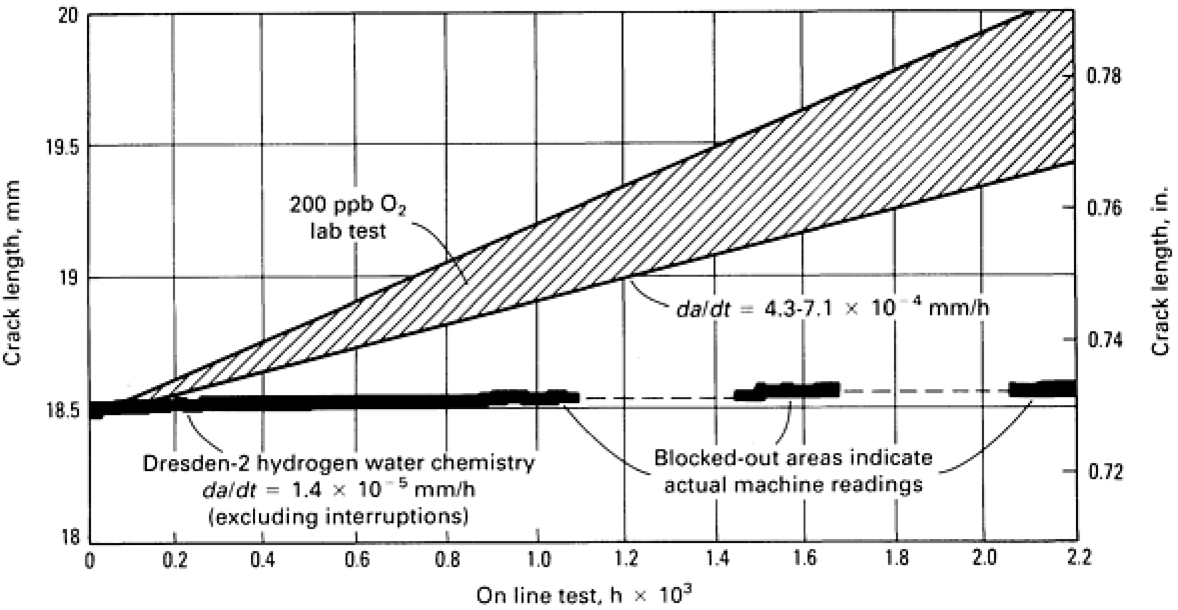

Fig. 14 Electrical potential monitoring results on furnace-sensitized type 304 stainless steel in Dresden-2 BWR. Crack growth is reduced by a factor of approximately 50. Source: Ref 22

The laboratory hydrogen water chemistry materials program was characterized by an extensive test matrix (Ref 23). The testing techniques utilized in the program included full-size pipe tests; fracture mechanics studies; electrochemical investigations; constant extension rate tests; straining electrode tests; constant load tests; bent beam tests; fatigue testing; cyclic crack growth studies; general, galvanic, and crevice corrosion investigations; and corrosion oxide analysis. All of

these laboratory studies clearly demonstrated that hydrogen water chemistry, which is currently defined as an electrochemical potential of type 304 stainless steel of <280 mV_{SHE} and water conductivity of <0.3 μS/cm, mitigates many forms of environmental cracking.

Summation of Intergranular SCC Mitigation

The above discussion has indicated the following conclusions concerning the mitigation of intergranular SCC in BWR piping systems and its impact on future BWR performance.

- The causes of the intergranular SCC of BWR piping (material, tensile stress, and environment) are understood and can be prevented
- Several countermeasures/mitigation techniques have been qualified and are available. To achieve a greater margin against intergranular SCC, more than one remedy should be applied to a plant, such as the use of type 316NG stainless steel and hydrogen water chemistry
- The contribution of intergranular SCC in piping to BWR plant unavailability can be expected to decrease in the future if one or more of the qualified countermeasures are implemented by the BWR utilities

SCC in Nitrided Stainless Steel

Positive core reactivity control is maintained in the domestic BWR by the use of movable control rods interspersed throughout the core. The rods are moved vertically by hydraulically actuated, locking-piston drive mechanisms. The drive mechanisms are bottom-entry upward-scramming drives that are mounted on a flanged housing on the reactor vessel bottom head (Fig. 15). The control rod drive mechanism is a double-acting hydraulic piston that uses condensate water as the operating fluid. An index tube and a piston, coupled to the control rod, are locked at fixed increments by a collet mechanism. One of the key components of this device is the collet retainer tube (CRT).

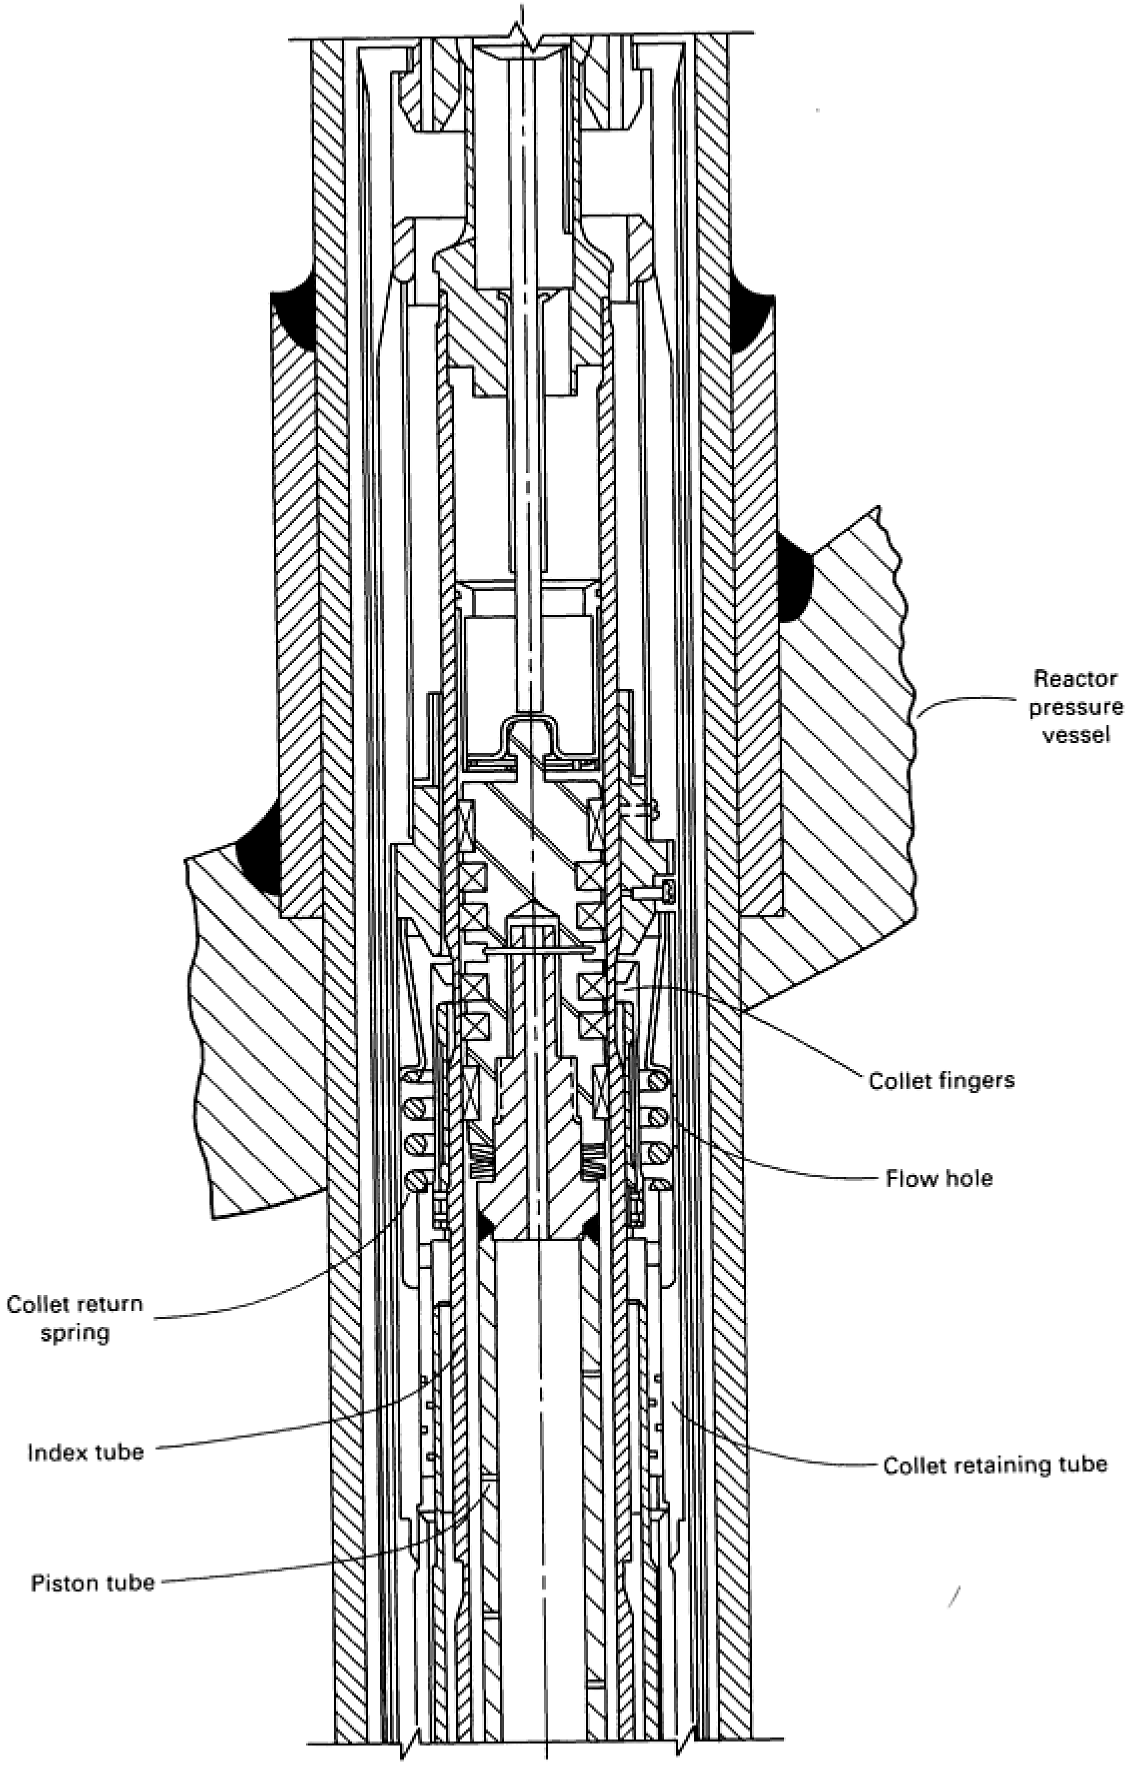

Fig. 15 Control rod drive schematic

The CRT is a short tube welded to the upper end of the drive. Its three primary functions are to carry the hydraulic unlocking pressure to the collet piston, to provide an outer cylinder, with a suitable wear surface for the metal collet piston rings, and to provide mechanical support for the guide cap, a member that incorporates the cam surface for holding the collet fingers open and provides the upper rod guide or bushing.

The CRT (Fig. 16) is fabricated from wrought type 304 stainless steel. The inner surface, where contact is made with the collet piston seal ring, is hard surfaced by nitriding. Under normal conditions, the stresses on the CRT are quite small. However, during rapid (2.5 s) control rod insertions (scrams), the tube experiences high thermal stresses when the outer surface is initially subjected to a sudden flow of 288-°C (550-°F) water. The normal CRT operating range is 65 to 150 °C (150 to 300 °F). The water flow pattern during a scram is such that the inside of the CRT is cold, while the outside has alternating zones of hot and cold water.

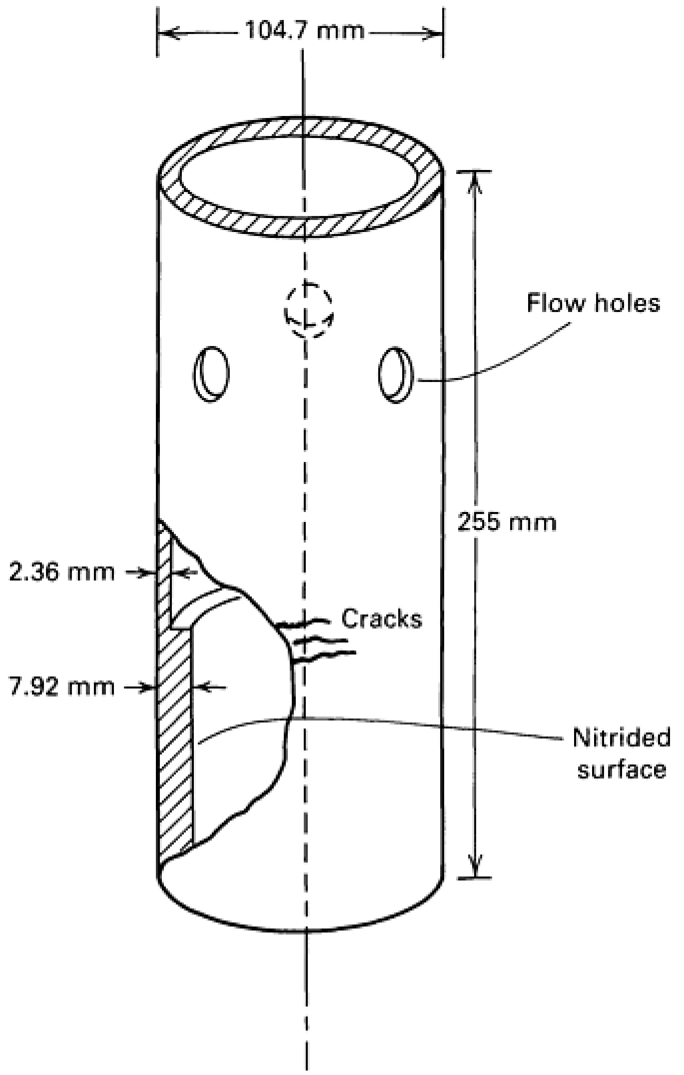

Fig. 16 Geometry of the collet retainer tube

Field Experience With the CRT. During a routine maintenance inspection of disassembled control rod drives at a domestic BWR in June 1975, fine cracks were observed by liquid-penetrant examination in a limited number of CRTs (Fig. 17). Subsequent inspection of drives in other operating BWRs also disclosed occasional occurrences of CRT cracking. Inspection of several test drives having simulated service histories for an excess of the 300 hot scram design life also indicated evidence of cracking. The cracks, which were determined to be intergranular, were generally circumferential and appeared with greatest frequency below and between the cooling ports in the area of the change in wall thickness (Fig. 18).

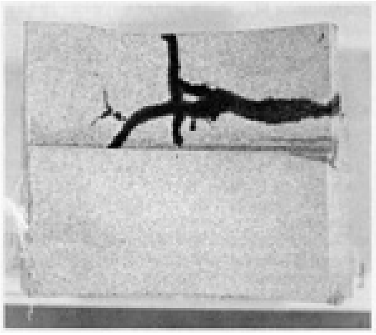

Fig. 17 Intergranular SCC of collet retainer tube revealed by liquid-penetrant examination

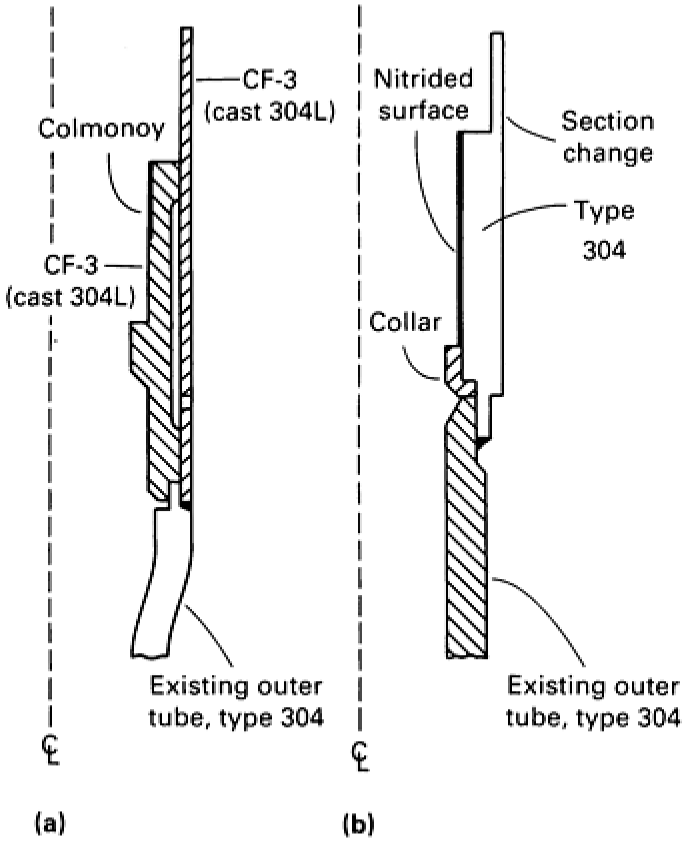

Fig. 18 Collet retainer tube improvements. (a) Improved design. (b) Old design

Mechanism of Cracking of the CRT. A detailed analytical and experimental investigation was performed to determine the cause of cracking and to assess the margin to failure (Ref 14). As was the case with stainless steel piping, the cracking was intergranular SCC produced by the simultaneous combination of sensitization, as discussed above, due to the nitriding thermal cycle, tensile stress, and highly oxygenated water. Specifically, it was determined that there were four sources of thermal stresses near the location of the cracks (Ref 24):

- Thermal shock stresses due to the sudden increase in temperature
- Bending stresses due to the through-wall temperature gradient
- Discontinuity stresses due to the difference in heat-up rates between the thick and thin sections
- Bending stresses due to circumferential temperature gradients

The environment of the control rod drive is typically supplied by the condensate storage tank. This cooling water was often characterized by a conductivity of ~1 μS/cm (25 °C, or 77 °F), and the typical dissolved oxygen content is 5 mg/L. This high-oxygen/high-conductivity environment will accelerate intergranular SCC.

Mitigation of Intergranular SCC in the CRT. It has been shown that the CRT cracking was due to intergranular SCC caused by high thermal stresses with material sensitized by nitriding plus exposure to a high-oxygen water environment. Therefore, the problem can be mitigated by attacking each one of these three necessary factors.

To eliminate the high thermal stresses, the design of the CRT was changed by installing a two-piece CRT, which eliminated the section change and thus reduced the discontinuity stress. To reduce stresses further, the new design (Fig. 18a) has 12 cooling water exit holes rather than the original 3. The effect is to reduce the circumferential variation in temperature below the flow holes during a scram cycle.

The CRT material was changed from wrought type 304 stainless steel to a centrifugally cast CF-3 with ferrite control, a proven BWR material with known resistance to intergranular SCC. The newer-design CRT is also hardfaced with Colmonoy 6, a nickel-base hardfacing material applied by the flame spray process rather than by nitriding.

The environment was changed by a recommendation to BWR operating plant utilities to use high-purity deaerated water (conductivity: ≤0.1 μS/cm, measured at 25 °C, or 77 °F; dissolved oxygen: <5 mg/L) for control rod drive cooling water. This reduction in dissolved oxygen can increase the time to crack initiation of the older CRT by a factor of 100. The recommendation identified approaches to achieving water quality limits, water sampling, and monitoring additions.

The main conclusions of this case study can be summarized as follows:

- The intergranular SCC observed in the CRT was due to the simultaneous interaction of sensitized material, high thermal stresses, and highly oxygenated water
- The problem has been mitigated by eliminating sensitization by a change of material to CF-3, by redesigning to reduce the discontinuity stresses and circumferential stresses, and by reducing the oxygen content and conductivity of the environment
- The intergranular SCC of BWR collet retainer tubes is understood, and a solution is now available

SCC of Alloy X-750 Jet Pump Beams

Jet pumps located within the reactor vessel are used in the BWR recirculation system (Fig. 3). The jet pumps, which have no moving parts, provide a continuous circulation path for a major portion of the core coolant flow. The water from the recirculation system flows up the riser pipe, reverses direction through the 180° bend nozzle, and draws surrounding water in the downcomer region into the jet pump throat, where the two flows mix and then diffuse in the diffuser (Fig. 19).

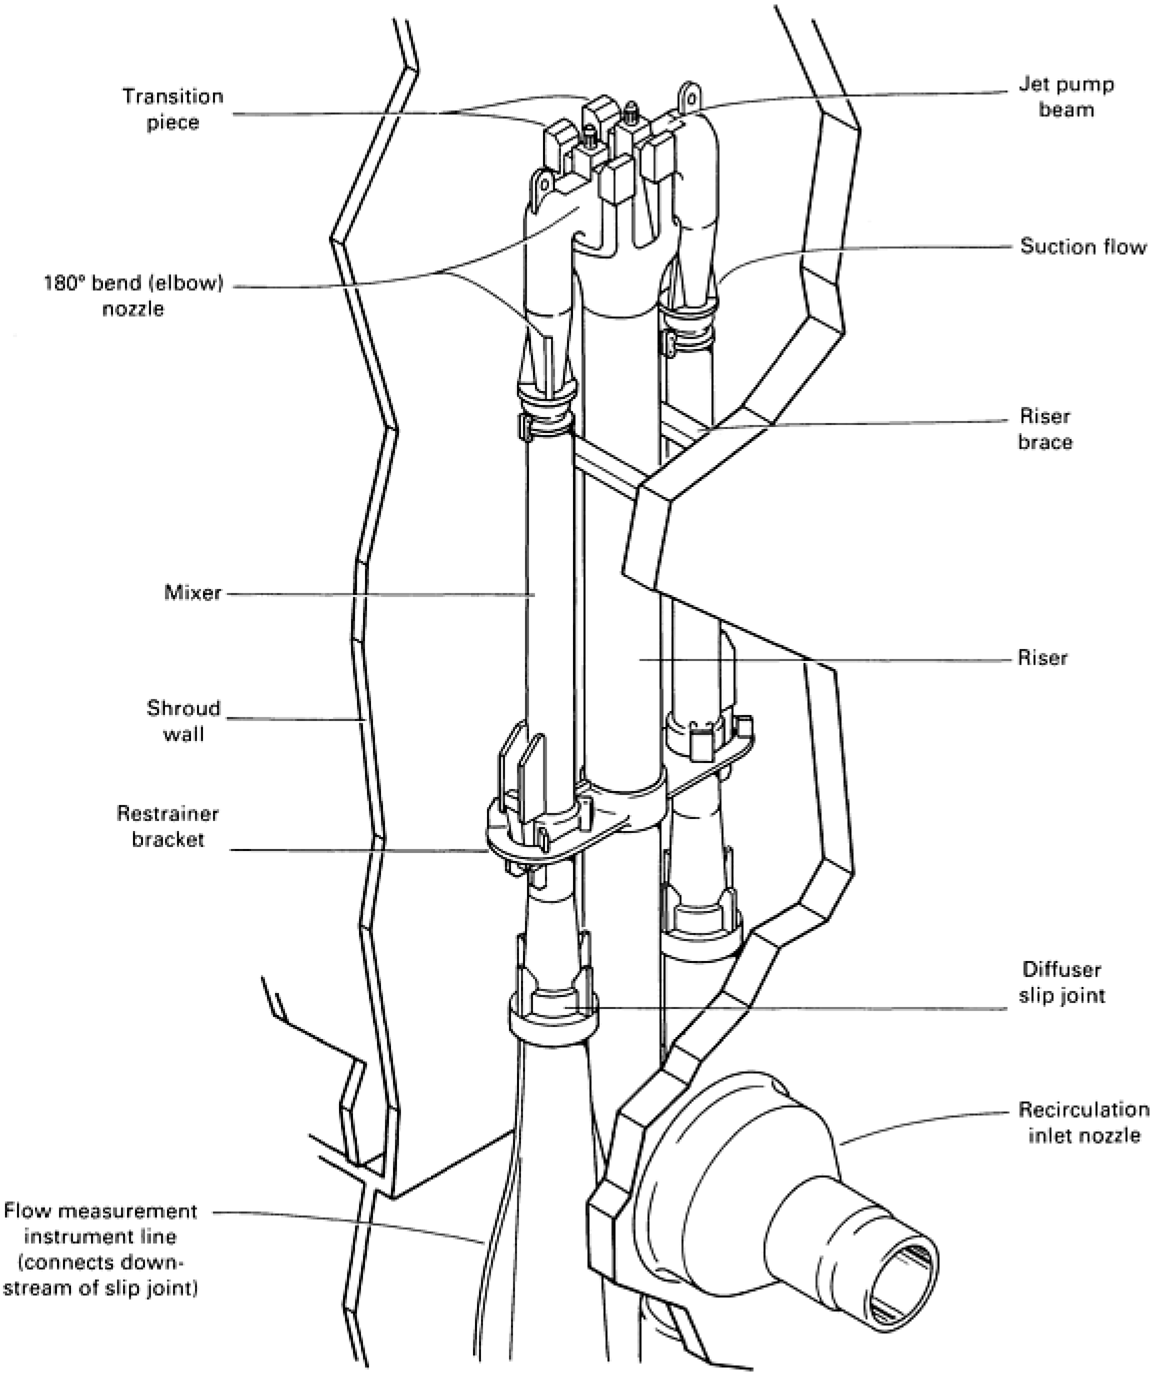

Fig. 19 Jet pump assembly

Field Experience With Jet Pump Beams. The inlet mixer section of each jet pump, from the entrance to the 180° bend to the diffuser slip joints, is removable for inspection. The inlet mixer is held in place by a beam-bolt assembly located in the riser transition piece and is centered in the diffuser by a three-point contact of the restrainer bracket. The beam ends are positioned in pockets in the transition piece, and the beam load is transferred to the elbow through a bolt located in the center of the beam.

In mid-1979 and early 1980, a jet pump hold-down beam fabricated from Alloy X-750 containing 70% Ni (min), 14 to 17% Cr, and 5 to 9% Fe failed during plant operation at one overseas and one domestic BWR plant (Fig. 20). Metallurgical examinations of the failed beams revealed that intergranular SCC under sustained loading was responsible for the failure. Figure 21 shows a detailed illustration of the beam-bolt assembly and the beam top view.

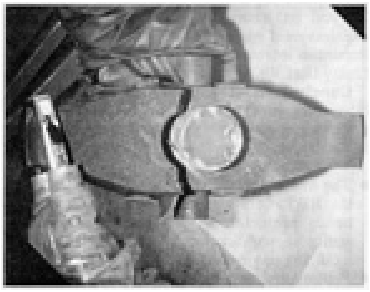

Fig. 20 Failed jet pump beam due to intergranular SCC. Approximately $\frac{1}{3}$ ×

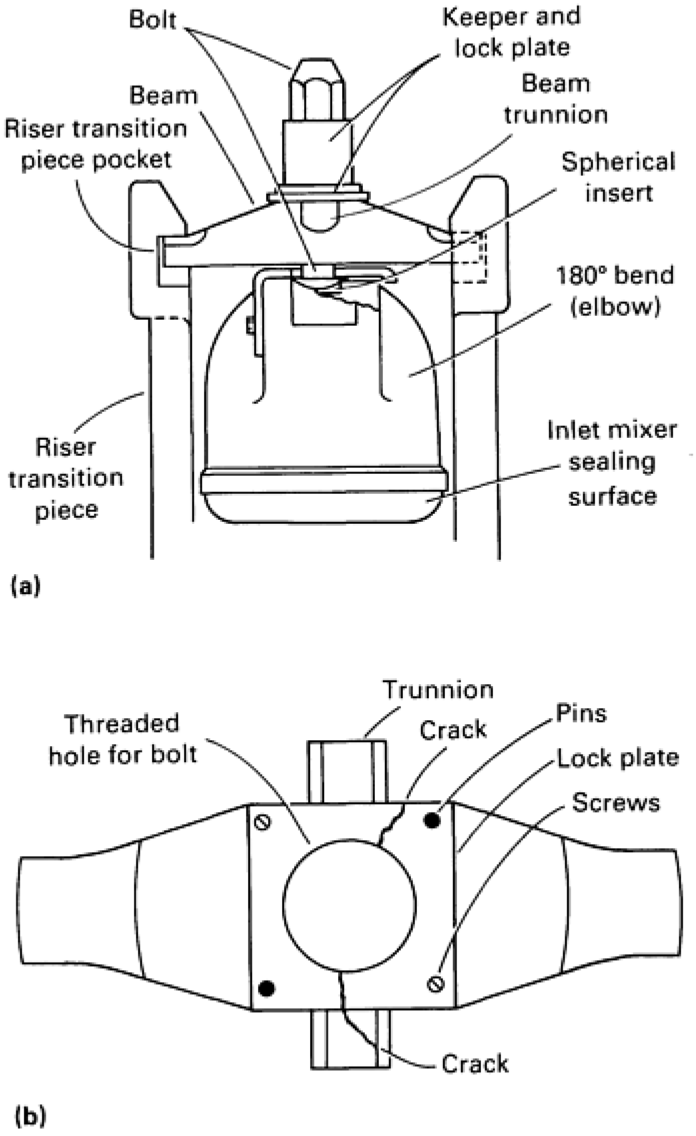

Fig. 21 Jet pump beam/bolt assembly (a) and beam top view (b)

Mechanism of Cracking of the Jet Pump Beam. The Alloy X-750 jet pump beams had received the following heat treatment: heating to 885 °C (1625 °F), holding at this temperature for 24 h (equalizing), followed by aging at 705 °C (1300 °F) for 20 h. This heat treatment is known as equalized and aged.

A stress analysis revealed that the maximum stress occurs at the beam mid-plane top surface. The results of this analysis are consistent with examination of actual beams with cracks in various stages of propagation. The older beam model, using a preload of 111.2 kN (25 kips), resulted in a maximum tensile stress of 593 MPa (86 ksi), but the newer-style beam with a larger cross section, using a preload of 133.5 kN (30 kips), resulted in a maximum tensile stress of 496 MPa (72 ksi).
